JOURNAL OF APPLIED PHYSICS

Proceedings of the 40th Annual Conference on Magnetism and Magnetic Materials

AMERICAN INSTITUTE OF PHYSICS

JOURNAL OF APPLIED PHYSICS

CODEN: JAPIAU
ISSN: 0021-8979

Submit manuscripts (3 copies) to Editor, *Journal of Applied Physics,* Argonne National Laboratory, Bldg. 203, Room R-127, 9700 South Cass Avenue, P.O. Box 8296, Argonne, IL 60439-8296.

Physics Auxiliary Publication Service (PAPS) and/or Electronic PAPS (E-PAPS): For a nominal fee, authors may submit material that is part of and supplemental to a paper, but is too long to be included in the journal. PAPS deposits may be on paper or in electronic media, and can include text, data in graphic or numeric form, computer programs, etc. Retrieval instructions are footnoted in the related published paper. Direct requests to the editor.

The *Journal of Applied Physics* (ISSN: 0021-8979) is published semimonthly by the American Institute of Physics, 500 Sunnyside Blvd., Woodbury, NY 11797-2999. Second-class postage paid at Woodbury, NY, and additional mailing offices. POSTMASTER: Send address changes to *Journal of Applied Physics*, AIP, 500 Sunnyside Blvd., Woodbury, NY 11797-2999.

The *Journal of Applied Physics* is the American Institute of Physics' (AIP) archival journal for significant new results in applied physics. The journal publishes articles that emphasize understanding of the physics underlying modern technology. There are two issues per month. The subject coverage includes, but is not limited to, experimental or theoretical physics applied to all aspects of materials: for example, charge and mass transport, superconductivity, magnetism; surfaces, interfaces, thin films, crystal lattice defects; electrical, optical, magnetic, and structural properties; processing; ion implantation. Materials covered include semiconductors, superconductors, metals and alloys, amorphous materials, and oxides. Other important topics are: electrical, optical, and magnetic devices; optics and lasers; nonlinear optics; electrical discharges; acoustics. The Proceedings of the Annual Conference on Magnetism and Magnetic Materials is a regular feature. *Applied Physics Reviews* is a series of occasional review articles on similar subjects.

Publication Charge: To support the cost of wide dissemination of research results through publication of journal pages and production of a database of articles, the author's institution is requested to pay a page charge of $55 per page (with a one-page minimum) and an *article charge* of $20 per article. For any regular, published article that exceeds 10 journal pages, a mandatory $150 page charge will be added for each page in excess of 10 pages. For Errata the minimum page charge is $10, with no article charge.

Subscription Prices* (1996)	U.S.A. & Poss.	Can., Mex., Central & S. Amer. & Caribbean	Foreign Surface Mail	Air Freight Europe, Asia, Africa & Oceania	Optional Air Freight
Members†	$210	$295	$295	—	$480
Nonmembers	$2045	$2130	—	$2315‡	—

*The journal is available on microfiche at $210 per year to members and $2045 per year at the nonmember rate.
†AIP Member and Affiliated Societies. ‡Includes air freight service.

Back-Number Prices: 1996 single copies: $95. Prior to 1996 single copies: $26 for members; $95 for nonmembers. Prices for conference supplements available on request.

Subscription, renewals, and address changes should be addressed to *AIP Circulation and Fulfillment Division (CFD), 500 Sunnyside Blvd., Woodbury, NY 11797-2999.* Allow at least six weeks advance notice. For address changes please send both old and new addresses and, if possible, include a mailing label from a recent issue.

Claims, Single Copy Replacement and Back Volumes: Missing issue requests will be honored only if received within six months of publication date (nine months for Australia and Asia). Single copies of a journal may be ordered and back volumes are available in print or microform. Members—contact AIP Member Services at (516) 576-2288; (800) 344-6901. Nonmember subscribers—contact AIP Subscriber Services at (516) 576-2270; (800) 344-6902; Internet: subs@aip.org.

Page Charge and Reprint Billing: Contact: AIP Publication Page Charge and Reprints—CFD, 500 Sunnyside Blvd., Woodbury, NY 11797-2999; (516) 576-2234; (800) 344-6909.

Publisher Item Identifier: A Publisher Item Identifier (PII) has been adopted by AIP and other publishers to provide unique and concise identification of individual published documents. The PII appears at the end of the abstract of each article. The PII should be included in all document requests for copies of the article.

Document Delivery: Copies of articles can be ordered for $15 per copy from the AIP/Member Society document delivery service, "Articles in Physics," 1722 Gilbreth Road, Burlingame, CA 94010-1305; Fax: 415-259-6044; Telephone: 800-480-PHYS (in U.S. and Canada), or 415-259-6002; Internet: articles@aip.org.

Reprints: Reprints can be ordered with or without covers only in multiples of 50 (with a minimum of 100 in each category) from AIP, Circulation & Fulfillment/Reprints, 500 Sunnyside Boulevard, Woodbury, NY 11797-2999; Fax 516-349-9704; Telephone: 800-344-6909 (in U.S. and Canada), or 516-576-2234.

Microform: *Journal of Applied Physics* is available on microfiche issued at the same frequency as the printed journal and annually on microfilm. A microform catalog is available from AIP, Circulation & Fulfillment/Single Copy Sales, 500 Sunnyside Boulevard, Woodbury, NY 11797-2999; Fax: 516-349-9704; Telephone: 800-344-6908 (in U.S. and Canada), or 516-576-2277.

Online Availability: Abstracts of journal articles published by AIP and Member Societies (and several other physics publishers) are available in the SPIN database via the AIP online service PINET. Also available on PINET are *Advance Abstracts*, a current awareness

PROCEEDINGS OF THE FORTIETH ANNUAL CONFERENCE ON MAGNETISM AND MAGNETIC MATERIALS

PART B

November 6–9, 1995
Philadelphia, Pennsylvania

Edited by E. Dan Dahlberg, W.-Y. Ching,
J. K. Howard, Y. Idzerda, M. Lederman, and J.-G. Zhu

Journal of Applied Physics
Volume 79, Number 8, Part 2, 1996

International Standard Serial Number: 1087-3848
International Standard Book Number: 1-56396-613-1
CONF-951101—Vol. 2

Published by the American Institute of Physics
500 Sunnyside Blvd., Woodbury, New York 11797-2999
Printed in the United States of America

All papers in this volume, and in previous Proceedings of the Conference on Magnetism and Magnetic Materials published in this series, have been reviewed for technical content. The selection of referees, review guidelines, and all other editorial procedures are in accordance with standards prescribed by the American Institute of Physics.

We present a series of magnetic force microscope (MFM) images of epitaxial magnetic thin films. The films studied, Ni/Cu/Si(001) capped by 2 nm of Cu, exhibit perpendicular anisotropy over an exceptionally broad thickness range, 2 nm$<h<$14 nm. The magnetic domain structure of the as-grown films shows a sharp transition to a finer length scale above a finite critical thickness of 12 nm. Micromagnetic theory provides the first quantitative description for these general but previously unexplained phenomena. Further we discuss MFM data obtained on films with a thickness larger than 14 nm. These films show a pronounced in-plane anisotropy. © *1996 American Institute of Physics.* [S0021-8979(96)19308-3]

I. INTRODUCTION

The study of magnetic thin films in which perpendicular magnetization is realized is of particular importance in many applications such as information storage media and diverse sensors for magnetic field, strain and acceleration. A perpendicular orientation of **M** defies the magnetostatic energy which tends to keep the magnetic moments in plane. The study of thin film systems in which perpendicular magnetization is realized, e.g., fcc Fe/Cu(001),[1–3] bcc Fe/Ag,[4] Co/Pt,[5] Co/Au,[6,7] Ni/Cu,[8–11] remains very active. In many cases the behavior of the magnetization with field is modeled assuming the ultrathin film is comprised of a single magnetic domain. However, in some ultrathin film cases such as Co/Cu,[12] Co/Au,[13,14] and Cu/Ni/Cu[15,16] where domains have been observed, this assumption is not correct. Further, it is expected that as film thickness increases domain size should first decrease then increase.[17] Also, at sufficiently large film thickness the magnetostatic energy increases to a level at which **M** falls into the film plane. There is as yet no clear understanding of the conditions under which domains should exist in ultrathin films or of the evolution of their domain structure with film thickness. Further, the mode by which the magnetization reverts to an in-plane orientation with increasing film thickness (coherent rotation, domain wall expansion, or formation of surface layers with perpendicular magnetization, while the magnetization inside of the film falls in-plane) has not been resolved.

We have made an extensive magnetic force microscopy study of the magnetic domain structure in Cu/Ni/Cu/Si(001) over a Ni thickness range of 2 nm$<h<$17.5 nm. The samples studied are a series of MBE-grown, epitaxial Ni/Cu/Si(001) films capped with 2 nm of Cu. These films had previously been fully characterized *in situ*, before capping, using RHEED[18,19] and after capping by magneto-optic Kerr effect[8,10] and *ex situ* after capping using vibrating sample magnetometry[11] and optical interferometry (for strain measurements).[18,19] The Cu/Ni/Cu/Si(001) system shows an extremely broad thickness range (2 nm to 14 nm) over which perpendicular magnetization is observed.[9,11] Here we show that a magnetic force microscope (MFM) can resolve domains in magnetic films as thin as 2 nm and report the first detailed experimental confirmation of a micromagnetic model predicting a transition to an essentially infinite domain size below a critical thickness of a magnetic film. Finally, the MFM images indicate that the perpendicular to in-plane transition with increasing film thickness is not achieved by coherent rotation of domain magnetization but by a more complex process which is not yet fully understood. We propose a first model which explains both, the MFM data and the magnetization measurements.

II. MFM ON PERPENDICULARLY MAGNETIZED THIN FILMS

We use a new, sophisticated MFM which was built for low temperature and ultrahigh vacuum (UHV) use. The small size of the instrument (diameter: 40.4 mm, length: 120 mm), the thermally well compensated construction not containing any ferromagnetic materials allows its use in a magnetic field produced by a Cu-wire-solenoid. The technical details and properties of the microscope will be published later. All measurements presented here are taken in air, at room temperature and in zero magnetic field (no special precautions were taken to shield the earths magnetic field). The MFM is operated in the static, variable deflection mode which is well suited for high-speed images of large areas.[20,21] The force on a magnetic force microscope tip in the magnetic stray field of a sample is given by

 0021-8979/96/79(8)/5609/6/$10.00

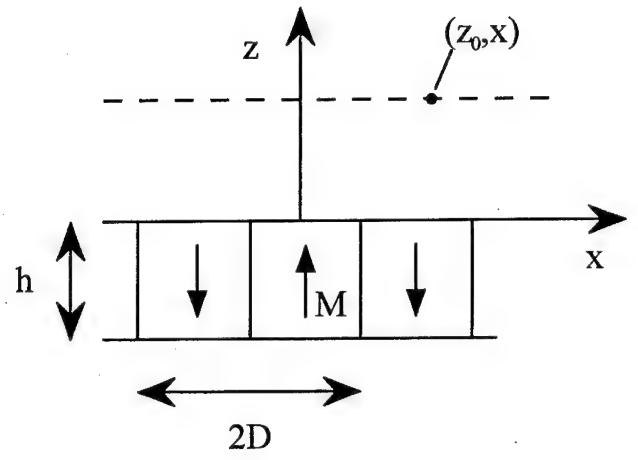

FIG. 1. Model domain structure with the coordinate system. M—magnetization (arrow up=1, arrow down=−1); h—film thickness; $2D$—domain size; (z_0,x)—position of MFM tip.

$$F_z = -\mu_0 \cdot \int_{V_{\mathrm{Tip}}} \left[\mathbf{M}_{\mathrm{Tip}} \cdot \frac{\partial}{\partial z} \mathbf{H}_{\mathrm{Sample}}(x,y,z) \right] dV. \tag{1}$$

To obtain a tip with a well defined direction of the magnetization we have used an electron microscope to grow a deposition tip on a standard pyramid tip of a commercially available cantilever. The needle like tip was grown in an angle of approximately ten degrees to the vertical axis of the pyramid tip to have the needle like tip perpendicular to the surface of the sample. The tip is made sensitive to magnetic stray fields by a 25-nm-thick Co film which was deposited on the side of the needle like tip by thermal evaporation.[22] The strong shape anisotropy of the thin film keeps the magnetization along the tip axis

$$\mathbf{M}_{\mathrm{Tip}} = (0,0,M_{z,\mathrm{Tip}}). \tag{2}$$

With the tip magnetization being purely along the z-axis Eq. (1) can be rewritten as

$$F_z = \oint_{A_{\mathrm{Tip}}} [\rho_{m,\mathrm{Tip}} \cdot H_{z,\mathrm{Sample}}(x,y,z)] dA, \tag{3}$$

where $\rho_{m,\mathrm{Tip}}$ is the magnetic surface charge density of the tip. Approximating the tip as a long and thin, homogeneously magnetized cylinder with magnetic charges at the bottom surface, A_{bottom} and the top surface, A_{top} Eq. (3) simplifies to

$$F_z = \mu_0 \cdot M_{z,\mathrm{Tip}} \cdot \left(\int_{A_{\mathrm{bottom}}} H_{z,\mathrm{Sample}} dA - \int_{A_{\mathrm{top}}} H_{z,\mathrm{Sample}} dA \right). \tag{4}$$

Since the distance of the top surface of the tip to the surface of the sample is about 1 μm larger than the one of the bottom surface to the sample. Thus the part of the force produced by the top surface can be neglected. Then the force, F_z [Eq. (4)] reflects the local stray field averaged over the area of the bottom surface of the tip. The size of the bottom surface sets a natural limit to the resolution of the stray field of the MFM experiment. However, for all images presented in this work the distance between two image points is approximately 60 nm and therefore about a factor of two larger than the diameter of the bottom area, A_{bottom} of the tip. Equation (4) further simplifies to

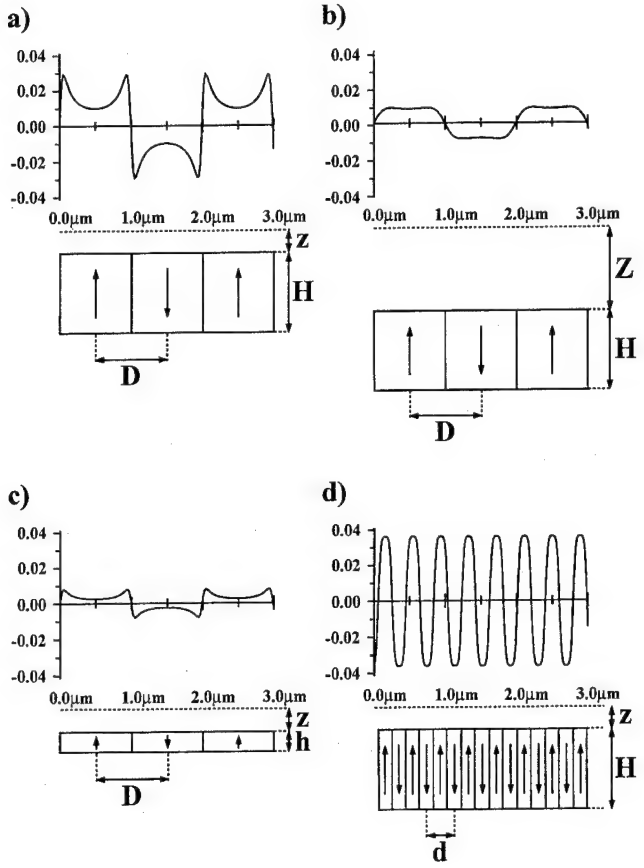

FIG. 2. Model calculation of the stray field above a periodical domain structure in a perpendicularly magnetized thin film. Magnetization—arrow up=1, arrow down=−1; field in same units as the magnetization; domain size—$D=1$ μm, $d=0.2$ μm; film thickness—$H=10$ nm, $h=2.5$ nm; tip-to-sample distance—$Z=200$ nm, $z=50$ nm. (a) Stray field above model structure. (b) Stray field for a larger tip-to-sample distance ($Z=200$ nm). (c) Stray field for a thinner film ($h=2.5$ nm). (d) Stray field for smaller domains ($d=0.2$ μm).

$$F_z = q_{\mathrm{Tip}} \cdot H_z, \tag{5}$$

where $q_{\mathrm{Tip}} = \mu_0 \cdot M_{z,\mathrm{Tip}} \cdot A_{\mathrm{bottom}}$ is the magnetic charge of the bottom surface of the magnetic tip. Note that, within these limits the magnetic force microscope image is proportional to the z component of the stray field of the sample.

To have a better understanding of the MFM images obtained on the Ni sandwiches we analytically calculate the stray field of a periodical, perpendicularly magnetized model thin film sample (Fig. 1).[20,23] For a film thickness, h, a domain period, $2D$, and a tip-to-sample distance, z_0, we obtain

$$H_z(x,z=z_0) = \frac{2}{\pi} \cdot M_{z,\mathrm{Tip}} \cdot \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} \left[1 - \exp\left(-(2n+1) \frac{2\pi h}{2D} \right) \right] \exp\left[-(2n+1) \frac{2\pi z_0}{2D} \right] \times \cos\left[(2n+1) \frac{2\pi x}{2D} \right]. \tag{6}$$

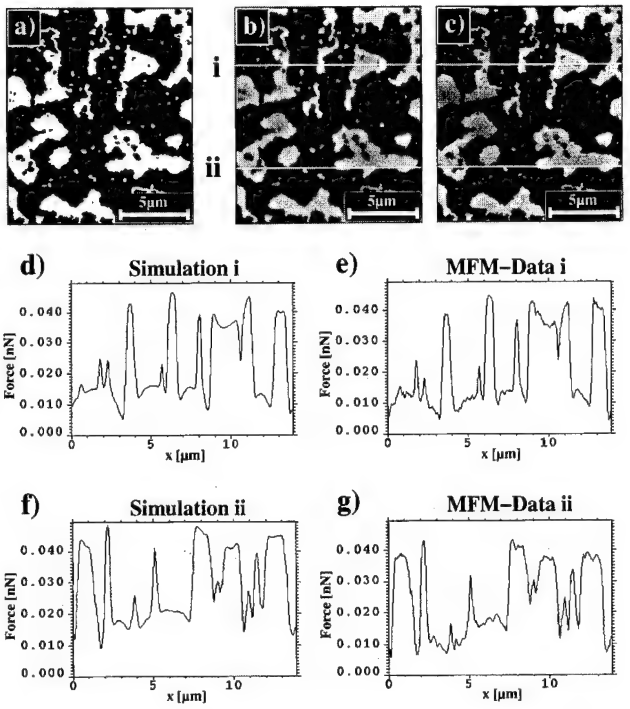

FIG. 3. Simulation of MFM data. (a) Domain Structure. (b) Calculated stray field (force) using the domain structure (a) and a film thickness of 10 nm. (c) MFM data acquired on a film with a thickness of 10 nm [the domain structure of Fig. 3(a) was derived from this data]. (d and f) Cross sections of simulation to be compared with (f) and (g) cross section of MFM data.

From Eq. (6) we learn that the stray field becomes smaller towards the center of a domain [Fig. 2(a)], for increasing tip-to-sample distance [Fig. 2(b)] and for decreasing film thickness [Fig. 2(c)]. Note that the force contrast does not decreased as the domain size is decreased by a factor of four [Fig. 2(d)]. This rather unexpected behavior is a special property of thin films. For an infinitely thick sample the decay of the force contrast with decreasing domain size is governed by the first exponential factor in the second line of Eq. (6). Clearly a domain structure of smaller size (in an infinitely thick sample) produces a smaller force contrast. In thin films, however, the situation can be different, as shown in Fig. 2(d). The difference is due to the two magnetic charges of opposite sign induced on the top and bottom surface of the film. Thus a small distance above the center of a large domain we expect to have a very small stray field [Fig. 2(a)]. In contrast to the large domain, the field above the small domain is mainly dominated by the fringe fields at the site of the domain wall and can therefore be larger [Fig. 2(d)].

Using a new theoretical approach[24] the stray field for an arbitrary complex two-dimensional perpendicularly magnetized domain pattern [Fig. 3(a)] can be calculated. The obtained stray field [Fig. 3(b)] perfectly matches the measured MFM data [Fig. 3(c)]. This is impressively demonstrated by comparing the calculated cross sections (i,ii) [Figs. 3(d) and 3(f)] with experimental cross sections [Figs. 3(e) and 3(g)].

III. DOMAIN STRUCTURES OF FILMS CONTAINING 2 nm TO 12.5 nm OF Ni

The MFM images confirm dramatically that the magnetization is indeed strongly held to a perpendicular direction as indicated by magneto-optic KERR effect measurements[8,10] and vibrating sample magnetometry.[4] In these images the contrast is due to magnetization into and out of the plane; no regions of in-plane magnetization were observed other than the domain walls themselves.

It is noteworthy that the domain walls show no orientational correlation with the easy in-plane ⟨110⟩ crystallographic directions in these epitaxial Ni films. This will be the subject of a forthcoming paper. The domain walls are Bloch walls, not Néel walls, so the wall magnetization runs along the wall length with no cost in magnetostatic energy. (Néel walls are preferred only in thin films exhibiting in-plane magnetization.) Based on our magnetic anisotropy measurements,[11] the wall width, $\delta_{dw}=\pi(A/K)^{1/2}$ should be of order 30 nm for a Ni thickness of 8.5 nm and increases for thinner or thicker films.

The domain structure of the as-grown films is characterized by two types of behavior in different thickness ranges. At and below 8.5 nm of Ni the domain patterns are irregularly spotted [Figs. 4(a)–4(d)] and tend toward serpentine patterns at larger thickness, h [Fig. 4(e)]. The length scale of this coarse structure is poorly defined but its average decreases with increasing thickness, h. Relative to the film thickness, these patterns are essentially infinite in lateral scale (1–4 μm) and so may be characterized by a reduced domain size parameter $D/h\approx\infty$. The weak energies that govern these features are not yet well understood. Above 8.5 nm the relatively large serpentine domains begin to break down by internal fragmentation (submicron bubble domain formation) as seen in Figs. 4(e) and 4(f). It is noteworthy that the larger domain features that characterize the thinner Ni films [Figs. 4(a)–4(d)] are preserved even as the internal fragmentation of the domains progresses with increasing thickness above 8.5 nm [Figs. 4(e) and 4(f)]. This suggests that these separate-scale structures may be governed by different energies and/or kinetics. As the Ni thickness increases, magnetostatic energy is reduced by refinement of the interior bubble domain structure rather than by more complex contortions of the existing domain walls. This occurs because the magnetostatic energy well inside a domain is $(\mu_0/2)M_z^2$ while it is significantly reduced near an existing domain wall. We can calculate the transition to this finer domain structure and its length scale by extensions of domain theory as outlined by Kittel[25] and developed by others.[17,26] As shown in Ref. 2, the energy difference between stripe and checker domain patterns is small. Neglecting the finite width of the domain walls, we may use the expression for the energy per unit surface area for a stripe domain structure, i.e.,

$$u=16M_S^2\frac{D}{\pi^2}\cdot\sum_n^{\text{odd}}\frac{1-\exp(-n\pi h/D)}{n^3}+\frac{h\sigma_{dw}(h)}{h}, \qquad (7)$$

where we write the domain wall energy density, $\sigma_{dw}(h)=4(AK_{eff})^{1/2}$ as a function of Ni thickness because of the strong dependence of the measured effective anisotropy, K_{eff}, on thickness.[9,10] We have numerically minimized Eq. (7) with respect to the domain size,[27] using the methods of Malek and Kambersky.[28] For the range of interest here, $h<14$ nm, we have plotted the numerical solution in Fig. 5 using the experimentally measured[10] effective anisotropy,

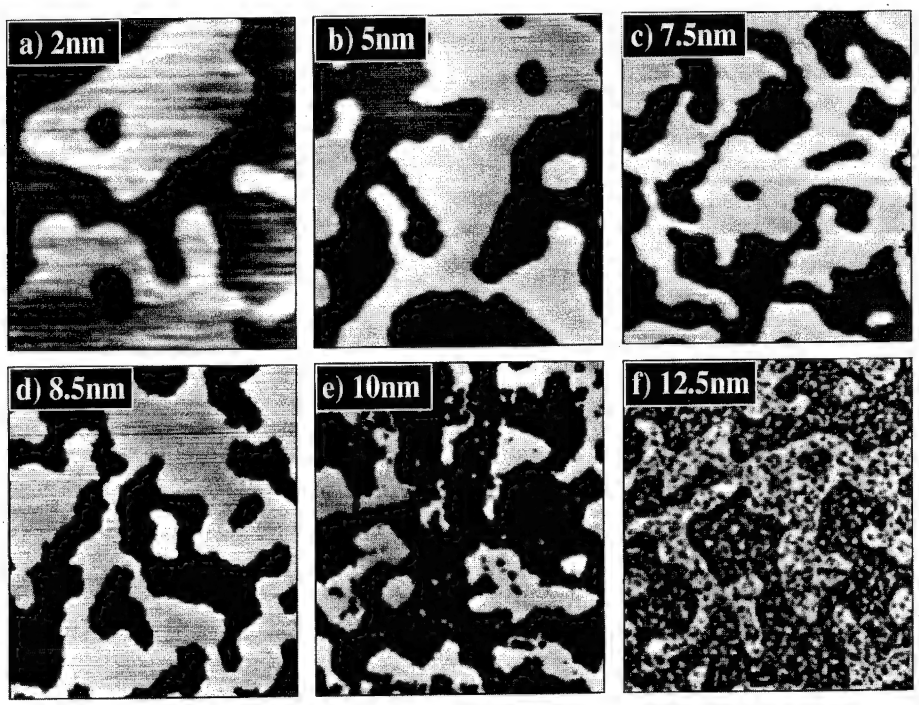

FIG. 4. MFM data acquired on Cu/Ni/Cu films containing (a) 2 nm, (b) 5 nm, (c) 7.5 nm, (d) 8.5 nm, (e) 10 nm, (f) 12.5 nm Ni. (Image size: 13.9 μm×15.8 μm.)

K_{eff}, in σ_{dw}, $A=1\cdot10^{-6}$ erg/cm and $M_S\approx435$ emu/cm^3. This magnetization density is smaller than the bulk value for Ni, 485 emu/cm^3, but is typical of that measured for our films in this thickness range.

The thickness, h, corresponding to the onset of domain fragmentation is calculated to be approximately 8.5 nm and the average domain spacing is calculated to decrease to about 0.6 μm for $h=12$ nm. The domain images indicate that between $h=8.5$ and 10 nm [Figs. 4(d) and 4(e)] the fine domains first appear in our Cu/Ni/Cu sandwiches but a complete breaking up into submicron domains occurs between $h=10$ and 12.5 nm [Figs. 4(e) and 4(f)]. Thus the observed domain structure breaks up into small bubbles at a thickness, h, where the domain-size vs thickness function develops a pronounced energy minimum (Fig. 5, insets). Below 10 nm film thickness, the minimum of the energy, u, vs the domain size, D, from Eq. (7) is extremely shallow, suggesting that at finite temperatures a broad range of D values would be allowed. Indeed the measured domain size for films with thicknesses below 8.5 nm is smaller than expected from our model. The model is only valid for a thickness h above 10 nm where the energy minimum becomes well defined.

IV. TRANSITION OF THE EASY AXIS OF MAGNETIZATION ABOVE 14 nm Ni-FILM THICKNESS

Above a Ni thickness of 14 nm where magnetometry[9–11] indicates the easy magnetization axis is in plane (Fig. 6), the

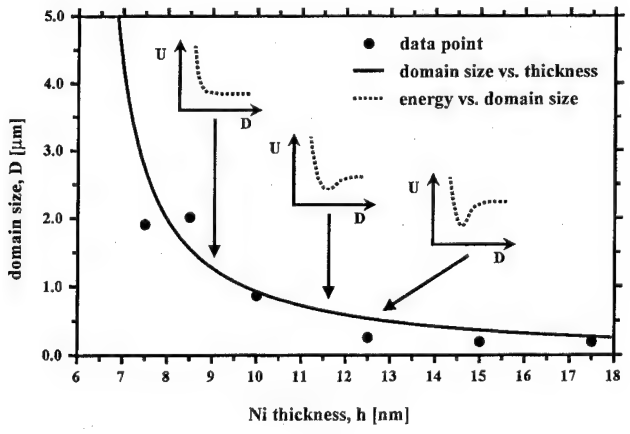

FIG. 5. Domains size versus Ni film thickness. — domain size versus Ni film thickness; ··· energy versus domain size; and ● experimental value.

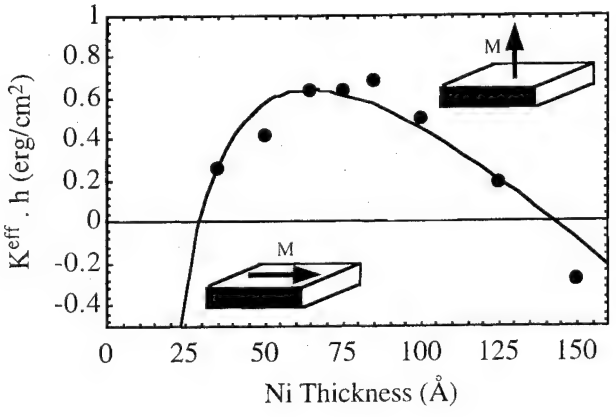

FIG. 6. Dependence of $k^{\text{eff}}\cdot h$ on Ni film thickness in Cu/Ni/Cu/Si(001) sandwiches. The perpendicular magnetic anisotropy dominates over a large Ni thickness range from 2 nm to 14 nm.

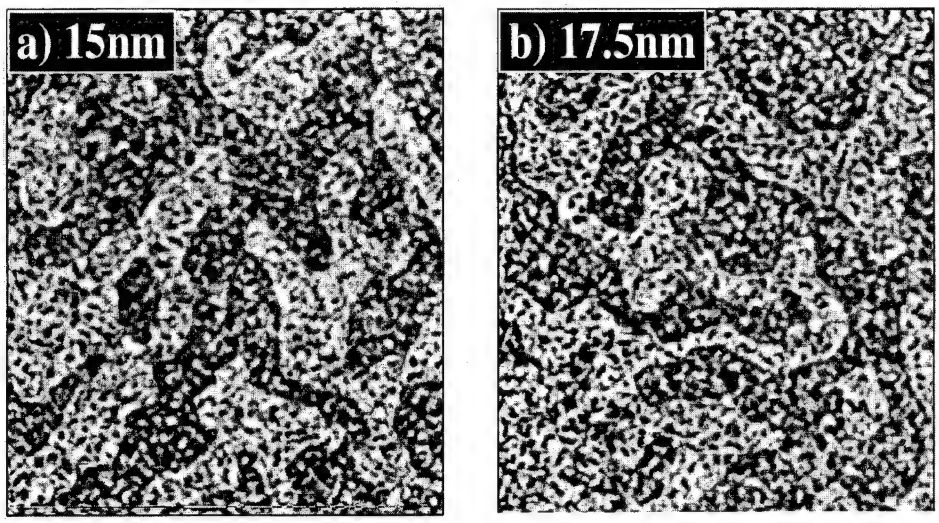

FIG. 7. MFM data acquired on Cu/Ni/Cu films containing (a) 15 nm and (b) 17.5 nm of Ni. (Image size: 13.9 μm×15.8 μm.)

MFM data reveals small bubbles still magnetized perpendicularly (Fig. 7). This suggest that the net in-plane magnetization measured by magnetometry at 15 nm Ni may be due to a layer of in-plane magnetization burried inside the Ni film and/or due to the broad Bloch walls between smaller, perpendicularly magnetized regions at the surface of the film. Magnetization measurements reveal the net in-plane moment whereas MFM detects the z component of the fringe field above the small perpendicularly magnetized regions. From Refs. 9, 10, and 11 we know that the strong perpendicular anisotropy observed in Cu/Ni/Cu-sandwiches with an Ni thickness between 2 and 14 nm (Fig. 6) is mainly caused by the magnetocrystalline surface anisotropy and the combination of misfit strain and the large positive bulk magnetoelastic coupling coefficient.

In sandwiches with a sufficiently large Ni thickness[9] the misfit strain decays towards the inside of the film due to misfit dislocations. Thus, perpendicular anisotropy caused by the bulk magnetoelastic coupling becomes less important inside the film whereas the positive magnetocrystalline surface anisotropy still keeps the magnetization perpendicular at the surface of the film.

Thus the easy axis transition in these films appears to be the result of wall broadening of the perpendicularly magnetized surface regions and possibly a complex rotation of the magnetization into the film plane in the inside of the film. This is the subject of a forthcoming publication.

V. CONCLUSION

We have measured the domain size in a series of epitaxial Cu/Ni/Cu films over the Ni thickness range 2 nm$<h<$17.5 nm using a high-resolution MFM. From 2 nm up to 10 nm of Ni the domains are large and of a relatively irregular size; their average size decreases with increasing Ni thickness. Between 8.5 and 10 nm of Ni internal fragmentation of the larger domains into sub-micron bubble domains begins. The size and spacing of these internal bubble domains decreases to approximately 0.3 μm at $h=12.5$ nm for the as-grown films. In contrast, the demagnetized films show such a small domain size already at smaller Ni thicknesses around 10 nm. These finer domains are more uniform in their spacing than are the coarser domains observed below 8.5 nm. All of these features in films with Ni thicknesses up to 12.5 nm are well described by micromagnetic domain theory. At larger Ni-thicknesses the MFM data indicates that the transition of the easy axis of magnetization from out-off-plane to in-plane as revealed by magnetometry is due to a rather complex interplay of perpendicularly magnetized surface layers and laterally magnetized regions in the inside of the film. Further MFM studies on much thicker sandwiches as well as MFM measurements searching for domain walls of the laterally magnetized regions in the inside are underway.

Magnetization and finite-size effects in Gd/W multilayers

J. Samuel Jiang and C. L. Chien
Department of Physics and Astronomy, The Johns Hopkins University, Baltimore, Maryland 21218

We have studied the magnetization and finite-size effects of thin Gd layers in sputter-deposited Gd/W multilayers. The interfacial Gd atoms lose about 9% of their moment, as the result of being in proximity with W. Annealing the multilayers at high temperatures improves the crystalline quality and sharpens the susceptibility peaks. The Curie temperature T_C decreases with decreasing d_{Gd} according to the finite-size scaling relation $[T_C(\infty)-T_C(d)]/T_C(\infty)=(d/d_0)^{-\lambda}$. The shift exponent λ has been found to be 1.5 ± 0.1 and the constant d_0 to be 13 Å. © *1996 American Institute of Physics.* [S0021-8979(96)19408-X]

Magnetic multilayers with ferromagnetic metals separated by thin nonmagnetic spacer layers have attracted much attention recently in the investigation of oscillatory interlayer exchange coupling,[1] a phenomenon where the exchange interaction between the adjacent magnetic layers alternates between ferromagnetic and antiferromagnetic, and decays with increasing spacer layer thickness. Multilayers containing gadolinium (e.g., Gd/Y) are the first systems in which the RKKY-like interlayer exchange coupling was clearly demonstrated.[2] It has recently been reported that the saturation magnetization of Gd oscillates as the intervening W layer thickness is varied,[3] and an enormous enhancement of the saturation magnetization has been claimed in Gd/W multilayers at thin Gd thickness.[4] It has been postulated that the exchange interaction induces a moment in the W layers by polarizing the conduction band,[3] or the induced moment comes from the polarization of a hybrid band of Gd and W.[4] However, this does not seem very likely since the amount of enhancement, in excess of $6\mu_B$ per W atom, would require a complete mixing of Gd and W and a very substantial polarization of the conduction band. Furthermore, a recent photoemission study of Fe on Pd has shown that even for Pd, which has a very large magnetic susceptibility, an interfacial hybrid state provides an induced moment of only $0.32\mu_B$ for Pd at the interface.[5] On the other hand, when the magnetic layers are as thin as a few atomic planes, surface and interface effects may play an important role in affecting the magnetism. Polarized neutron diffraction studies of the magnetization profile in Gd/Y have shown a significant reduction of the interfacial Gd moment, which cannot be explained by alloying alone.[6] In light of these results, it is important to ascertain the magnetic properties of thin Gd layers.

We have prepared Gd/W multilayers to investigate the thickness dependence of the magnetic properties. Multilayer films with uniform layers for one component and wedge-shaped layers for the other component have been made, so that samples taken from different positions in the film differ only in the thickness of one component layer. This eliminates inconsistencies in material parameters that might arise if the samples were prepared separately. We will denote the samples as $Gd_{d_{Gd}}/W_{d_W}$, where d_{Gd} and d_W are Gd and W layer thicknesses. Here we present results from two series of samples: $Gd_{37\ Å}/W_{0-40\ Å}$ (*series A*) and $Gd_{0-50\ Å}/W_{26\ Å}$ (*series B*), both have 30 bilayers.

The Gd/W multilayers were deposited on Si(100) substrates using dc magnetron sputtering from 99.9% pure solid Gd and W targets. The deposition chamber was evacuated to 10^{-8} Torr prior to sputtering. Deposition was carried out in 99.9995% argon atmosphere at 4 mTorr. A liquid nitrogen-cooled Meissner trap was used during sputtering. The substrates were at ambient temperature and the Gd and W deposition rates were kept at 5 Å/s. The multilayers were sandwiched between two 350 Å W layers to protect the Gd layers from substrate reaction and oxidation. Some of the films were subsequently annealed in a high vacuum at 600 °C for 20 min, with a temperature ramping rate of 15 °C/min, to improve the crystalline quality and to relieve interfacial strain. Each of the films, 50 mm long in the wedge direction, was cut into 2 mm wide stripes perpendicular to the wedge direction for measurements. The area of each sample was determined optically. Because of the finite width of the samples, the wedge layers have a built-in thickness variation of about 1.6 Å (*series A*) or 2 Å (*series B*) from edge to edge.

The structural properties of the multilayers have been characterized using θ-2 θ x-ray diffraction. Figure 1 shows

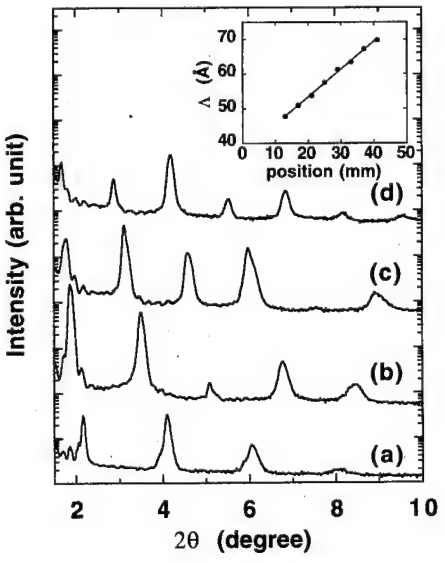

FIG. 1. Low-angle x-ray diffraction patterns of four Gd/W multilayers annealed at 600 °C with $d_{Gd}=37$ Å and $d_W=8$ Å (a), 17 Å (b), 24 Å (c), and 30 Å (d). Inset: The bilayer thickness Λ as a function of position for the same series of wedged multilayers.

 0021-8979/96/79(8)/5615/3/$10.00

the low-angle diffraction patterns of four multilayers with d_{Gd}=37 Å and d_W=8, 17, 24, and 30 Å from *series A* after annealing at 600 °C. Several orders of low-angle diffraction peaks are seen, indicating that the layered structure remains intact after annealing. In fact, Gd and W are mutually insoluble at the equilibrium condition, annealing at high temperatures might improve the interface sharpness. The bilayer thickness Λ can be calculated from the position of the low angle diffraction peaks. In the inset of Fig. 1, we plot Λ as the function of the position of the multilayers within the series. The linear relation indicates a constant thickness gradient as intended. The W thickness gradient from least square fit is 0.80 Å/mm, and the Gd layer thickness is 37 Å, both agree well with the designed values. In the *B series*, the Gd layer thickness gradient as 1.06 Å/mm and d_W=26 Å. The good agreement between the measured and designed thicknesses and the linearity of the wedge layer profile have allowed us to determine the layer thicknesses in each sample accurately. This is of crucial importance if magnetization and magnetic moments are to be determined.

High-angle x-ray diffraction patterns indicate that W layers are (110) textured. We did not observe any gadolinium oxide phase. The Gd layers in the as-deposited sample are mostly (002) oriented, with a low and broad (101) contribution that is almost indistinguishable from the background. Upon annealing at 600 °C, the (002) peak grows sharper and significantly higher in intensity, indicating an increase in Gd crystallite size and relief of interfacial strain. The absence of high-angle satellite peaks suggests that although the samples have a very well-defined layered structure, they are not structurally coherent. Annealing at high temperatures improves the crystallinity of the Gd layers. As will be seen later, this has great ramifications on the magnetic properties of the multilayers.

The dc magnetization and ac susceptibility of the multilayers have been measured using a Quantum Design SQUID magnetometer, which has been calibrated against a platinum reference issued by NBS. It has been reported that in Gd/Y supperlattices, the interfacial Gd moments do not order ferromagnetically, and the magnetization shows a linear rise with the applied field when measured at 25 K and relatively low fields (15 kOe) due to the paramagnetic Gd moments at the interface.[7,8] Since the Brillouin function for paramagnetic Gd moments (J=7/2) reaches 99.5% saturation at an H/T of 3 T/K, we have measured the dc magnetization of the multilayers at 1.7 K, so that the magnetization at 5 T can be used to approximate the saturation magnetization. We have also measured at 1.7 K the susceptibilities of W metal and the Si substrate used. From the known thicknesses of the layers and the sample area, the magnetization of Gd can be calculated after correcting the measured total magnetic moment from the paramagnetic contribution of W and the diamagnetic contribution of Si.

The as-deposited samples are quite difficult to saturate even at 1.7 K with an in-plane field, similar to what has been observed in Ref. 4. However, after annealing at 600 °C, the hysteresis loops become more square, especially for samples with thicker Gd layers. All samples with $d_{Gd} \geq 9$ Å have nonzero remanence and coercivity, indicating ferromagnetic ordering. Figure 2 shows the M–H curves of the sample $Gd_{32\ Å}/W_{26\ Å}$, with the applied field parallel and perpendicular to the sample plane. In an ideal thin film, the parallel and perpendicular saturation fields differ by $H_K = 4\pi M_S$ due to the shape anisotropy. As seen in Fig. 3, the saturation magnetization is 1900 emu/cm^3 and the difference in saturation fields is about 23 kOe. The fact that the demagnetization factor is to a good approximation equal to 4π confirms that the layered structure is preserved during annealing. However, the saturation magnetization is slightly less than the Gd bulk magnetization of 2060 emu/cm^3. In fact, in the thickness range studied ($d_{Gd} \leq 50$ Å), none of the samples reaches the bulk Gd saturation magnetization, as shown in the inset of Fig. 2 for multilayers with d_{Gd}=8.7, 13, 17, and 40 Å measured at 1.7 K. As the Gd thickness is decreased, the Gd saturation magnetization decreases. This feature becomes more evident in Fig. 3, where we plot the Gd saturation magnetization (M_S) as a function of inverse Gd layer thickness ($1/d_{Gd}$). The data points in Fig. 3 can be fitted to a linear relation:

$$M_s = 2017 - 2112 \times \left(\frac{1}{d_{Gd}}\right). \tag{1}$$

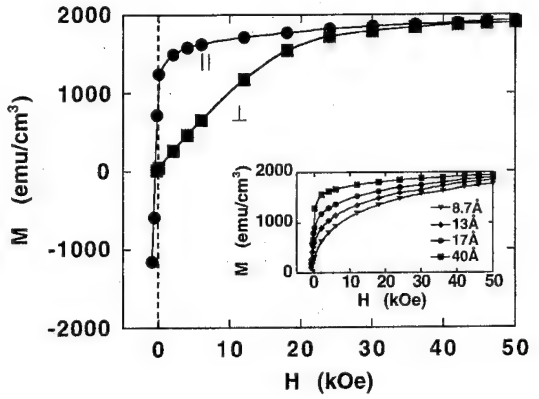

FIG. 2. The Gd Magnetization curves at 1.7 K for annealed $Gd_{32\ Å}/W_{26\ Å}$ with the field applied parallel and perpendicular to the sample plane. Inset: Magnetization of Gd for multilayers with 8.7, 13, 17, and 40 Å Gd layers.

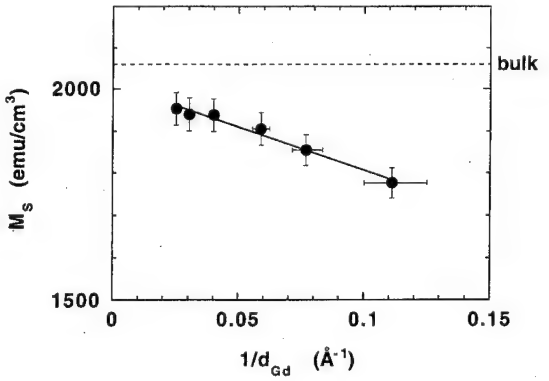

FIG. 3. Saturation magnetization of Gd (M_S) as a function of inverse Gd layer thickness ($1/d_{Gd}$) for a series of annealed multilayers. The dotted line represent the bulk Gd magnetization.

In an approach similar to that used by Kwo *et al.*,[7] we model this behavior by assuming that two interfacial regions of thickness t in the Gd layers have a reduced magnetization of M', whereas the interior of the Gd layers retains the bulk magnetization M_{bulk}. The Gd saturation magnetization M_S can then be expressed as

$$M_S = M_{\text{bulk}}\left(1-\frac{2t}{d_{\text{Gd}}}\right)+M'\,\frac{2t}{d_{\text{Gd}}}. \tag{2}$$

Comparing Eq. (2) with Eq. (1) gives $M_{\text{bulk}}=2017$ emu/cm^3, which is only about 2% less than the bulk value, and is within experimental error. Polarized neutron diffraction studies of the magnetization profile in Gd/Y indicate that two atomic layers of Gd have reduced moments,[6] and since the Gd layers here are mostly (002) oriented, we assume $t \approx c = 5.78$ Å. This gives an M' of 1834 emu/cm^3, i.e., the interfacial Gd atoms have lost about 9% of their moment. The bulk saturation moment of Gd is $7.63\mu_B$ per atom, of which $7\mu_B$ comes from the localized $4f$ core, and the excess moments of $0.63\mu_B$ represents the polarization of the conduction electrons. The 9% reduction in magnetization suggests that the conduction electrons of the interfacial Gd atoms possibly lose the polarization as the result of their local environment.

Magnetization measurements on sample series A with fixed $d_{\text{Gd}}=37$ Å but varying d_{W}(0–40 Å) did not show evidence of antiferromagnetic exchange coupling. The Gd layers behave independently, and the Gd saturation magnetization is constant with no indication oscillation, contrary to what has been reported.[3]

In thin magnetic films, the surface energy contribution causes the decreasing of the ordering temperature. Finite-size scaling theory predicts that the Curie temperature T_C of magnetic films will decrease from the bulk value $T_C(\infty)$ with decreasing thickness d, following a power law: $[T_C(\infty) - T_C(d)]/T_C(\infty) = (d/d_0)^{-\lambda}$, where d_0 is a characteristic length scale and λ is the shift exponent.[9] In the ideal case, the susceptibility in a second-order phase transition diverges at the critical temperature as the coherence length diverges. However, it has been pointed out that a number of factors, such as dislocations, lattice defects, and locally varying strains restrict the divergence of coherence length at T_C, and this cluster-size effect influences the ordering temperature.[10] The ferromagnetic ordering in a real sample shows up as a peak in the temperature dependence of the susceptibility, and the Curie temperature can be determined from the susceptibility peak position.

To study the finite-size effect on the ferromagnetic ordering temperature of Gd/W multilayers, we have measured the AC susceptibility as a function of the temperature for multilayers with different d_{Gd}. The low excitation filed (0.5 Oe in amplitude and 11 Hz) lies in the film plane. The inset of Fig. 4 shows the temperature dependence of the susceptibility of the as-deposited and annealed $Gd_{40\ Å}/W_{26\ Å}$ samples. The as-deposited film has a low Curie–Weiss susceptibility peak at 200 K, while for the annealed sample the susceptibility peak increases by a factor of 4, and is shifted to

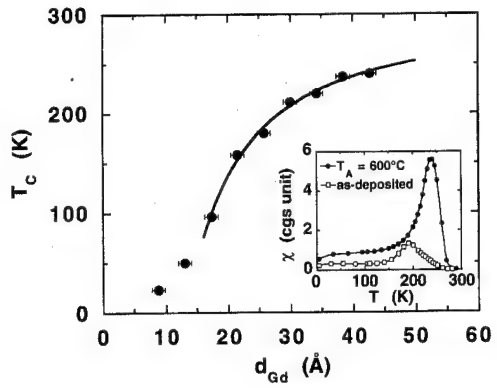

FIG. 4. Curie temperature as a function of the Gd layer thickness for a series of multilayers with $d_{\text{W}}=26$ Å annealed at 600 °C. The solid curve is a fit to the finite-size scaling law. Inset: Temperature dependence of the AC susceptibility (in cgs units) of the as-deposited and annealed $Gd_{40\ Å}/W_{26\ Å}$ samples.

235 K. This is a clear demonstration that ferromagnetic ordering depends sensitively on the crystalline quality. We have determined the Curie temperatures from the position of the susceptibility peaks for a series of multilayers. In Fig. 4 we plot T_C of the annealed multilayers as a function of Gd layer thickness. It is seen that the Curie temperature decreases as the thickness of the Gd layer is reduced, and the multilayer films order ferromagnetically down to a Gd thickness of 9 Å. A similar behavior has also been observed in Gd/Nb multilayers.[11] Fitting the results at large Gd thicknesses with the scaling relation gives the shift exponent $\lambda=1.5\pm0.1$ and $d_0=13$ Å. It has been shown that the shift exponent λ is the inverse of the correlation length ν.[12,13] Renormalization group calculations indicate $\nu=0.687$, and thus $\lambda=1.456$. Our result is in agreement with the expectation of scaling theory.

Magnetism and structure of ultrathin fcc Fe_xCo_{1-x} films on Cu(001) (abstract)

A. Dittschar, M. Zharnikov, W. Kuch, C. M. Schneider, and J. Kirschner
Max-Planck-Institut für Mikrostrukturphysik, Weinberg 2, D-06120 Halle, Germany

Ultrathin films of 3*d*-transition metal alloys, and in particular FeCo alloys, currently receive considerable interest because of their potential technological application and the possibility to adjust magnetic properties via the variation of composition and structure. To study magnetic and structural properties of the otherwise unstable fcc phase of FeCo, this structural phase was stabilized by epitaxial growth on Cu(001). Ultrathin Fe_xCo_{1-x} films were deposited at room temperature by coevaporation from two separate Knudsen cells, operated under stabilized conditions. The film thickness was varied between 2 and 9 monolayers (ML) and the Fe concentration between $x=0.2$ and $x=0.95$. The growth process was monitored by medium energy electron diffraction (MEED). Auger electron spectroscopy and low energy electron diffraction (LEED) were employed to analyze the composition and structure of the films. A nearly perfect layer-by-layer growth up to at least 9 ML, as seen by MEED, is encountered for $x\leqslant 0.7$. For higher Fe concentrations and thicknesses greater than 4 ML, deviations from the layer-by-layer growth are observed, indicating a structural rearrangement. LEED-I(V) curves reveal the coexistence of two structural phases with different interlayer spacings, the relative amount of which depends on the composition. Magnetic properties were characterized by the magneto-optical Kerr effect (MOKE). The remanent magnetization was found to lie within the film plane over the whole range of thicknesses and concentrations investigated. A linear increase of the Kerr signal at saturation magnetization with increasing thickness indicates that practically the whole film is magnetic. As a function of composition, the saturation Kerr signal develops continuously with increasing Fe content. This suggests that in fcc FeCo alloys the contribution of Fe and Co to the total magnetic moment is nearly constant over the whole compositional range. [S0021-8979(96)42908-5]

Magnetization reversal properties near the reorientation phase transition of ultrathin Fe/Ag(100) films

A. Berger[a] and H. Hopster
Department of Physics and Institute for Surface and Interface Science, University of California, Irvine, California 92717

We have measured the magnetization reversal properties of ultrathin Fe/Ag(100) films in the vicinity of the reorientation phase transition using the magneto-optical Kerr effect. Near the reorientation temperature T_r, we observe a characteristic change in the perpendicular magnetization curves $M(H)$ from a strongly nonlinear behavior for $T<T_r$ to a simple linear field dependence above T_r. The experimental observations are discussed within the context of the expected temperature-dependent magnetization structure and the corresponding magnetization reversal processes. © *1996 American Institute of Physics.* [S0021-8979(96)19508-6]

I. INTRODUCTION

Ultrathin ferromagnetic films have been found to exhibit a much stronger magnetocrystalline anisotropy than their bulk counterparts due to the broken crystallographic symmetry at the surface.[1] The magnetocrystalline anisotropy can even be sufficient to overcome the demagnetizing field and align the magnetization perpendicular to the surface.[1] For films in which the magnetocrystalline and dipolar self-energy are of comparable size, the so-called reorientation phase transition (RPT) can be observed as a function of film thickness or temperature.[2] The occurrence of this phase transition is caused by the different thickness or temperature dependence of these two competing energies. Both the temperature as well as the thickness-dependent reorientation transition have attracted a large amount of attention lately.[3] From an experimental point of view, the investigation of the temperature effect has the advantage of being measured on one particular sample, whereas thickness-dependent studies have to be performed on a series of samples. Thus, these samples are not necessarily comparable with regard to film morphology, etc., and we focus on the temperature-dependent RPT henceforth.

The temperature-dependent reorientation transition is characterized by two major experimental observations, as shown in Fig. 1. With increasing temperature, one first observes that the remanent out-of-plane magnetization is vanishing at a characteristic temperature T^*, with no in-plane magnetization found yet. At temperatures $T>T_r$ with T_r significantly larger than T^*, an in-plane magnetization occurs and increases strongly in a narrow temperature range, above which it saturates. Thus, for an intermediate temperature range $T^*<T<T_r$, no remanent magnetization can be observed.

Performing microscopic studies, Allenspach *et al.*[4] have been able to confirm that samples exhibit a multidomain state with alternating (see the inset in Fig. 1) out-of-plane domain magnetization in this intermediate temperature region. The domain state reduces the dipolar energy and therefore represents the lowest-energy state for films with an out-of-plane magnetization. In a recent study, we have been able to demonstrate that the occurrence of the remanent out-of-plane magnetization at low temperatures is actually a nonequilibrium effect, caused by the activation energy necessary to initially form domains.[5] Thus, the occurrence of the in-plane magnetization marks the real reorientation transition.

II. EXPERIMENT

In this paper, we investigate the characteristics of perpendicular magnetization curves $M(H)$ in the vicinity of the reorientation transition at T_r. For this purpose, we performed magneto-optical Kerr effect (MOKE) measurements for Fe/Ag(100) films with a thickness of approximately four monolayers, which exhibit a reorientation transition in an easily accessible temperature range of $T_r=200-400$ K. Similar to the results of previous experimental investigations, we observe that T_r decreases strongly with increasing thickness.[6] The complete experiment, i.e., film preparation and magnetic characterization, were done under ultrahigh vacuum conditions. The Fe films were grown by evaporation from an e-beam evaporator onto a clean and well annealed Ag(100)

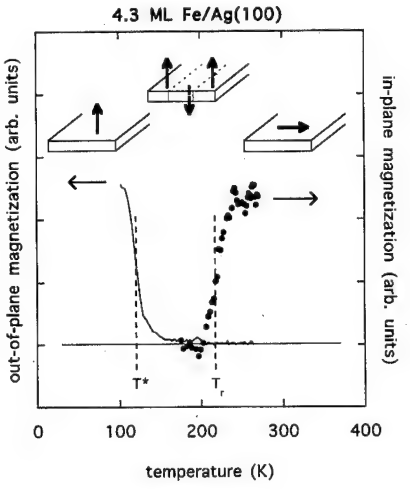

FIG. 1. Temperature-dependent magnetization in remanence for a 4.3 ML Fe/Ag(100) film (solid line: out of plane; circles: in plane); the thin solid line represents $M=0$ for both quantities. The corresponding magnetization states are illustrated.

substrate, held at room temperature. The growth rate was chosen to be approximately one monolayer per minute and was controlled *in situ* by a quartz monitor. After deposition, the films were heated to 440 K for 30 mins, which improved the sharpness of the LEED spots significantly, as previously demonstrated by Qiu *et al.*[6] Using two sets of coreless coils and a conventional MOKE setup,[7] we were able to measure the in-plane as well as out-of-plane magnetization.

III. RESULTS AND DISCUSSION

Figure 2 shows a set of perpendicular magnetization curves for a 3.8 monolayer Fe/Ag(100) film, measured at various temperatures in the vicinity of the reorientation transition temperature $T_r = 370 \pm 10$ K, which has been determined by measurements of the in-plane magnetization. As one can easily see from the data in Fig. 2, there is a quite extended temperature range in which no hysteresis effect is observed for the out-of-plane magnetization curves. Therefore, these curves can actually be compared to theoretical predictions derived from a thermodynamic treatment of the RPT phenomenon. For $T<316$ K, hysteresis effects occur due to the increasing significance of activation barrier limited processes, which eventually result in a metastable remanent out-of-plane magnetization at low temperatures.[5] It is obvious from Fig. 2 that the remanent magnetization is zero in the entire temperature range shown, but a very small magnetic field in the 10 Oe range is sufficient to fully saturate the sample. This observation is in excellent agreement with predictions for the multidomain state with domain magnetization perpendicular to the surface.[8] The reason for such a small value of the critical field H_{cr} at which saturation occurs is the fact that the energy gain of a multidomain structure is very small in ultrathin films.[9] Thus, a small external field already destabilizes the domain structure and produces a saturated single domain state. Furthermore, one can see from the curves in Fig. 2 that the critical field H_{cr} for the phase transition between the multidomain, and the single domain state is decreasing with decreasing temperature. This is also consistent with theoretical predictions, because at lower temperatures one expects an enhanced effective anisotropy, which corresponds to a reduced energy gain by domain formation.[9] Therefore, at lower temperatures an even smaller critical field H_{cr} is already sufficient to produce the saturated single domain state.

On evaluation of the detailed shape of the $M(H)$ curves in Fig. 2, one finds that the transition region between positive and negative saturation is not simply a straight line but has some curvature, at least for the low-temperature curves. To visualize this nonlinearity, we have determined the derivative dM/dH from our $M(H)$ data, which is shown in Fig. 2 as well. For low temperatures, the dM/dH curves exhibit a double peak structure in the magnetization reversal region; i.e., the susceptibility dM/dH has a strongly enhanced value at the critical field H_{cr}, where the system undergoes the phase transition to the saturated out-of-plane state. As the temperature increases, the peak structure at H_{cr} decreases gradually and cannot be observed anymore for temperatures $T \geqslant 363$ K. In this high-temperature range only a steplike structure is found. These measurements of $M(H)$ clearly demonstrate that the magnetization reversal process undergoes a qualitative change in the vicinity of T_r, which should be associated with the observed reorientation phase transition itself. To discuss these magnetization reversal properties in more detail, we compare our experimental data to the available theoretical models. Figure 3 shows the essential features for the magnetization states and magnetization reversal that one expects in the vicinity of T_r. For temperatures above T_r, the film is in a single domain state with in-plane magnetization. Under the assumption that an applied field (perpendicular to the surface) preserves the existence of a uniform state, one expects the out-of-plane magnetization to linearly increase with the applied field strength up to the critical field H_{cr}, where the magnetization is saturated. Thus, the susceptibility dM/dH should simply follow a steplike structure, as shown in Fig. 3. For temperatures below T_r, the magnetization behavior is very different. Due to the existing domain structure, the sample contains domains in which the magnetization is already aligned along the magnetic field direction. Thus, the magnetization reversal is associated with domain growth or domain wall displacement processes, which is fundamentally different from the rotation process occurring at higher temperatures $T>T_r$. So, it is not surprising that the $M(H)$ characteristic is very different for this domain state, resulting in a pronounced nonlinear behavior of the $M(H)$ curve. Kashuba *et al.* have evaluated the $M(H)$ behavior be-

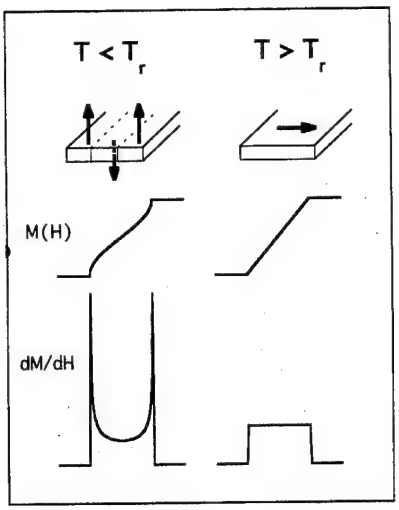

FIG. 3. Schematic of the expected magnetization states and the corresponding magnetization reversal properties in the vicinity of the reorientation phase transition.

low T_r for a simple stripe domain structure.[8] In their calculation they derived

$$M(H)=\frac{2}{\pi}M_S \arcsin\left(\frac{H}{H_{cr}}\right)$$

for the magnetization reversal region, resulting in a singularity of the susceptibility at the critical field H_{cr} (see Fig. 3). Thus, our measurements show exactly the features one expects for the magnetization reversal in the vicinity of the reorientation transition, namely, a linear $M(H)$ dependency for $T>T_r$ corresponding to a uniform rotation of the film magnetization, and a nonlinear $M(H)$ behavior associated with a domain structure and domain wall displacement processes for $T<T_r$. Therefore, our results do not only represent a study of the reversal process in the vicinity of the RPT, but they also confirm the existence of an equilibrium domain structure for $T<T_r$. But, even though the measurements exhibit the most essential features one expects in the vicinity of T_r, there are also some discrepancies between our measurements and the present theoretical description. First, calculations predict that very close to T_r, the critical field H_{cr} should decrease again with increasing temperature.[10] We do not observe this behavior. All our measurements show only a monotonic increase of H_{cr} with temperature. Second, we observe a gradual decrease of the peak height in the dM/dH data with temperature, which is also not expected within the available theoretical description. To our understanding, these discrepancies are caused by the fact that the theoretical model describing the magnetization reversal is restricted to a perpendicular magnetization direction within the domains, independent of the temperature.[8] It has been shown that the total energy of a stripe domain structure can actually be reduced by an inclined domain magnetization near the RPT.[9] Thus, one expects the magnetization state to show a gradual transition from an out-of-plane domain state to an in-plane uniform state. In this case, one would also expect that the magnetization reversal process gradually changes from a pure domain wall displacement to a pure magnetization rotation, producing the gradual alteration of the $M(H)$ and dM/dH characteristics we have found in our experiments. The observed discrepancies also imply that recent evaluations of the phase diagram in the immediate vicinity of T_r are insufficient because they do not include the possibility of a gradual change in the domain magnetization direction.[10]

Structure and magnetism in fcc magnetic transition metals on (001) diamond (abstract)

J. A. Wolf,[a] J. J. Krebs, Y. U. Idzerda, G. A. Prinz, and K. M. Kemner[a]
Naval Research Laboratory, Washington, DC 20375

We have prepared single crystal face centered cubic (fcc) magnetic transition metal films (Co,Ni,Fe) on (001) diamonds, the thickness of the films varying between a few tenths of a nanometer to over 100 nm. The crystalline quality and fourfold symmetry of these layers was monitored *in situ* during the film growth with RHEED and a chemical analysis was performed using Auger spectroscopy. In addition, the structure of the samples was investigated *ex situ* using X-ray diffraction and EXAFS, demonstrating the single crystal, fcc (001) structure throughout each entire film. The magnetic characterization was performed with Ferromagnetic Resonance (FMR) and Superconducting Quantum Interference Device (SQUID) hysteresis loops. The saturation magnetization of the Co films is only slightly lower than the literature values. The coercive fields are very small (~25 Oe) and the magnetization reversal very sharp. The FMR yielded a fourfold anisotropy comparable to literature values. The observation of the first standing spinwaves underlines the good quality. The Ni films are tetragonally distorted due to the 1.2% mismatch. The FMR data indicate a significant perpendicular anisotropy slightly smaller than $4\pi M$, the fourfold in-plane anisotropy being comparable to the bulk value. The saturation magnetization is reduced by 30% compared to bulk values, probably due to nickel-carbide which was observed in the XRD data from some samples. Neither the in-plane ⟨110⟩ nor the in-plane ⟨100⟩ axis show an easy axis behavior and both require fields in excess of 6000 Oe to saturate, the coercive fields being about 200 Oe. The RHEED patterns of the Fe films show single crystal growth with a lattice constant comparable to diamond, indicating an fcc structure. A similar structural and magnetic characterization of these films will also be presented. [S0021-8979(96)43008-9]

Anomalous perpendicular magnetism in Ni/Cu(001) films and the effects of capping layers

W. L. O'Brien
Synchrotron Radiation Center, University of Wisconsin—Madison, 3731 Schneider Drive, Stoughton, Wisconsin 53589

B. P. Tonner
Department of Physics, University of Wisconsin—Milwaukee, 1900 East Kenwood Blvd., Milwaukee, Wisconsin 53211 and Synchrotron Radiation Center, University of Wisconsin—Madison, 3731 Schneider Drive, Stoughton, Wisconsin 53589

X-ray magnetic circular dichroism (XMCD) measurements on wedges of Ni grown on Cu(001) are used to investigate magnetic properties in Ni/Cu(001) ultrathin films. A sharp transition from in-plane to perpendicular magnetization is found near 7 ML, and a gradual transition back to in-plane magnetization begins near 37 ML. The critical thickness for epitaxial growth, 13 ML, is determined from a rapid rise in the coercive field versus film thickness. Both transitions in the direction of easy axis are well explained by considering the effects of the surface, shape, and the strain-induced magnetoelastic anisotropies. The critical layer thickness of 13 ML plays a critical role in understanding the transition near 37 ML. Capping the Ni wedge with 2 ML of Co increases the magnitude of the surface anisotropy, forcing the magnetization to remain in plane for thickness up to at least 18 ML. Addition of an Fe capping layer has no effect on the direction of magnetization, suggesting the importance of interface anisotropies or intermixing. © *1996 American Institute of Physics.* [S0021-8979(96)19608-2]

Ultrathin films and multilayers possessing easy axes of magnetization perpendicular to the surface have recently attracted much interest[1–4] due to their potential advantages in magneto-optical recording. The existence of perpendicular magnetization is determined by the combined effects of all the magnetic anisotropies present. These anisotropies include shape, surface, interface, and crystalline anisotropies, strain-induced magnetoelastic anisotropy, and anisotropies due to roughness and atomic mixing at the interfaces. An important goal in the research on these thin films and multilayers is to understand which anisotropies are important in determining the easy axes of magnetism.

In the past few years a number of studies have been performed on the magnetism of Ni/Cu(001) thin films.[1–3] Ni/Cu(001) films show a transition from in-plane magnetization to perpendicular magnetization as the film thickness increases. This unusual behavior is opposite to what would be predicted by the effects of a surface anisotropy by itself. Schulz and Baberschke,[2] using FMR, showed that the unusual magnetic behavior of Ni/Cu(001) could be explained by the competition between a negative surface/interface anisotropy and a uniaxial magnetoelastic volume anisotropy due to the strain caused by psuedomorophic growth. For films less than ~7 ML thick the surface anisotropy dominates and the films have an in-plane easy axis of magnetization. Films thicker than ~7 ML have an easy axis of magnetization perpendicular to the surface due to the volume effect of the magnetoelastic anisotropy, which favors perpendicular magnetization.

In this paper we discuss the results of experiments designed to more fully understand the magnetic anisotropies in Ni/Cu(001) thin films. The experiments were performed on the 10 m TGM beamline located at the Synchrotron Radiation Center, Stoughton, WI. All magnetic measurements were made using x-ray magnetic circular dichroism (XMCD), which gives element specific magnetic information. Details of the XMCD measurements are published separately.[5] Measurements were made at room temperature on Ni wedges grown on a clean Cu(001) single crystal at a base of 2×10^{-10} Torr. The pressure during film growth was 8×10^{-10} Torr. Five different wedges, with overlapping thickness ranges were used in this study.

Hysteresis curves obtained for different Ni thicknesses are shown in Fig. 1 for magnetization applied perpendicular to the sample surface. The curves were obtained by setting the photon energy to the Ni L_3 absorption maximum and sweeping the magnetic field. The height of the loops are normalized to the total Ni L_3 cross section and are propor-

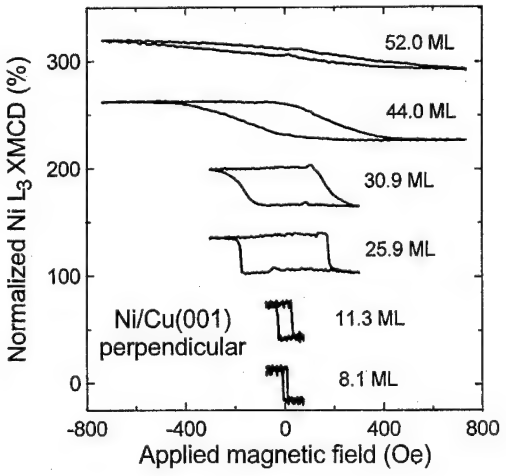

FIG. 1. Hysteresis curves for different Ni film thicknesses from Ni/Cu(001) wedges. The magnetic field was applied perpendicular to the film surface.

 0021-8979/96/79(8)/5623/3/$10.00

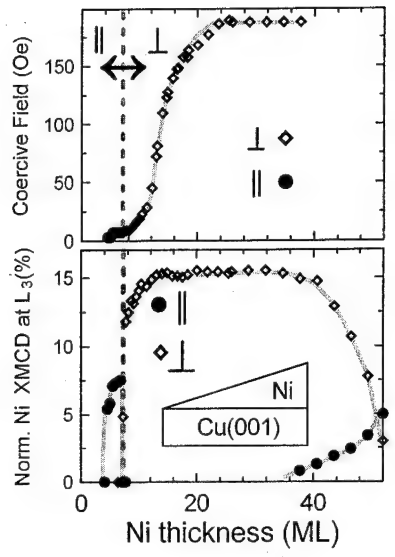

FIG. 2. Coercive field (top) and normalized remanent dichroism intensity (bottom) vs thickness across Ni/Cu(001) wedges. There is sharp transition from an in-plane to perpendicular easy axis of magnetization at 7 ML and a gradual transition from a perpendicular to an in-plane easy axis of magnetization beginning near 37 ML. Note the sharp increase in H_c beginning near 13 ML.

tional to the average magnetization per Ni atom. In Fig. 2(a) the coercive field, H_c, is plotted versus film thickness. H_c increases rapidly beginning near 13 ML, and reaches a constant value of ~190 Oe near 24 ML. In Fig. 2(b) the normalized dichroism intensity is plotted versus film thickness. Below 7 ML the easy axis of magnetization is in plane, between 7 and 36 ML the easy axis of magnetization is perpendicular to the surface, for thicknesses greater than 37 ML the film could be magnetized both in plane and perpendicular to the surface.

Following Schulz and Baberschke,[2] the easy axis of magnetization for Ni/Cu(001) is determined by the surface, interface, and magnetoelastic anisotropies. Perpendicular magnetization in the Ni/Cu(001) films will result when

$$K_{\mathrm{ME}} > \frac{-K_S - K_I}{d} + 2\pi M^2, \tag{1}$$

where K_{ME}, K_S, and K_I are the magnetoelastic, surface and interface anisotropy constants, respectively, d is the film thickness, and M is the magnetization. The use of (1) is complicated due to the dependence of T_c on film thickness and of M on T_c/T. At room temperature, $K_{\mathrm{ME}}=29$ μeV/atom in the pseudomorphic region and $K_I+K_S=-154$ μeV/atom.[2] Using experimental values[3] of M and T_c versus film thickness we find that the transition from in-plane to perpendicular magnetization should take place near 6 ML at room temperature. This is consistent with the results in Fig. 2 and with the results of Schulz and Baberschke.[2]

Both Ni and Cu crystallize in the fcc structure with the Ni lattice constant being 2.5% smaller than the Cu lattice constant. Structural investigations[6,7] of Ni growth on Cu(001) show that the Ni films initially grow pseudomorphically. This growth mode continues up to a critical thickness, d_c, where the onset of strain relaxation causes the formation of misfit dislocations. Strain relaxation also reduces the magnetoelastic energy, causing the magnetism to switch back to in plane for thicker films. In magnetoelastic theory, the magnetoelastic anisotropy is proportional to the strain, ϵ. In the pseudomorphic growth region $\epsilon=-\eta$, where η is the lattice misfit. Chappert and Bruno[8] have derived an expression for the residual strain for film thicknesses greater than d_c, $\epsilon=-\eta\, d_c/d$. Using this and the value of K_{ME} for $d<d_c$ determined by Schulz and Baberschke,[2] we obtain $K_{\mathrm{ME}}=29\, d_c/d$ μeV/atom for $d>d_c$.

The transition from perpendicular to in-plane magnetization at higher coverages due to strain relaxation can now be determined. Assuming $d_c=8$ ML[6] we find that the magnetization in the film should be in plane again above 14 ML. This is clearly not in agreement with the results in Fig. 2, which show that the perpendicular to in-plane transition occurs at ~37 ML. Either the assumption that $\epsilon=-\eta\, d_c/d$ or that $d_c=8$ ML must be incorrect. This value of $d_c=8$ ML is the generally accepted value of d_c.[2,3] It comes from an *ex-situ* TEM study of a Ni/Cu(001) wedge.[6] The Cu(001) substrate was grown on a NaCl surface in high vacuum (10^{-7} Torr). After Ni deposition (2×10^{-8} Torr) the bilayer was floated off the NaCl surface and examined by TEM and diffraction. Due to the greatly different techniques and conditions in film preparation between our experiment and the TEM experiment we suspect that the value of $d_c=8$ ML may not be valid for our experiment. In fact, recent XPD experiments on 10 ML Ni/Cu(001)[7] are well explained by assuming that no strain relaxation has taken place. This sets a lower limit of 10 ML on d_c.

The need for an accurate value of d_c is apparent. We look again at the H_c results presented in Fig. 2. It is well known that the strain in pseudomorphic films is relieved by the formation of misfit dislocations once the critical thickness for epitaxial growth has been exceeded. It is equally well known that defects and dislocations in magnetic single crystals increase the coercive field.[9] These two arguments taken together allow us to interpret the rapid rise in the coercive field vs Ni film thickness as being due to the formation of misfit dislocations. We can also take the onset of the rapid rise in H_c as an estimate for d_c. From Fig. 2 $d_c\sim13$ ML for Ni/Cu(001). Using $d_c=13$ ML, we determine that the crossover from perpendicular to in-plane magnetization should occur at 34 ML, in better agreement with the results in Fig. 2.

To show that the rapid increase in H_c versus film thickness is a general phenomena that is useful for measuring d_c, we have investigated the magnetism in Co wedges grown on Cu(001). We find a trend in H_c versus film thickness similar to that shown in Fig. 2, with a rapid increase from $H_c=20$ Oe to $H_c=100$ Oe, beginning at 12 ML. Co grows pseudomorphically on Cu(001) in a metastable face centered tetragonal structure up to a critical thickness of ~11 ML, as determined by TEM.[10] The onset of the rapid rise in H_c near 12 ML is consistent with d_c measurements by TEM. We have performed similar experiments on a number of other thin film systems, including Fe/Pd(001) and Fe/Ag(001). In each case we find a trend in H_c versus film thickness similar to that shown in Fig. 2. For each system studied, the onset in

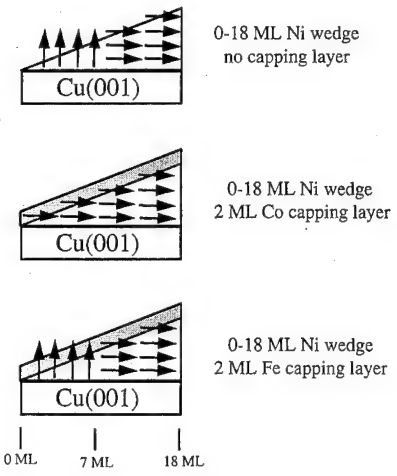

FIG. 3. Effects of capping layers on an easy axis of magnetization for a 0–18 ML Ni/Cu(001) wedge. Addition of 2 ML Co causes the magnetization direction to lie in plane along the entire wedge while the addition of 2 ML Fe has no effect on the direction of magnetization vs film thickness.

the rapid rise of H_c can be equated with the critical thickness for epitaxial growth.

Both transitions in the direction of magnetization, Fig. 2, are now explained using (1). It would be informative to measure the changes in magnetization influenced by altering one or more of the anisotropy constants in (1). Toward this purpose we have studied the magnetization of Ni/Cu(001), wedges, 0–18 ML, capped with a 2 ML film of either Co or Fe. This should alter the value of K_S in (1). The Ni wedge capped with Co has an in-plane easy axis of magnetization over the entire Ni thickness range, while capping with Fe has no effect on the magnetization direction versus Ni thickness. These results are summarized in Fig. 3. For each position on both wedges the magnetic bilayers were ferromagnetically coupled, as determined by measuring the hysteresis curves of each element separately, which is possible using XMCD.

To discuss the effects of the capping layers (1) must be modified to include an additional interface anisotropy term, and K_S is now dependent on the capping layer. Fe has a positive surface anisotropy[4] and Co has a large negative surface anisotropy, ~ -400 μeV/atom,[11] for growth on Cu(001). As a starting point, we assume that K_S of Fe and Co are the same for growth on Ni(001) and Cu(001), and consider only the effects of changing K_S (we assume intermixing is negligible and that $|K_S| \gg |K_I|$). Capping with Co increases K_S by a factor of ~ 2.5 and should cause the transition from in-plane to perpendicular magnetization to shift to higher Ni thicknesses. This is consistent with our experiment. Capping with Fe changes the sign of K_S, which should cause Ni films less than 7 ML thick to magnetize perpendicular to the surface. This is not consistent with our experiment. Interface anisotropies or intermixing are apparently important and need to be considered.

The magnetic structure of nanoscale alloy films has been probed using the magnetic x-ray linear dichroism in photoelectron spectroscopy. FeNi and CoFe epitaxial films were grown on Cu(001), *in situ* and using molecular beam epitaxy techniques. The magnetic x-ray linear dichroism measurements were made at the Spectromicroscopy Facility of the Third Generation Advanced Light Source. Because soft x-rays were used to generate photoemission from the $3p$ core levels, both elemental selectivity and magnetic sensitivity were achieved simultaneously. © *1996 American Institute of Physics.* [S0021-8979(96)41808-9]

A full elucidation of the underlying principles driving magnetic properties in complex systems will require the applications of probes which couple elemental specificity and magnetic sensitivity. Two important classes of magnetic devices, spin valves[1] and giant magnetoresistance (GMR) materials,[2] are typically composed of several nanoscale layers or aggregations[3] composed of different elements or alloys. The ultra-thin nature of these films or clusters further complicates the picture by introducing the impact of interfacial effects, including pseudomorphic strain and spin-specific scattering at the interfaces.[4] One avenue to address such issues is to build epitaxial ultrathin alloy films and probe them directly using techniques that are both elementally selective and magnetically sensitive. Here we report the beginnings of such a study, using CoFe and FeNi films grown with molecular beam epitaxy (MBE) techniques and investigated with magnetic x-ray linear dichroism[5–7] (MXLD) in the core-level photoelectron spectroscopy of the $3p$ states of Fe, Co, and Ni. (See Fig. 1).

The measurements were made at the Spectromicroscopy Facility (Beamline 7) of the Advanced Light Source at Lawrence Berkeley Laboratory.[8] Extraordinarily bright, linearly polarized x-rays were generated by the U 5.0 undulator and wavelength selection was achieved using the spherical grating monochromator, with a resolving power of over 8000. The photoelectrons were detected using the angle-resolving, multichannel, 5.4 in. radius, Perkin–Elmer hemispherical deflector system. Sample alignment (including pseudomorphic growth), cleanliness, and composition were measured using the hemispherical deflector and a separate Mg Kα source, thus freeing up the beamline for other uses during our periods of sample preparation. The actual MXLD measurements (Fig. 2) used the highly polarized synchrotron radiation and were performed with a total instrumental energy resolution bandpass of <100 meV and angular resolution of 2°. The angle of incidence of the x-rays was 30° relative to the surface plane. The electrons were collected along the surface normal, i.e., "normal emission." Typically, the magnetic alloy was magnetized in the plane of the surface but perpendicularly to the plane containing the emission direction (surface normal) and the Poynting vector and electric polarization vector of the x-rays. Thus, the "transverse-chiral" condition necessary for MXLD was achieved: reversing the magnetic field causes two mirror-image configurations which are equivalent but totally nonsuperimpossible. By comparing spectra from these configurations, it is possible to directly probe the magnetic perturbations of the elementally specific electronic structure of the systems.

The alloy systems under consideration were CoFe and FeNi. Ultra-thin films of each were grown on Cu(001) at room temperature, using well-developed MBE techniques.[9] Studies of the bulk electronic structures have been performed,[10–13] but the properties of these pseudomorphic overlayers are further complicated by epitaxial strain and other nanoscale effects. Examples of our spectroscopic results are shown in Figs. 3 and 4. In this energy regime, the

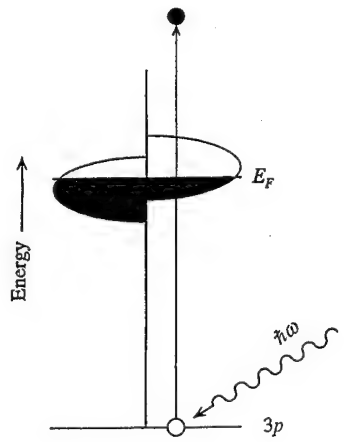

FIG. 1. The ejection of a $3p$ electron by a linearly polarized x-ray is shown here. The spin-polarized d-states, near the Fermi level, are also included. The presence of these magnetically polarized valence bands are the root cause of the MXLD effect.

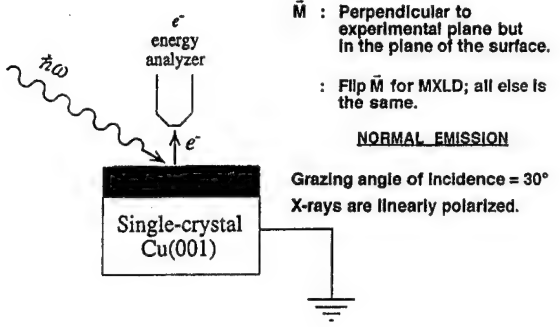

FIG. 2. The experimental configuration is schematically shown here. The grazing angle of incidence of the linearly polarized x-rays was 30°, relative to the surface plane. Electrons injected perpendicularly to the surface were collected by the angle resolving detector (i.e., normal emission). The plane containing the ejected electron and the Poynting vector of the x-ray also contained the electric polarization vector of the x-ray as well. The magnetization vector was perpendicular to this experimental plane, but in the plane of the surface. To achieve MXLD, comparisons were made between spectra in which only the direction of the magnetization was reversed; all else was kept the same.

cross sections for the Fe, Co, and Ni $3p$ are strongly photon-energy dependent:[14] hence, the peaks do not scale with concentration without further correction. The asymmetry in the case of the Fe and Co in Fig. 3 is actually underestimated. It would be appropriate to set the prepeak region, before the Co and Fe, respectively, to zero for that calculations. (See Figs. 3 and 4.)

Presently, we are pursuing studies of these systems where we vary the thickness and composition of the magnetic overlayers and probe the $3p$ levels of each element. In essence, we are attempting to use the MXLD measurements as element-specific, surface magnetometers. Our initial studies suggest a concentration dependent quenching similar to that observed in bulk Invar but with different elementally specific contributions than those of the bulk.[10–13] It appears that template and thickness dependent relaxation effects may be competing in this system. Additional studies will include not only MXLD but also surface magneto-optic Kerr effect

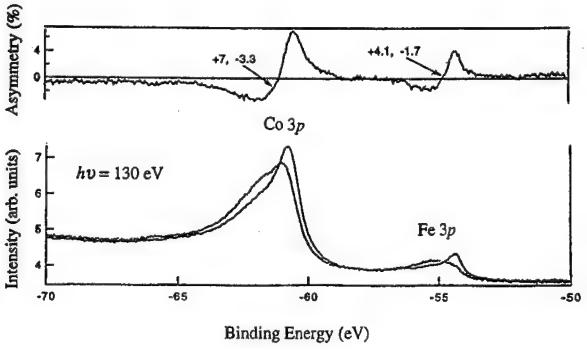

FIG. 3. Photoelectron spectra of Fe[1]Co[8]/Cu(001), taken using a photon energy of 130 eV. Also shown is the asymmetry for these two spectra. The asymmetry is equal to $(I^+ - I^-)$ divided by $(I^+ + I^-)$. The asymmetry values shown here, positive peaks of 7% for Co and 4% for Fe, are the most conservative estimates. These were calculated using the entire underlying electron background in I^+ and I^- (see vertical scale). If one instead uses the prepeak (lower binding energy) regions as an estimate of zero intensity, values near 40% for Fe and 15% for Co are found.

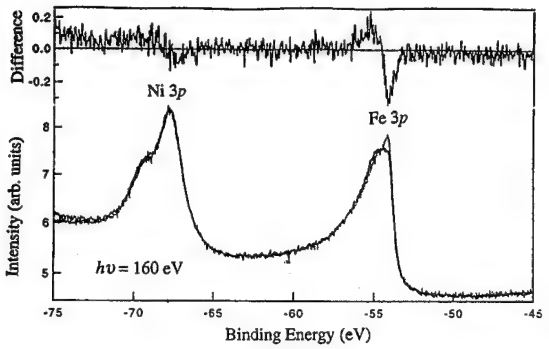

FIG. 4. Photoelectron spectra of Fe[1]Ni[4]/Cu(001), taken using a photon energy of 160 eV. Here, a difference spectrum is also shown. Using the prepeak regions as estimates of zero intensity, asymmetry values near 5% for Fe and 2% for Ni can be obtained. The relatively larger spin-orbit effect in Ni results in a more consistent structure with a peak and shoulder, compared to the Fe spectra.

(SMOKE) measurements.[9,15] Furthermore, analysis based upon the MXLD effects may not be quite as straightforward as it might seem: it is not clear that simple perturbative models are accurate.[16,17] In fact, for the $3p$ levels of Fe, Co, and Ni, it may be that simple perturbative pictures fail and that both the spin-orbit and exchange splitting need to be dealt with on an equal footing[16,17] (Fig. 5). However, as one moves across the series from Fe to Ni, the ratio of magnetic moment to spin orbit splitting decreases substantially, suggesting the plausibility of a perturbative approach for Ni (Table I). This is reflected also in Fig. 4. Thus, our initial results are promising in terms of understanding key effects in magnetic nanoscale films, including such possibilities as strain-modified invar quenching, but it may require more sophisticated analysis, including multiple-scattering calculations[16,17] and more extensive examination of thickness and composition effects.

We are using the elementally specific and magnetically sensitive technique of MXLD photoelectron spectroscopy to probe nanoscale magnetic alloys. These structures are the building blocks of many new magnetic devices, including spin-value and GMR materials. The variation of classical

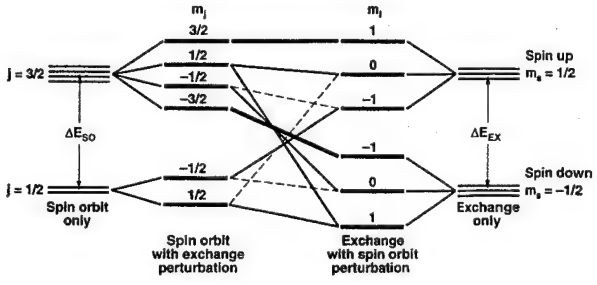

FIG. 5. The effect of spin-orbit and exchange splitting upon a p core-level is illustrated here. Two perturbative approaches are shown: Large spin-orbit and small exchange splitting (left hand side) and small spin-orbit and large exchange splitting (right hand side). The Ni $3p$ would fall to the left while the Fe $3p$ is near the center, where spin-orbit and exchange effects are nearly equal and a nonperturbative approach is required. State mixing is indicated by dashed and solid lines (Table I).

TABLE I. A rough comparison of exchange and spin orbit splittings in Fe, Co, and Ni is shown here. Assuming that the spin-orbit splitting scales as z, the atomic number, to the fourth power,[18] it is possible to crudely estimate the spin-orbit splitting in Fe and Co from spectroscopic data (Ref. 19) for Ni, Cu, and Zn. By comparison to the ratio of the magnetic moment (Ref. 20) vs the spin orbit splitting in Ni, we see that such a ratio is seven times larger for Fe than Ni. Thus, while it might be possible to view the Ni $3p$ from the limiting case of an exchange splitting perturbing a larger spin-orbit splitting, such an approach is unlikely to be appropriate for the Fe $3p$.

New magnetic phases of Fe on fcc Co(001) and Ni(001)

W. L. O'Brien
Synchrotron Radiation Center, University of Wisconsin—Madison, 3731 Schneider Drive, Stoughton, Wisconsin 53589

B. P. Tonner

A sequence of three distinct magnetic phases of Fe are found for growth on both fcc Co(001) and Ni(001) using x-ray magnetic circular dichroism. For Fe coverages below 5 ML the films are ferromagnetic, with the magnetic moments aligned perpendicular to the surface for growth on Ni and parallel to the surface for growth on Co. Between 5 and 11 ML the Fe films are nonferromagnetic at room temperature. Above 11 ML the Fe films are once again ferromagnetic. An identical sequence of magnetic phase transitions is known to occur for Fe growth on Cu(001). Based on this comparison and on the nearly identical lateral lattice constants of fcc Co, Ni, and Cu, we conclude that Fe growth on fcc Co(001) and Ni(001) follows the same sequence of crystalline phase transitions as Fe growth on Cu(001). © *1996 American Institute of Physics.*
[S0021-8979(96)19708-9]

Metastable magnetic phases of Fe grown on Cu(001) are perhaps the most intensely studied thin film magnetic system.[1–5] These films exhibit a variety of different magnetic properties and crystalline structures, depending on film thickness and temperature. Three phases of Fe, identified by their different magnetic properties, are found in films grown at room temperature using physical vapor deposition. Fe films less than five monolayers (ML) thick are ferromagnetically ordered, with an easy axis of magnetization perpendicular to the surface.[1,2] Films between 5 and 11 ML thick are antiferromagnetic with a Néel temperature below room temperature. The outer two surface layers of this antiferromagnetic phase are ferromagnetically aligned with the moment oriented perpendicular to the surface.[1,2] Films thicker than 11 ML are ferromagnetic with an in-plane moment.[1,2]

These three regions of different magnetic behavior correspond to three distinct surface structures, which can be identified by their low-energy electron diffraction (LEED) patterns.[3] The ferromagnetic phase present at coverages below 5 ML has an $(n\times 1)$ LEED pattern, where $n=4$ or 5.[1–3] The antiferromagnetic phase has been reported by various groups to have either a (1×1)[2] or (2×1)[1,3] LEED pattern. For coverages above 11 ML, a (3×1) LEED pattern is observed.[1–3] The crystalline structure of these three phases has been investigated by a number of techniques, including x-ray photoelectron diffraction,[6] scanning tunneling microscopy (STM),[5] and extended x-ray absorption fine structure (EXAFS).[4] EXAFS and STM both find evidence of a fcc to bcc phase transition as the film thickness increases beyond 10 ML. This identifies the antiferromagnetic Fe phase present between 5 and 11 ML as fcc Fe and the ferromagnetic phase present at coverages above 11 ML as bcc Fe. The low coverage (<5 ML) ferromagnetic phase has been identified as a face-centered-tetragonal, fct, structure by EXAFS.[4]

An important open question is whether the metastable fct and fcc structures of Fe can be observed on other substrates, or if they are only present in the Fe/Cu(001) system. We have chosen to investigate both fcc Ni(100) and metastable fcc Co(100) as substrates for Fe epitaxy, where the substrates are in the form of films grown on Cu(100). For Co/Cu(001) the growth mode is nearly perfectly layer by layer, resulting in metastable fcc Co films with the same surface unit cell as Cu(001)[6] for films below the critical layer thickness for dislocation formation. Ni on Cu(001) also grows in the fcc structure,[7] owing to the close lattice match between Ni and Cu. Because of the nearly identical surface unit cell of Cu(001), metastable fcc Co(001), and Ni(001), we expect that there is a strong likelihood that the Fe/Co(001) and Fe/Ni(001) structures are very similar to those of Fe/Cu(100).

In this paper we report on the magnetism and structure of ultrathin Fe films grown on the ferromagnetic substrates, fcc Co(001) and fcc Ni(001). The experiments were performed on the 10 M toroidal grating monochromator beamline located at the Synchrotron Radiation Center. The fcc Co(001) (10 ML) and fcc Ni(001) (15 ML) thin-film substrates were grown on a clean Cu(001) crystal at room temperature by evaporation from pure Co and Ni wires. These film thicknesses were chosen to reduce the possibility of Cu diffusion to the surface. Both of these substrates are ferromagnetic with the magnetization vector lying in plane for Co and perpendicular to the surface for Ni. Fe films of different thickness were deposited at room temperature, by evaporation from a pure Fe wire. The base pressure of the vacuum chamber was 2×10^{-10} Torr, and the pressure during evaporation was below 2×10^{-9} Torr. LEED was used to determine substrate and film order.

X-ray magnetic circular dichroism (XMCD) measurements were made with the sample located between the poles of an electromagnet. Two geometries were used for the XMCD measurements, as shown in Fig. 1. The photon angle of incidence was 45° for both perpendicular and in-plane measurements. XMCD spectra were taken at room temperature by switching the direction of the magnetic field and measuring the total electron yield, $Y(\hbar\omega)$, while sweeping the incident photon energy at a fixed polarization. Dichroism

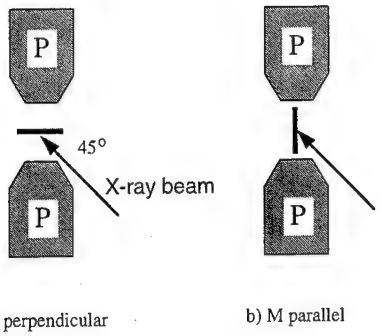

FIG. 1. Experimental geometry for (a) magnetization perpendicular to the sample surface and (b) parallel to the sample surface. The sample is rotated 90° to change the measurement geometry.

intensities were normalizing to the total absorption cross section and are proportional to the magnetization.

There are a number of important reasons why the specific measurement geometry of Fig. 1 was chosen. We have shown earlier[8] that the approximation $\sigma(\hbar\omega) \propto \hbar\omega \cdot Y(\hbar\omega)$, where $\sigma(\hbar\omega)$ is the absorption cross section, is not always valid for studies of magnetic films with photon angles of incidence greater than 50°. This is due to saturation effects in the total electron yield. Our geometry was chosen so that the approximation $\sigma(\hbar\omega) \propto \hbar\omega \cdot Y(\hbar\omega)$ is valid to within 5%.[8] The symmetry of our experimental geometry allows a direct comparison of the XMCD intensities between the parallel and perpendicular magnetization cases. This geometry, together with azimuthal rotation, also allows the easy axis of magnetization to be determined unambiguously.

The normalized Fe dichroism intensities at L_3 measured at remanence, Σ_R(Fe), were found to vary greatly depending on Fe film thickness and substrate. Figure 2 shows a graph of Σ_R(Fe) as a function of Fe film thickness on the three substrates we studied. For Fe growth on Cu(001), no ferromagnetic ordering is observed for films less than 11 ML thick. Above 11 ML the films are ferromagnetically ordered in-plane, as shown by the nonzero dichroism intensity. The saturation in Σ_R(Fe) at 14 ML shows that the entire film is magnetized at this thickness.

Three regions of different magnetic behavior are found for Fe growth on the ferromagnetic substrates fcc Co(001) and fcc Ni(001). These regions are characterized by different values of Σ_R(Fe). For coverages less than 4 ML, the Fe is ferromagnetically aligned, as determined by the large value of Σ_R(Fe) ~32%. The easy axis of magnetization is in plane along ⟨110⟩ for 1–4 ML of Fe on Co(001). At the same thickness range on Ni(100), the easy axis is perpendicular to the surface.

Between 5 and 11 ML, Σ_R(Fe) is reduced to nearly zero for growth on both Co and Ni. The easy axis of magnetization for this thickness range remains in plane for growth on Co, ⟨110⟩, and perpendicular to the surface for growth on Ni. For coverages greater than 11 ML, Σ_R(Fe) increases. For growth on Co, Σ_R(Fe) at 16 ML coverage is nearly equal to Σ_R(Fe) for thick bcc Fe films grown on Cu(001). For growth on Ni, Σ_R(Fe) gradually increases over the thickness range from 12 to 18 ML, but does not quite reach the value of

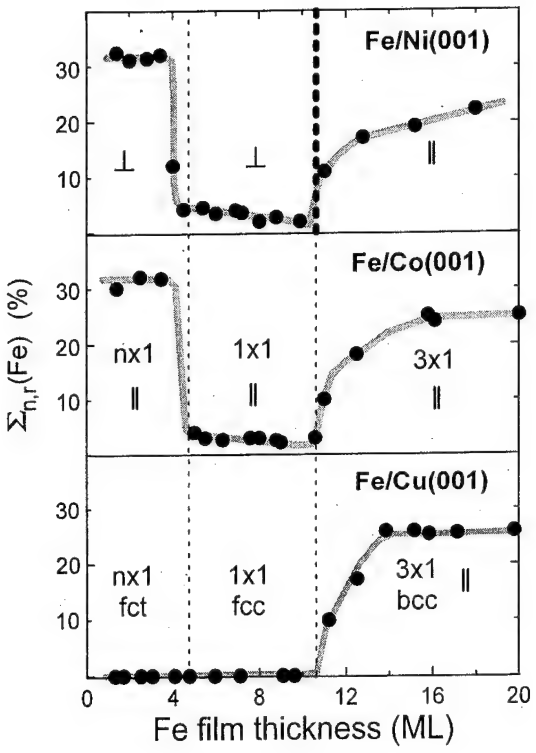

FIG. 2. Normalized dichroism intensities of Fe measured at remanence, Σ_R(Fe), which is proportional to the average vector magnetic moment per Fe atom, vs the film thickness for growth on Cu(001), Co(001), and Ni(001). The vertical dashed lines represent regions of different growth for Fe/Cu(001), fct, fcc, and bcc. Different surface reconstructions, as observed by LEED, are given for Fe growth on Cu(001) and Co(001). The symbols ⊥ and ∥ signify magnetic alignment perpendicular and parallel to the sample surface, respectively.

Σ_R(Fe) for thick bcc Fe films grown on Cu(001). The easy axis of magnetization for Fe films thicker than 11 ML switches from perpendicular to the surface to in plane for Fe films grown on Ni, and remains in plane for Fe films grown on Co(001). Element specific hysteresis measurements show predominantly square hysteresis loops, $M_R > 0.9M_S$, with ferromagnetic coupling between the substrate and Fe for all Fe thicknesses.

It is important to examine the magnetization of the substrate before discussing the results presented in Fig. 2. In Fig. 3 we show the values of Σ_R(Co) and Σ_R(Ni) vs Fe coverage. Σ_R(Co) does not change with Fe coverage, and the easy axis of magnetization is always in the surface plane. For Fe/Ni, Σ_R(Ni) is 18% for Fe coverages less than 11 ML and 12% for Fe coverages greater than 11 ML. This change in Σ_R(Ni) is accompanied by a change in the easy axis of magnetization, which is perpendicular to the surface for coverages below 11 ML and in plane for coverages above 11 ML. The decrease in Σ_R(Ni) may be due to complex magnetic domain structures in the Ni films magnetized in plane. The sharp decline in the Fe magnetization near 5 ML has no counterpart in the substrate signals. The rise in Fe magnetization above 11 ML is absent in the Co data, and for Ni there is an opposite behavior at this point. This means that the magnetization changes seen in the Fe films at 5 and 11 ML must be

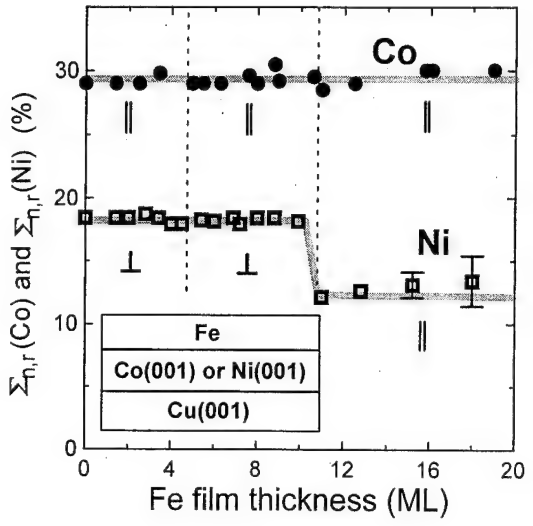

FIG. 3. Normalized dichroism intensities of the Co and Ni substrates vs Fe coverage.

due to phase changes in the Fe itself, rather than arising from changes in the substrate magnetization.

The dashed lines in Fig. 2, at 5 and 11 ML, separate the regions of different crystal structures found for Fe growth on Cu(001).[1,2] The onset of ferromagnetic ordering at 11 ML for Fe/Cu(001) is due to the antiferromagnetic fcc to ferromagnetic bcc phase transition. We do not see magnetic ordering in the fcc phase (5–11 ML), since we are measuring at room temperature. Both the Néel temperature of the fcc phase (T_N=200 K) and the Curie temperature of the live surface bilayer (T_C=250 K) are below room temperature.[2] Similarly, we observe no perpendicular magnetization for fct Fe/Cu(001) films (5 ML and below), since room temperature is only slightly below the Curie temperature of these films.

The regions of different magnetic behavior of Fe for growth on Co and Ni nearly coincide with the regions of different crystal structure for Fe growth on Cu. This is strong evidence that Fe has the growth mode on Cu(001), Co(001), and Ni(001). Further evidence comes from LEED. For Fe growth on Co, we observe $(n\times1)$, n=4 or 5, diffraction patterns for Fe coverages less than 5 ML, (1×1) diffraction patterns for Fe coverages between 5 and 11 ML, and (3×1) diffraction patterns for coverages greater than 11 ML. This is identical to the LEED results we obtain for Fe growth on Cu(001), and is in agreement with published LEED results for Fe/Cu(001).[2] For Fe growth on Ni(001), we do not observe sharp higher-order diffraction spots, just intensity modulated streaks along the ⟨110⟩ directions. Given the identical surface unit cells of the three substrates, the coincidence of the changes in magnetism with anticipated changes in crystalline structure, and the identical surface reconstructions for growth on Cu(001) and Co(001), we propose that the sequence of structures for Fe grown on Ni(001) and Co(001) is the same as for Fe growth on Cu(001).

The magnetic transitions of the Fe/Co and Fe/Ni thin films (Fig. 2) can now be explained in terms of the structural changes in the films and the influence of the magnetic substrates. At coverages below 5 ML, the Fe films grow in the fct structure, which is ferromagnetic. Ferromagnetic ordering is evident in the large dichroism intensity we find for films between 1 and ~4 ML thick. Between 5 and 11 ML, the Fe films grow with a fcc structure. For growth on Cu(001), fcc Fe is an antiferromagnet (T_N=200 K). Since T_N for the Fe/Cu(001), Fe/Co(001), and Fe/Ni(001) films are likely to be similar, at room temperature these films will be nonmagnetic. However, the dichroism signal in this phase is greatly reduced, but does not go to zero. This nonzero dichroism intensity is most likely due to magnetism at the Fe/Co and Fe/Ni interfaces. Above 11 ML, the critical thickness for fcc Fe growth is exceeded, and the Fe films gradually transform into the bcc structure. This is the room temperature stable crystal structure, and it is ferromagnetic, which is evident in the increase in the dichroism intensity. The larger value of Σ_R(Fe) for fcc Fe may be due to an enhanced surface moment, or complex domain structures in the bcc Fe/fcc Ni and bcc Fe/fcc Co films.

We have measured the polar nonlinear magneto-optical Kerr rotation and the total generated second harmonic intensity from a perpendicularly magnetized Co(0001)/Au(111) thin film (6 ML) versus the thickness of a Au overlayer. For both experiments we find a clear oscillation with a period of about 13.5 ML. This behavior can be interpreted as arising from quantum-well states (QWSs) in the Au overlayer, though interestingly, the observed period is twice the expected one. Especially for the reflected intensity this oscillation is very pronounced: the intensity changes by a factor of 10 when the Au overlayer thickness changes from 7 to 13 ML. These strong effects make this nonlinear technique very suitable for the study of these QW oscillations. © *1996 American Institute of Physics.* [S0021-8979(96)19808-5]

Since the discovery that magnetic films separated by a nonmagnetic spacer layer could be coupled antiferromagnetically,[1] and the subsequent discovery that this coupling could oscillate between ferromagnetic and antiferromagnetic,[2] there have been intense efforts to understand these phenonema. It was shown that in ultrathin films, due to the electronic potential discontinuities experienced by electronic states at interfaces, the perpendicular component of the wave vector can become quantized, giving rise to resonances in the density of states. Those quantum-well states (QWSs) may act as the mediator for this magnetic coupling.[3] Magneto-optical Kerr effect (MOKE) and direct- and inverse photo emission experiments have shown direct evidence of such QWSs in thin noble metal films on magnetic substrates (Fe and Co),[4–6] and in a bcc Fe(100) layer on Au(100).[7,8] More recently, oscillations of the Kerr angle with changes of overlayer film thickness have been observed for a Au/Co/Au system.[9] These results showed the existence of quantum size effects in the thin Au overlayer and also gave an indication of possible interface contributions.

Due to the fact that optical second harmonic generation (SHG) is known to be surface sensitive on an atomic scale, it seems that SHG studies might be particularly suitable for improving our knowledge of the electrodynamics of ultrathin metallic films. Though the absolute nonlinear signals are small, the nonlinear magneto-optical effects can be large: compared to the linear Kerr angle, enhancements up to a factor of 1000 have been observed.[10] Wierenga *et al.*[11] were the first to report about the possibilities of this nonlinear optical technique for detecting QW oscillations. They have found very strong oscillations in the magnetization-induced SHG signal for the Cu/Co/Cu system as a function of the thickness of the Cu overlayer, which are probably related to QWSs in these films.[11] These strong effects are directly related to the extreme interface localization of the nonlinear response.

In this paper we report the unambiguous observation of QWSs in a Au(111) overlayer on Co(0001). The oscillations are found in both the polar nonlinear MOKE as well as in the total generated second harmonic intensity, as measured as a function of the Au overlayer thickness. These are the first nonlinear MOKE results in the polar geometry, showing an enhancement of two orders of magnitude with respect to its linear equivalent.

For our experiments we used a Ti:sapphire (Tsunami) laser operating at a repetition rate of 82 MHz and a pulse width of about 100 fs. The incoming laser light was filtered and focused onto the sample. Polarization control of both incident fundamental and reflected SH light was achieved by means of polarizers. Appropriate optical filtering was used before the signal was detected by a photon counter. Our sample consists of a six monolayer (ML) Co(0001) film on a 30 nm thick Au buffer layer, covered with a stepped Au wedge, consisting of 13 terraces of $t_{\mathrm{Au}}=6-18$ ML. The terraces have a width of 1.5 mm, so the laser beam can easily be focused on each separate step. Details about the sample preparation can be found in Ref. 9. Note that this sample has a perpendicular easy magnetization axis.

SHG arises from the nonlinear polarization $\mathbf{P}(2\omega)$ induced by an incident laser field $\mathbf{E}(\omega)$. In the electric dipole approximation, this polarization can be written as

$$P_i(2\omega)=[\chi^{+}_{ijk}(M)+\chi^{-}_{ijk}(M)]E_j(\omega)E_k(\omega), \tag{1}$$

where $\chi^{+}_{ijk}(M)$ and $\chi^{-}_{ijk}(M)$ are the even and odd elements of the nonlinear susceptibility tensor that fulfill $\chi^{\pm}_{ijk}(-M)=\pm\chi^{\pm}_{ijk}(M)$, as suggested by Pan *et al.*[12] Since this susceptibility tensor has to reflect the symmetry of the crystal,[13] the nonzero elements are easily derived from the invariance of $\chi(M)$ under symmetry operations. Table I

shows the relevant tensor elements for our experiments. For s-polarized incident light (i.e., parallel to the y axis, see the inset to Fig. 1), only the even element can be excited. Therefore, no Kerr rotation can be expected for this configuration. For p-polarized incident light the Co/Au interfaces have two odd components, both giving rise to s-polarized SHG, and three even components, which produce p-polarized SHG. From this it follows that the SHG polarization ellipses for $\pm\mathbf{M}$ are each other mirror images in the plane of incidence, and we can define a nonlinear Kerr angle $\Phi_K^{(2)}$, analogous to the linear Kerr rotation. Experimentally, the Kerr angle is found by fitting a $\cos^2\alpha$ dependence to the measured intensity as a function of the analyzer angle α, for opposite directions of the magnetic field. This leads to a precision in the nonlinear Kerr angle of $\pm 0.12°$.

The experimental variation of $\Phi_K^{(2)}$ vs t_{Au} is given in Fig. 1, showing a clear oscillatory behavior. These measurements have been done with p-polarized incident light at a wavelength of 740 nm and at an angle of incidence of 45°. The observed amplitude of the oscillation is about two orders of magnitude larger than its linear counterpart, as measured on the same sample.[9] The solid line in the figure is a least-squares fit to the expression

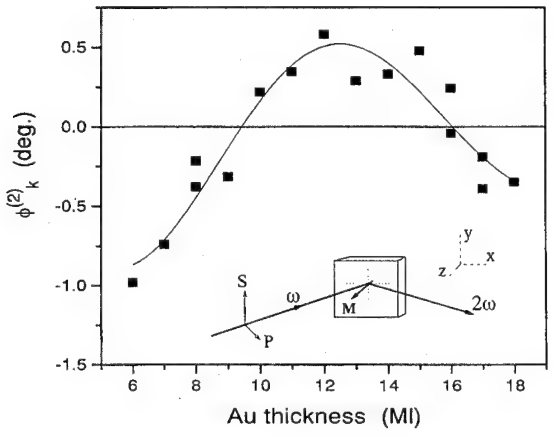

FIG. 1. Nonlinear polar Kerr rotation as a function of the Au overlayer thickness. The solid line is a fit to Eq. (2). The inset shows the experimental configuration.

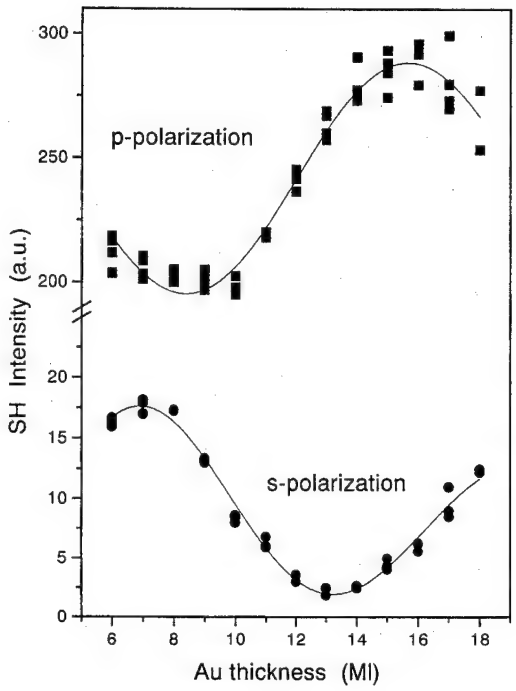

FIG. 2. Total generated SH intensity as a function of the Au overlayer thickness. Dots: s-polarized incoming light, squares: p-polarized incoming light. The solid lines are fits to Eq. (2).

$$\Phi_{\mathrm{K}}^{(2)}=A\times\exp\frac{-t_{\mathrm{Au}}}{\delta}\times\cos\left(2\pi\frac{t_{\mathrm{Au}}}{\Lambda}+\gamma\right)+\beta. \tag{2}$$

From this fit the period Λ of the oscillation is found to be 14 ± 3 ML with an attenuation length δ of 18 ± 4 ML. The maximum measured Kerr angle is about 1.0°. Although this value is a factor of 10 larger than its linear counterpart, the rotation is not as large as one would expect from earlier nonlinear Kerr experiments.[10] One reason for this is the 180° phase difference between the tensor components of the symmetric interfaces Au/Co and Co/Au. Because of the small thickness of the Co film (6 ML), the SH signals from these interfaces partly cancel each other and reduce the nonlinear magneto-optical effects.

The observed oscillatory character of the Kerr angle suggests that the quantum size effects have an influence on the tensor components. Since these effects will not only appear in the magnetic (odd), but particularly in the nonmagnetic tensor elements, the QWSs should also be observable in the total SH intensity. In Fig. 2 it can be seen that for both s- and p-input polarizations we found a clear oscillation in the total reflected SH signal. In the case of s-polarized incident light, we only have one nonzero tensor element χ_{zyy} present at both the Au/air and Au/Co interfaces, which explains the small signals here. The oscillation, however, comes out much more pronounced than in the Kerr measurements. By varying the Au overlayer thickness from 7 to 13 ML, the generated SH intensity drops by a factor of 10. The solid line in the figure is a least squares fit of the measured data according to Eq. (2). From this fit the period is found to be 12.6 ML, with an attenuation length of 18.3 ML. For p-polarized incident light, a clear oscillation can be seen on top of a large offset.

The solid line is again a fit by Eq. (2) with a period of 13.9 ML. In contrast with the s-input configuration, now no damping is found in the oscillation. This can possibly be explained by the different ways of penetration of the s- and p-polarized light into the material. For comparison we also measured the linear reflection as a function of the Au thickness. Within the experimental uncertainty of $\pm 2\%$, we found a constant value. Our observed period of about 13.5 ML is quite remarkable, as earlier linear Kerr measurements (at 632 nm) on the same sample gave a period of 7.8 ML.[9] Experiments on the oscillatory interlayer coupling between Co films across Au(111) gave a period of 6.5 ML.[14] The difference between the oscillation period in the linear and nonlinear Kerr rotation could possibly be due to the fact that these measurements were not done at the same wavelength, as Suzuki *et al.*[15] have shown that the period of the oscillation in the magneto-optical effect is energy dependent. To find out if there is any strong wavelength dependence, we repeated our Kerr and SH intensity measurements at different wavelengths between 740 and 1000 nm (the tuning range of our Ti:sapphire laser). In this range, however, no wavelength dependence of the period could be measured. A more likely explanation could be the difference between the selection rules involved in the linear and nonlinear optical response. However, this point needs more theoretical investigations. A final point of discussion is the interface roughness, as SHG is known to be extremely sensitive for this. The high quality of the thickness dependence fits suggests that the Co/Au interfaces are very smooth. The latter was also confirmed by other measurements.

In conclusion, we have observed large oscillations in both the nonlinear polar Kerr rotation and in the total generated SH intensity from a perpendicularly magnetized Au/Co/Au(111) sandwich versus the Au overlayer thickness. The period of the oscillation is for both experiments about 13.5 ML. The oscillations are believed to originate from QWSs in the Au overlayer. Specially for the total generated SH intensity, the quantum size effects can be very large: for the s-input polarization, the SH intensity drops by a factor of 10 when the Au overlayer thickness changes from 7 to 13 ML. These large effects make this nonlinear technique very suitable for detecting QW oscillations.

Growth and magnetic properties of Fe_xNi_{1-x} ultrathin films on Cu(100)

F. O. Schumann, S. Z. Wu, G. J. Mankey,[a] and R. F. Willis
Department of Physics, The Pennsylvania State University, University Park, Pennsylvania 16803

We have investigated ultrathin Fe_xNi_{1-x} films grown epitaxially on Cu(100) with different stochiometry. With the surface magneto-optic Kerr effect (SMOKE) we measured the variation of the Curie temperature T_C as a function of the film thickness n in monolayers (ML). Using the results of our previous investigations on finite-size scaling (Huang *et al.*), we are able to extrapolate the value $T_C(\infty)$ for samples with different Fe content. In particular, alloy films with Fe concentrations close to 65% remain ferromagnetic. This is in contrast to bulk $Fe_{65}Ni_{35}$, which shows a collapse of long range order, which is the so-called invar effect associated with a fcc to bcc structural transition. Growing these alloy films on a Cu(100) substrate forces them to adapt the Cu lattice spacing, thereby suppressing the structural relaxation. © *1996 American Institute of Physics.* [S0021-8979(96)19908-1]

I. INTRODUCTION

Molecular beam epitaxy (MBE) has offered the possibility of stabilizing materials as thin films in new metastable phases, e.g., fcc Co/Cu(100) and fcc Fe/Cu(100). Theoretical studies reveal that fcc Fe can have several magnetic states.[1] Depending on the lattice constant (or atomic volume) antiferromagnetic (AF), nonmagnetic (NM) or ferromagnetic with high spin (HS)/low spin (LS) phases are stable. At the Cu lattice constant, these magnetic phases are very close in energy, which made the Fe/Cu(100) system very attractive for experimental studies.[2–9] The LEED *I-V* study by Müller *et al.*[10] shows that Fe/Cu(100) films with thicknesses up to 4 ML order in a heavily distorted fcc structure, where the atomic volume of Fe is increased with respect to Cu. This has the result that the whole film is in a ferromagnetic state.[9,11] Going to higher thicknesses at 300 K, Fe adopts the Cu atomic volume, except for the top layer, which still has an increased atomic volume before Fe transforms into the bcc phase. This means that the ferromagnetism is only located in the top layer[9] while the rest of the film is antiferromagnetically ordered.[8] In simple terms one can say that the Fe atoms try to adopt the bulk bcc crystal atomic volume while at the same time fulfilling the constraints imposed by the Cu substrate.

A well-known moment instability in the bulk is the invar effect in Fe_xNi_{1-x} alloys. At a Fe concentration of 65% the magnetic moment deviates strongly from the Slater–Pauling curve, dropping quickly to zero, as does the Curie temperature, at which point a structural transition from the fcc into the bcc phase is observed.[12] Also, the thermal expansion is very low.[12] From a comparison with FePt and FePd alloys, which do not show a collapse of the magnetic moment, but have a small thermal expansion and strong reduction of the Curie temperature[12] it seems that the moment instability is not an invar relevant feature. A recent study[13] of 200 nm thick as-grown $Fe_{65}Ni_{35}$ films revealed that the magnetic moment follows the Pauling–Slater curve, but a small thermal expansion was still present. Again, stressing the point that the collapse of the magnetic moment is not an invar relevant feature.

The bulk lattice constants of fcc Fe_xNi_{1-x} vary between 3.55–3.59 Å for concentrations $0.7>x>0.2$.[14] This gives only a very small lattice mismatch with Cu. This fact motivates the growth of Fe_xNi_{1-x} films on Cu(100), for which we can expect good epitaxy with the above lattice matching argument. Furthermore, "clamping" Fe_xNi_{1-x} films on Cu(100) should extend the concentration range for which the fcc structure prevails.

At this point it is important to refer to the work of Abrikosov *et al.*,[15] which discusses bulk fcc Fe_xNi_{1-x} through the whole concentration range. They find that the magnetic moment collapses at $x=0.75$ and the lattice parameter drops noticeably, this is due to the fact that the LS/NM solution becomes lower in energy. We see that "clamping" Fe_xNi_{1-x} to a fcc structure alone does not prevent the deviation from the Slater–Pauling curve, but by keeping the lattice constant fixed we expect a suppression of the invar effect.

II. EXPERIMENTAL

The experiments were performed in an UHV apparatus previously described[16] with a base pressure of 1×10^{-10} mbar, which was better than 4×10^{-10} mbar during Fe, Ni codeposition. The Cu(100) crystal was mechanically polished and electropolished before inserting into the vacuum system. A few cycles of Ar^+ sputtering and annealing re-

sulted in an ordered and clean sample, as judged from LEED and Auger spectroscopy. The growth rate of the Fe and Ni sources were controlled by quartz crystal monitors (QCM), which were calibrated via RHEED oscillations of Fe/Cu(100) and Ni/Cu(100).[16]

The alloy films were grown at 350 K in order to avoid Cu segregation, we also observed RHEED oscillations during the growth of Fe_xNi_{1-x} films, which indicates good layer-by-layer growth; see Fig. 1. The thickness determined

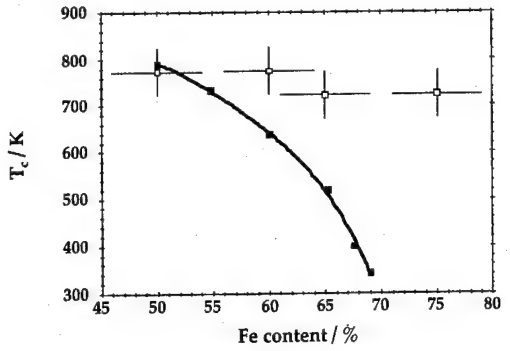

FIG. 3. Comparison between bulk Curie temperatures[12] (solid squares) and $T_C(\infty)$ of the thin film data (open squares). Error bars show variation of T_C on fit parameters and accuracy of composition.

by the calibrated QCM and by the RHEED oscillations of the Fe_xNi_{1-x} films agree to within 3%. This confirms our ability to control the thickness and the stochiometry very accurately.

The presence of $p(1\times1)$ LEED patterns confirmed pseudomorphic growth, which agrees with the observation of Dresselhaus *et al.*, who investigated 30 ML thick Fe_xNi_{1-x}/Cu(100) films, with $x=0.47$, 0.64, and $x=0.87$.[17]

Small C,O contamination were detectable at the end of the experimental run. With the surface magneto-optical Kerr effect (SMOKE) we measured the remanence as a function of temperature, thereby determining the Curie temperature T_C.

III. RESULTS AND DISCUSSION

Although the magnetic measurements focused on the invar concentration at $x\approx0.65$, we investigated the growth of Fe_xNi_{1-x}/Cu(100) through the whole concentration range. We found RHEED oscillations of the (0,0) beam for up to 10 ML, which is exceptional in metal epitaxy and confirms good epitaxial growth even better than, e.g., Ni/Cu(100). As an example we show the RHEED oscillation for a $Fe_{77}Ni_{23}$/Cu(100) film. This concentration is above the bulk invar concentration, where the transition to bcc has already occurred. This curve is qualitatively identical with the

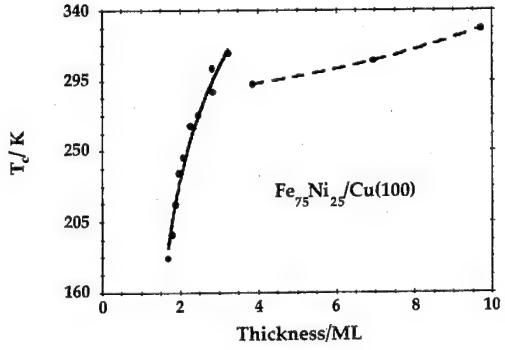

FIG. 4. Thickness dependence of T_C for a $Fe_{75}Ni_{25}$ alloy in the thin film limit and intermediate thickness. The solid line is fit to scaling law; the dashed line is a guide for the eye.

RHEED data for Fe_xNi_{1-x} films, with x below 65%. We can therefore rule out a sudden transformation into the bcc phase, which would also be accompanied by a drop in the RHEED intensity, like for Fe/Cu(100).[9,18]

In our previous studies,[16,19] we have shown that the variation of the Curie temperature $T_C(n)$ with film thickness n can be described with the empirical scaling law:

$$\frac{T_C(n)}{T_C(\infty)} = \frac{1}{1+[(n-n')/n_0]^{-\lambda}}. \quad (1)$$

Here n' is an empirical constant approximately equal to 1.[16] The value of n' determines the thickness for which T_C starts to be finite. n_0 is another empirical constant, which has a value of approximately 3.5.[16] $T_C(\infty)$ and λ are treated as independent fit parameters.

Equation (1) allows us to determine the $T_C(\infty)$ and compare this value with the bulk T_C of a given alloy concentration. Obviously, it would be desirable to measure T_C for very thick alloy films. This would give us directly $T_C(\infty)$, but the experimental window is limited, since at 400 K, Cu segregation is noticable, as Auger spectra show. In Fig. 2 we show T_C as a function of the number of monolayers for several alloy films near the invar concentration. The solid line represents the fit to Eq. (1). We see that all these curves show a large slope near the onset of long-range order. We can now plot $T_C(\infty)$ as a function of concentration and compare it with the Curie temperature of bulk Fe_xNi_{1-x} alloys,[12] see Fig. 3. The vertical error bars reflect the uncertainty of the determination of $T_C(\infty)$, whereas the horizontal error bars indicate the variation of the concentration during the deposition. The important point here is that $T_C(\infty)$ does not follow the bulk behavior and varies little within the accuracy of the fit with Eq. (1). Also important is that the alloy films are all ferromagnetic, even beyond the invar concentration, which is in contrast to the bulk behavior, but is also at odds with the theoretical work of Abrikosov and co-workers.[15]

Extending the measurements for a $Fe_{75}Ni_{25}$ alloy film up to 10 ML thickness reveals a strong deviation from the scaling law; see Fig. 4. At 4 ML T_C has dropped when compared with the scaling curve, and increases only slowly with further deposition. These results indicate a structural relaxation/spin reduction occurring between 3 and 4 ML thickness.

The electronic states that mediate the interlayer exchange coupling and the corresponding coupling strengths are calculated for Co/Cu(100). It is found that some states are strongly confined within the spacer layer. This is shown to lead to a strong RKKY-like coupling, but also to some weak contributions from higher harmonics. Weaker confined states only contribute by a rather weak RKKY coupling. © *1996 American Institute of Physics.* [S0021-8979(96)20008-1]

I. INTRODUCTION

The experimental observation of interlayer exchange coupling (IXC) of two magnetic layers through a nonmagnetic spacer layer in numerous systems has influenced much theoretical work. Out of these there are two models that have attracted most attention: the RKKY model[1] at one hand and the quantum well model (QW)[2,3] at the other. These models have many properties in common, especially that the coupling oscillates with periods given by the Fermi surface of the spacer layer, but they have two different physical origins. The RKKY model can be viewed as that one magnetic layer induces a magnetization in the spacer layer, which interacts with the second layer. In the QW model some Bloch states of the spacer layer are confined between the two magnetic layers. Often this confinement only occurs when the two magnetic layers have parallel magnetization, which then gives rise to a magnetic interaction of the two layers. In a more general formulation, both these two models appear as two limits of the same theory.[4] The significant quantity that enters this theory is the strength of the interface scattering, or, correspondingly, the degree of "confinement" of the electrons within the spacer layer.

In this paper we present a realistic calculation of the electronic states that are responsible for the IXC, and further on we analyze how the two "models," RKKY and QW, are describing these. The method we use here has recently been used successfully to calculate the IXC of Co/Cu sandwiches in different orientations[5–7] and to calculate the size-quantized states within a Cu overlayer on fcc Co.[8] The computational method we use is in many respects closely related to the general formulation by Bruno, and is hence very suitable for the present study of the size-quantized states coupling the two layers.

The system we have chosen to study here is fcc Co/Cu/Co(100), partly because our earlier work has shown that the method we employ is able to reproduce experimental results for this system. But also because neither the RKKY model, the QW model, nor our calculation take into account exchange enhancements within the spacer layer that might become of importance when it is consisting of a transition metal, instead of a noble metal as in the present case. It is also a natural choice, since due to its favorable properties, this system has become *the* standard model system in the field of IXC, both for theoretical work as well as for different experimental investigations.

II. INTERACTION-INDUCED DENSITY OF STATES

In this study we are focusing on the electronic states that arise from the scattering between two magnetic layers embedded in the nonmagnetic host. The magnetic layers are both consisting of five atomic layers, while the distance in between them is varied.

The change of the electronic structure when the interaction between the two layers is allowed for compared to the case of two independent layers is calculated in the way described in Ref. 7. There it is derived that the change of the integrated density of states (CIDOS) due to the interaction of the two magnetic layers with alignment α (F or AF), is given by

$$\Delta N_{\rm int}^{\sigma,\alpha}(\mathbf{k}_\parallel,\omega) = -\frac{1}{\pi}\,\mathrm{Im}\,\ln\det(1-G^n\tau_\sigma^{(1)}G^{-n}\tau_\sigma^{(2)}), \quad (1)$$

where ω is the energy and $\tau_\sigma^{(i)}(\mathbf{k}_\parallel,\omega)$ is the spin- (σ) and $\mathbf{k}_\parallel$-dependent t matrix of the magnetic layer, which takes care of all multiple scattering processes within the magnetic layer i. In Eq. (1), the Green's function matrix of the spacer, $G^n(\mathbf{k}_\parallel,\omega)$, describes a propagation from one layer to the other separated by n ML of unperturbed spacer material. It is worthwhile pointing out that all quantities entering Eq. (1) have been calculated from first principles (local spin density approximation to density functional theory) in the way described in Ref. 7.

In order to properly get the CIDOS we should work with the retarded Green's functions, which in turn means that $\omega=\epsilon+i\delta$, where δ is an infinitesimal imaginary part. For numerical reasons however, δ is here taken as a finite constant. By numerical differentiation of Eq. (1) with respect to the real part of the energy, ϵ, we finally obtain the change in the density of states (CDOS).

In Fig. 1 the CDOS is shown in an energy window around the Fermi energy for the case of spacer layers with thicknesses of 6 and 10 ML and for $\mathbf{k}_\parallel$ corresponding to one of the two RKKY calipers of the "dog-bone" of the Cu Fermi surface, i.e., $q_2=(1.08,0)\pi/a$, where a is the lattice constant of fcc Cu. In both curves in the region from 1 eV below to 1 eV above the Fermi energy, there are several

 0021-8979/96/79(8)/5638/3/$10.00

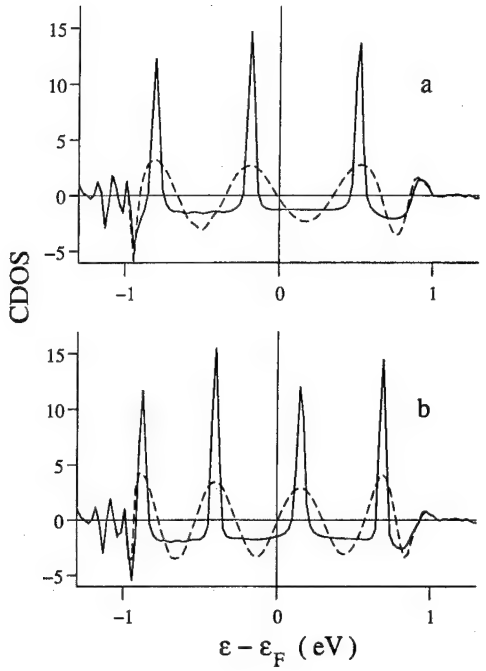

FIG. 1. The calculated CDOS for q_2, minority spin, ferromagnetic alignment, and with interlayer distances of (a) 6 ML and (b) 10 ML. Both the full calculation (solid curve) and its first-order approximation (dashed curve) is plotted. The Fermi energy is at zero energy.

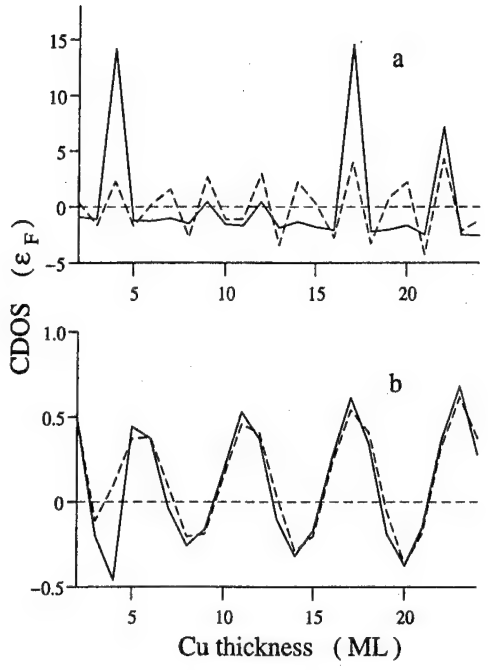

FIG. 2. The CDOS at the Fermi energy as a function of interlayer distance for the two stationary $\mathbf{k}_\parallel$ points: (a) q_2 and (b) q_1. The solid curves is for the full calculation and the dashed curve is for the first-order approximation.

sharp peaks. These CDOS was calculated for the states corresponding to the minority spin states of Co, and with ferromagnetic alignment. For majority spin states or antiferromagnetic alignment, the CDOS is much smaller without any sharp peaks. These peaks corresponds to electronic states strongly confined to the spacer layer due the presence of a partial gap in the minority spin states of the cobalt layer.[6] All this is in accordance with the QW models.[2,3] Also shown in Fig. 1 are the first-order approximations (FOA) to Eq. (1) when expanding the logarithm of the determinant according to

$$\ln \det(1-x) = \mathrm{Tr} \ln(1-x) = -\mathrm{Tr} \sum_{n=1} \frac{x^n}{n}. \tag{2}$$

These curves are smoothly oscillating as a function of the energy and may be viewed as rising from the interference when states are reflected only once at each layer. To be noted is that the maxima of the oscillations occur at exactly the same energies as the sharp peaks.

Almost bound states also exist for $q_1=(0,0)$, but only for larger binding energies. At the Fermi energy the full CDOS is here rather small and is oscillating smoothly. In Fig. 2 the CDOS at the Fermi energy is plotted as a function of the interlayer distances for the two stationary $\mathbf{k}_\parallel$, together with their respective FOA. For the q_1 curve it is clear that the two curves are in close agreement, and that a maximum occur about every 6 ML. On the other hand, for q_2, the FOA curve has a period close to 2.6 ML while the full calculation curve, due to its sharp peaks, has an effective period of ca. 13 ML. So while the q_1 indeed has a CDOS at Fermi energy oscillating with the corresponding RKKY period, 5.9 ML, as was suggested in Ref. 3, this is only true for the FOA in the case of q_2, or if the sharp peaks would be broadened. Also to be noted is that while the maxima of the CDOS are 30 times larger for q_2 than for q_1, the FOA is only five to eight times larger.

III. COUPLING ENERGY

From the CDOS one can also calculate the interlayer coupling energy (see, e.g., Ref. 7). To calculate the free energy for one alignment α of the two magnetic layers, we integrate the CIDOS over the two-dimensional Brillouin zone (BZ) and the occupied part of the energy,

$$\Omega_{\mathrm{int}}^{\alpha} = -\sum_{\sigma} \int^{\mu} d\omega \int_{\mathrm{BZ}} d\mathbf{k}_\parallel \, f(\omega) \Delta N_{\mathrm{int}}^{\sigma,\alpha}(\mathbf{k}_\parallel, \omega), \tag{3}$$

where f is the Fermi–Dirac distribution function. While maybe looking straightforward, this is a numerically demanding task. In order to avoid numerical problems the energy integral is here solved by a contour integral in the complex energy plane and the BZ integration is performed with a very dense mesh of special points.

For large interlayer distances it is possible to show that the contribution to this integral only will come from the Fermi energy and there from stationary calipers of the Fermi surface of the pure spacer layer. The fact that these calipers govern the asymptotic behavior of the IXC has been verified by direct calculation.[6]

The IXC energy is calculated for the same system as before. By dividing the BZ into two parts, the q_2 contribution is separated out as in Ref. 6. By expanding the logarithm of the determinant of Eq. (3), one can show that the FOA only contributes to the bilinear coupling, while in second

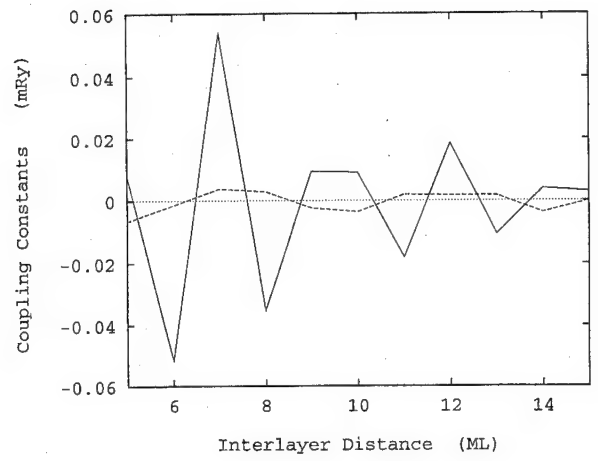

FIG. 3. The first- (solid curve) and second- (dashed) order contribution to the coupling constant J are plotted as a function of interlayer distance.

order (SO, the $n=2$ term) there are both contributions to bilinear, $-J\cos(\theta)$, and biquadratic, $-J_2\cos(2\theta)$, coupling (θ is the angle between the magnetic moments of the two layers). In Fig. 3 the two first contributions to the bilinear coupling constant J are plotted for the q_2 part of the coupling. As has been observed before, the largest part that is from the FOA follows closely the RKKY oscillation, with a period 2.6 ML. The SO contribution is much weaker and has a period between 4 and 5 ML, in good agreement with the expected 4.3 ML. This is the second harmonic of the RKKY period when the aliasing effect is taken into account. The calculated SO biquadratic contribution is of the same magnitude as the bilinear contribution, and has a similar period. Although small, the SO contribution to q_2 is almost of the same size as the FOA of q_1, for which the SO is truly negligible. The existence of higher-order contributions has been predicted within the QW model.[2]

In the calculations of IXC coupling here we have introduced a temperature of 1 mRy, which leads to a broadening of the CIDOS entering Eq. (3). A systematic investigation of the temperature effects will be published elsewhere.

IV. CONCLUSIONS

From a calculation of the electronic states mediating the IXC, it is found to be a fundamental difference of the nature between the states at the two different stationary $\mathbf{k}_\parallel$ points. First, for the q_1 point the confinement is small and a FOA describes the states well. On the other hand, due to the development of a partial gap in the Co layer,[6] there is a strong confinement for q_2 that leads to almost bound states, or "true" QW states.

Since it is the FOA part of the CDOS that gives rise to the RKKY-like IXC with $2k_Fd$ oscillations, the q_1 contribution is purely RKKY. However, also for q_2 the RKKY part is dominating, since the higher harmonics are largely canceled when the BZ integration is performed. Only a weak SO harmonic is found with the expected $4k_Fd$ oscillation. The intrinsic biquadratic coupling appears first in SO, and is therefore only found for q_2, where it is of the same magnitude as the SO contribution to the bilinear coupling, i.e., much weaker than the full bilinear coupling.

As a summary, although some IXC-mediating states are found to be confined QW states, their extra contribution to the IXC beyond the RKKY coupling is rather small for Co/Cu(100). But, since it is not much smaller than the q_1 contribution it could be possible to experimentally observe it, which has not been done hitherto.

The growth of Fe on sulphur passivated Ge(100): A technique for avoiding intermixing

G. W. Anderson,[a] P. Ma, and P. R. Norton
Interface Science Western, The University of Western Ontario, London, Ontario N6A 5B7, Canada

The growth of Fe on Ge(100) surfaces results in the intermixing of Ge with the Fe overlayer, producing relatively thick magnetic dead layers. In this paper we describe a new technique, the growth of Fe overlayers on S-passivated Ge(100), which successfully prevents the intermixing of Ge with the Fe overlayer. Bcc Fe(100) is observed to grow epitaxially on this substrate, with the S floating out as an ordered overlayer. The S prevents intermixing by acting as a surfactant, holding the Fe on top of the substrate and preventing interdiffusion. The Fe overlayers are observed to be ferromagnetic in nature, displaying sharp hysteresis loops with easy axes along the Fe[010] directions. A uniaxial in-plane anisotropy is observed, which results in the two easy axes being inequivalent. [S0021-8979(96)20108-8]

I. INTRODUCTION

There is great interest in developing simple and efficient methods for growing magnetic overlayers directly on semiconductors because of the potential for integrating the desired magnetic properties of these systems with computer circuitry. However, problems usually arise because of intermixing of the semiconductor elements into the overlayer, which results in a degradation of the magnetic properties of these systems.

Interest in the growth of Fe on Ge stems from the good lattice match between the materials (1.3% mismatch) and the fact that high purity, low defect Ge wafers are readily available. However, previous investigations of the growth of Fe on Ge(100) have shown significant difficulties, due to the fact that Ge and Fe form many alloys.[1] For Fe growth at 150 °C, while the films are well ordered, a large amount of Ge interdiffusion was observed. This resulted in layers up to 100 Å showing no magnetic moment.[2] For growth at lower temperatures, the amount of interdiffusion was not as great, but the overlayers were rough and highly defected.[2]

In this investigation, the use of sulphur passivated Ge(100) substrates has been examined as a means to prevent this interdiffusion. Treatment of Ge(100) samples in an aqueous ammonium sulphide solution has previously been shown to result in the formation of a S-passivating layer, which prevents surface oxidation in air.[3] It is hoped that, in the same manner as the growth of Fe on S-passivated GaAs(100),[4] this passivation layer would act to prevent Ge intermixing and permit the growth of a magnetic, epitaxial Fe overlayer.

In this investigation the growth of Fe overlayers on S-passivated Ge(100) substrates at 25 °C and 150 °C has been investigated with Auger electron spectroscopy (AES), angle resolved AES (ARAES), low-energy electron diffraction (LEED), and magneto-optic Kerr effect (MOKE) measurements. We will show that this method successfully prevents the intermixing of Ge with the Fe overlayer. Bcc Fe(100) is observed to grow epitaxially on this substrate, with the S floating out as an ordered overlayer. The S prevents intermixing by acting as a surfactant, holding the Fe on top of the substrate and preventing interdiffusion. The Fe overlayers are observed to be ferromagnetic in nature, displaying sharp hysteresis loops with easy axes along the Fe[010] directions. A uniaxial in-plane anisotropy is observed, which results in the two easy axes being inequivalent.

II. EXPERIMENT

The experiments were carried out on a two-chamber UHV system. The main growth/analysis chamber is diffusion and sublimation pumped, achieving a base pressure $<1\times10^{-10}$ Torr. The chamber is equipped with a Fe evaporation source, a four-grid retarding field analyzer for LEED measurements, and a CLAM electron energy analyzer (Fisons Instruments) for AES and ARAES measurements. It is also interfaced, via a two stage differential pumping station, to a 2.5 MV van de Graaff accelerator, which can be utilized for ion beam measurements. The LEED images were collected with a CCD camera from the LEED screen and recorded on videotape. The VCR is interfaced to a computer system, allowing subsequent analysis of the LEED spot intensities and widths.

The second chamber is a UHV loadlock chamber, pumped with a diffusion pump backed turbo pump (base pressure 2×10^{-10} Torr). This chamber has a magnetic transfer arm for sample transfer between the two systems and is equipped with the MOKE apparatus for magnetic characterization of the samples.

Ge wafers [aligned to within 0.25° of the (100) direction] from the Semiconductor Processing Company, were utilized in this investigation. The samples were prepared by an *ex-situ* S-passivation treatment. First, the samples were degreased in hot methanol (50 °C–60 °C) and then immersed in an aqueous ammonium sulphide $[(NH_4)_2S]$ solution at 65 °C for 20 min. At the end of this treatment the samples were rinsed in methanol, blown dry with He, and inserted into the loadlock chamber. Samples prepared in this manner exhibit a (1×1) LEED pattern without any further preparation. The presence of a small amount of C and O contamination was detected. Prior to Fe deposition the samples were

annealed to 190 °C, which results in an improvement in the surface order[3] and removal of the surface contamination.

The Fe was deposited from a liquid nitrogen shrouded sublimation source onto the substrate, at a rate of 1.6 ML min [where 1 ML corresponds to the Fe(100) surface density]. The Fe coverages were determined via a Rutherford backscattering calibration of the evaporation rate onto an Al substrate.[5]

III. RESULTS AND DISCUSSION

AES measurements were utilized to look for Ge interdiffusion into the Fe overlayer during Fe deposition. Figure 1 illustrates the intensity of the S (152 eV), Fe (703 eV), and Ge (1147 eV) AES signals during Fe deposition, with the substrate held at 25 °C. The Fe signal is observed to increase with coverage as expected, beginning to level off at about 7 ML. The S signal is observed to decrease slightly for Fe coverages up to 25 ML. This suggests that, as in the growth of Fe/S/GaAs(100),[4] the S floats out on top of the Fe surface during overlayer growth, perhaps helping to stabilize the high-energy Fe surface. The Ge signal is observed to decrease exponentially with Fe coverage, being undetectable by a coverage of about 18 ML. These results indicate that Ge is not intermixed through the Fe overlayer. For growth with the substrate held at 150 °C, similar results were observed, indicating that the interdiffusion is also prevented at elevated temperatures.

As most of the S floats out on top of the film, the most likely mechanism by which the S prevents interdiffusion is by acting as a surfactant. Thus, as Fe is deposited the S preferentially bonds to the Fe, holding it on top of the Ge substrate, preventing any chemical interaction. As further Fe is deposited, the S floats out, and is no longer attached to the Fe at the Fe/Ge interface. However, now the Ge can only diffuse into the overlayer by bulk diffusion (as opposed to surface diffusion in the absence of S). Bulk diffusion is a more highly activated process, and does not appear to be energetically feasible at these temperatures.

The structure of the Fe overlayers were investigated with LEED and ARAES experiments. LEED was used to examine the long range order of the samples during Fe deposition. Initially, the S/Ge(100) substrate showed a good, sharp (1×1) LEED pattern. As Fe was deposited at 25 °C the substrate pattern was observed to fade into an increasing background, completely disappearing by the time 2 ML of Fe had been deposited. As more Fe was deposited an overlayer pattern begins to develop at a coverage of approximately 5 ML. The diffraction beams were extremely broad, with the spots being approximately four times the width of the substrate pattern. As further Fe was deposited, the pattern increased in strength, but was never observed to sharpen. Thus, while growth at 25 °C proceeds without any significant interdiffusion, the overlayer is not well ordered and likely highly defected, as observed in the previous study of Fe/Ge(100).[2]

Figure 2 displays the intensity of two LEED spots during Fe deposition at 150 °C. As for deposition at 25 °C, the substrate LEED pattern is observed to fade into an increasing background during the initial phase of deposition, disappearing completely by an Fe coverage of 2 ML. With further Fe deposition, a pattern due to the Fe overlayer begins to form at a coverage of 4.5 ML. However, at this temperature the pattern is considerably sharper, with the spot widths being comparable to those of the initial substrate pattern, indicating that the Fe overlayer is as well ordered as the substrate. Comparison of the observed energy dependence of the pattern with previous LEED IV data[6] identified this pattern as being due to $c(2\times2)$S Fe(100).

ARAES measurements have proven to be a useful technique in examining the short range order of metal overlayer systems.[7] In this technique, modulations in the angular dis-

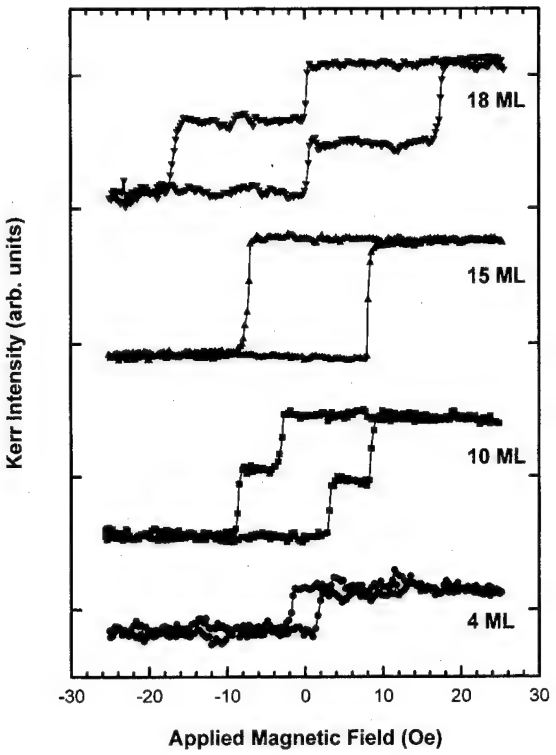

FIG. 3. MOKE hysteresis loops for various Fe films grown at 25 °C. The effect of the uniaxial anisotropy can be seen in the presence of two-step hystersis loops.

tribution of the AES electrons are used to gain information about the local structural environment of the emitting atoms. ARAES measurements of this system show that the Fe overlayers grow as bcc Fe(100) on the S/Ge(100) substrate.

The magnetic properties of the samples were determined by MOKE measurements. Ferromagnetic behavior is observed for samples grown at both temperatures for coverages above 3 ML, with the magnetic signal increasing in strength as the Fe coverage increases. The easy axes are located along the [010] directions, as expected. Figure 3 displays the hysteresis loops for some Fe overlayers. In some of the MOKE data a two-step hysteresis loop is observed. We propose that this is due to the presence of a uniaxial anisotropy (as previously observed for growth on GaAs[8] and MgO[9] substrates), which makes the two easy axes inequivalent (one is easier than the other). When the applied magnetic field is along the easier axis, a sharp, square hysteresis loop is observed. When it is along the less easy axis, the two-step loop is observed. In this loop, the outer transitions represent the switching to domains aligned with the magnetic field. The inner transitions represent the magnetic domains aligning along the easier axis in the low-field condition, only aligning with the applied field when it is strong enough to overcome the uniaxial anisotropy. The variation of the apparent coercivity of the inner-loop is puzzling and of unknown origin. Further FMR experiments are planned to investigate the presence of this anisotropy directly.

IV. CONCLUSIONS

We have shown that the use of S-passivated Ge(100) as a substrate for the growth of Fe overlayers, successfully prevents the interdiffusion of Ge into the overlayer at temperatures of 25 °C and 150 °C. Bcc Fe(100) is observed to grow on this surface, being stabilized by the continual segregation of the S into an ordered $c(2\times2)$ overlayer. The S prevents intermixing by acting as a surfactant, holding the Fe on top of the substrate and preventing interdiffusion. For deposition at 25 °C, the Fe overlayer is poorly ordered and likely highly defected. However, for deposition at 150 °C, the Fe overlayer is as well ordered as the initial substrate. The Fe overlayers are ferromagnetic in nature, displaying good MOKE hysteresis loops. The [010] directions are the easy axes, however, the presence of an uniaxial anisotropy results in the two (010) directions being inequivalent (one is magnetically easier than the other). A possible interpretation of these observations would be in terms of an in-plane anisotropy.

Data storage based on proximal probe techniques (invited) (abstract)

H. J. Mamin, B. D. Terris, and D. Rugar
IBM Research Division, Almaden Research Center, 650 Harry Rd., San Jose, California 95120

Recently, there has been considerable interest in examining the feasibility of using proximal probe techniques as the basis for a data storage device. These techniques, derived from the scanning tunneling microscope (STM) and atomic force microscope (AFM), provide a potential pathway to reaching the ultrahigh densities needed in the decades ahead. While these techniques offer high areal density, a number of formidable technical challenges must be met, however, in order to produce a device with realistic data rate, error rate, and overall reliability. In this talk we will review some of the approaches that have been taken, including those based on the STM, the AFM, and near-field optics. We will focus on the efforts in our laboratory to demonstrate realistic data rates at reasonably high densities using thermomechanical writing with an AFM tip,[1] and near-field recording with a solid immersion lens.[2] The prospects for parallel tip arrays and issues of overall implementation will also be addressed. This spin-stand measurement study focuses on recording characteristics at submicron scale track width. The pole tips of a set of identical thin film heads were trimmed from the air-bearing surface by focused ion beam etching. A set of thin film heads with track widths ranging from $W=2$ μm to $W=0.5$ μm were produced. Recording experiments were performed on a high precision spin-stand tester using these heads. Both on-track and off-track performances were studied and analyzed. As the track width is scaled down, degrading of recording performance is observed. When the width of a recording head is decreased, the onset of partial erasure occurs at a lower density, and the noise power per unit head track width increases. Further investigation on the track profiles reveals that the extent of partial erasure is higher at the track edge as density increases, and this phenomenon is more pronounced in narrower track width heads. © *1996 American Institute of Physics.* [S0021-8979(96)10208-0]

I. INTRODUCTION

In the recent IBM 3 Gbits/in.^{2} recording demonstration, it was shown that high track density approach seemed to have a fundamental advantage over high linear density approach.[1,2] In order to achieve high tracks per inch (TPI), understanding of the recording performance of narrow track thin film heads becomes critical. Here, we present an experimental study on recording and side writing properties of submicron track width thin film heads. Focused ion-beam etching process was employed to trim the pole tips from the air bearing surface (ABS). The recording characteristics at submicron scale track width were investigated by spin-stand measurements using the trimmed heads. The performance of the test heads was first evaluated in terms of their frequency responses, which include frequency domain partial erasure,[3,4] resolution, and integrated noise power measurements. Comparison among the test heads was made based on these basic signal and noise measurements. Finally, the use of frequency domain partial erasure measurement was extended to off-track measurements. Combining partial erasure and track profile measurements, the actual track width and the integrity of the track edge of narrow tracks at different linear densities were compared.

II. EXPERIMENT

The pole tips of two sets of identical thin film inductive heads, 4.5 μm wide each, were trimmed from the ABS by high precision focused ion beam etching with a beam diameter less than 10 nm. The final widths of the trimmed heads ranged from $W=2$ μm to $W=0.5$ μm. The trimming depth was about 1 μm, approximately equals to the throat height of the heads. One head in each set was left untrimmed for comparison of recording performance. The sliders of the heads in set A are conventional designs with a fly height of about 3 μin. The sliders of the heads in set B are of "tripad" type with a fly height less than 1 μin. The parameters of the heads and disk are given in Table I.

The recording experiments were performed on a high precision spin-stand tester with a close loop laser interferometer positioning mechanism, which had a resolution of 0.026 μm. The linear velocity between the head and medium was kept at 12 m/s in each test, and the same head was used for writing and playback. Write current was adjusted to obtain the best overwrite for each head.

III. SPIN-STAND TEST RESULTS AND DISCUSSION

A. Nonlinear partial erasure and resolution

The recording performance of the test heads was first examined by a partial erasure measurement. Nonlinear partial erasure is defined as the nonlinear amplitude reduction of playback voltage at high recording densities. In this measurement, all 1's patterns were recorded at two recording densities D and D', such that the higher density was three times greater than the lower one ($D'=3D$). By comparing the amplitude of the fundamental component of the voltage spectrum for the high density ($3D$) pattern to that of the 3rd harmonic for the low density (D) pattern, the nonlinear partial erasure can be measured by the ratio R, defined as

$$R=V_{3D}(1\text{st})/3V_{1D}(3\text{rd}) \tag{1}$$

where $V_{3D}(1\text{st})$ is the amplitude of the 1st harmonic of a squarewave track written at density $3D$, and $V_{1D}(3\text{rd})$ is the amplitude of the 3rd harmonic of a track written at density D. In the experiments, density D was kept low enough to ensure that linear superposition was valid for the lower density track. Figure 1(a) shows the measured partial erasure ratio as a function of the density (D') for the three heads in set A (high fly height). The partial erasure ratio R is unity at low density when linear superposition still holds for both tracks, then it starts to drop below unity as density increases, indicating the onset of partial erasure for the high density track. It is interesting to note that the onset of the partial erasure for narrower heads occurs at significantly lower recording densities. The slope of the partial erasure drop also becomes slightly steeper for narrower heads at high densities. Figure 1(b) shows the partial erasure curves for the three heads in set B (low fly height). At this lower fly height, similar dependence of the onset of the partial erasure is ob-

 0021-8979/96/79(8)/5645/3/$10.00

TABLE I. Parameters of the heads and disk used in the experiments.

Head	P1/P2 width(μm) W	Gap(μm) g	Fly height(μin.) y
A1	4.50	0.25	3
A2	2.00	0.25	3
A3	0.50	0.25	3
B1	4.50	0.22	1
B2	2.00	0.22	1
B3	0.75	0.22	1
Disk	Hc(Oe)	MrT(memu/cm^2)	S*
	2200	0.79	0.87

served, which is the quickening of the onset of partial erasure with reducing head width. Comparing the two sets of heads, lower fly height delays the onset of partial erasure, while the rate of partial erasure drop remains virtually unchanged.

The strong dependence of the onset of partial erasure on head width can be accounted for by two factors: (1) As head width decreases, the on-track field gradient is degraded, resulting in intertransition percolation at lower recording densities; (2) partial erasure can be dominated by transition percolation near the track edges which results in an effective track width reduction. Since the fly height and gap length of the heads in the experiments are still significantly smaller than the head width, the on-track field gradient should not be seriously affected by the width, and the dependence is most likely to be attributed to the second factor: transition percolation at the track edges.

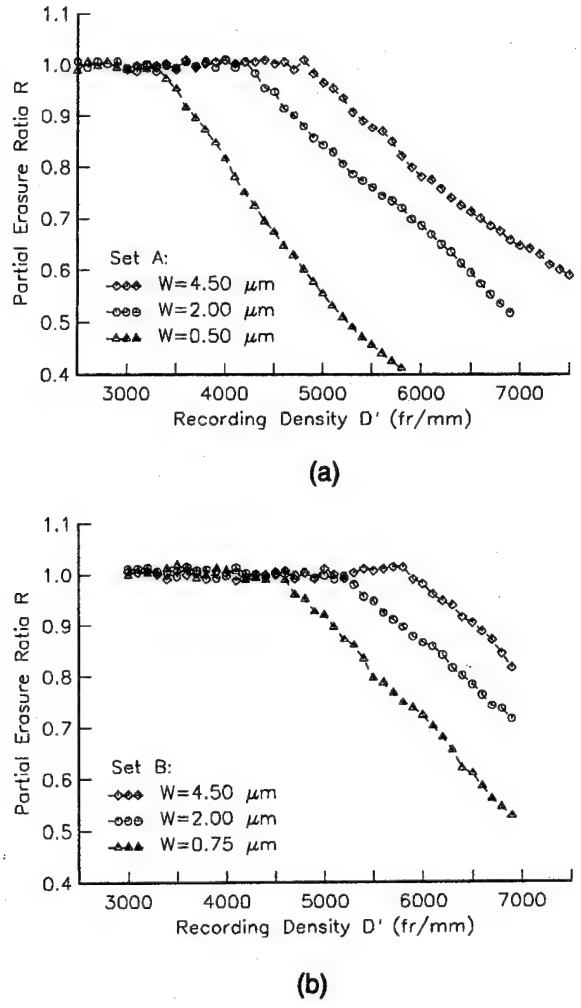

FIG. 1. Partial erasure vs recording density for the (a) high flying heads (set A), and (b) low flying heads (set B).

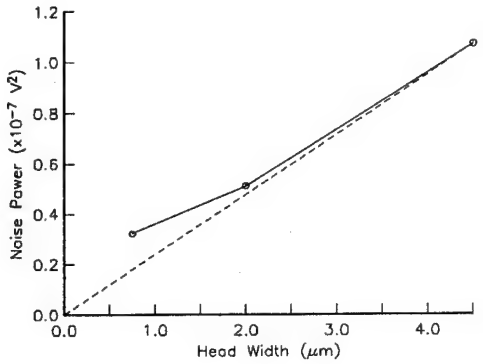

FIG. 2. Measured noise power (at 3900 fr/mm) as a function of head width. Dashed line represents the expected noise power using the 4.5 μm head as a reference. Excess noise is sensed by the head as head width decreases.

Since better performance was obtained for the heads in set B, only these heads were used in further signal and noise measurements. Resolution measurements show the D_{50} (density at which the signal amplitude drops to half of its low density value) for heads $B1$, $B2$, and $B3$ are 5200, 4600, and 3400 fr/mm, respectively, which again indicates recording performance degrades with decreasing head width. The differences among the resolution curves can be explained by the differences in the isolated pulse width. For heads $B1$, $B2$, and $B3$, the widths are 358, 403, and 546 nm, respectively. Therefore, the degrading of recording performance can be attributed to an effective broadening of transitions, probably due to edge percolation caused by the poor writability of the saturated corners of the pole tips.

B. Medium noise power

Since edge effects become significant for these narrow heads, noise near the track edge can be a significant portion of the total amount of medium noise. Transition noise can increase significantly in submicron tracks due to the mentioned edge transition broadening effects. In addition, as the head width is reduced to submicron scale, the so-called erased band, in which track edge noise manifest itself,[5] can have a width comparable to the recorded track. Therefore, the measured medium noise power at a high density (3900 fr/mm) no longer scales linearly to zero with the head width, as shown in Fig. 2. The "expected" noise power, or linear extrapolation of noise power against head width is obtained using the 4.5 μm wide head as a reference. As the head width is reduced, the measured medium noise power exceeds the linear extrapolation by an increasing amount. This indicates the medium noise power sensed by the narrower heads

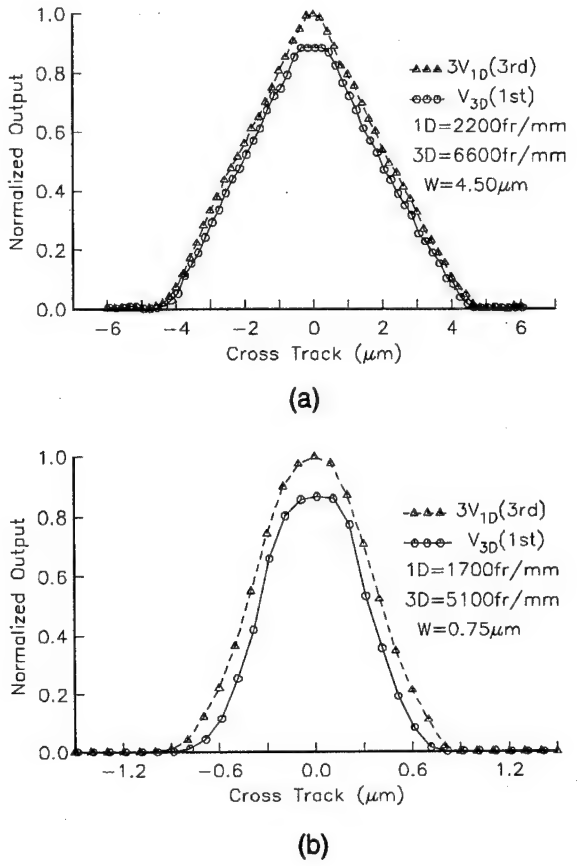

FIG. 3. Track profiles of the $1D$ and the $3D$ tracks. 3rd harmonic of the $1D$ track and 1st harmonic of the $3D$ track are measured using the (a) 4.50 μm wide and (b) 0.75 μm wide low flying heads.

is dominated by the noise near the track edge, which includes noise from broadened edge transitions and track edge noise.

C. Cross-track profile

In order to examine the integrity of recorded transitions in the cross-track direction, the same technique as used in the partial erasure measurements was employed to study the cross-track profiles at different recording densities. Figure 3(a) shows two measured cross-track profiles for head $B1$ (W=4.50 μm), measured using a step size of 0.2 μm. The triangular symbols represent the 3rd harmonic voltage amplitude for a track recorded at density D=2200 fr/mm and the amplitude is scaled up by a factor of three. The circular symbols represent the fundamental component of the voltage amplitude for a track recorded at density $D'=3D=6600$ fr/mm, at which the partial erasure ratio R is 0.88. Since the voltage harmonics were measured at the same frequency, the same head sensitivity functions were assured for these two different recording densities. In the absence of partial erasure, the two profiles should coincide with each other. However, in our case, the cross-track profile for the higher density track exhibits a plateau in the center, whereas the plateau is much less significant for the lower density track. Also, the slopes beyond the plateau of the cross-track profiles are similar for the two recording densities. The triangular shaped profile for the lower density track indicates that the read and write widths are essentially the same. The pronounced plateau for the higher density track indicates that the actual track width becomes smaller than the read track width. This measurement confirms that the onset of the partial erasure shown in Fig. 1(b) is mainly due to transition percolation at track edges. In other words, partial erasure starts from the track edge and yields an effective track width reduction.

Figure 3(b) shows similar track profiles measured using head $B3$ (W=0.75 μm). In this case, D=1700 fr/mm and the step size is decreased to 0.1 μm. A reduction in track width in the higher density track is again observed, as indicated by the increased plateau width and narrow base. The extent of the reduction, however, is relatively more significant in this case of a much narrower track. The decrease in the width of the higher density track is much more pronounced, and there is also an increase in the curvature of the slopes near the base of the profile. This increased curvature indicates the signal near the edge of the higher density track is weaker compared to the rest of the track, due to track edge percolation.

The track profile measurement confirms the poor writability of the edges of the heads, which is likely to be caused by the saturation at the corners of the pole tips. This corner saturation degrades the effective write field gradient, reduces track width, and essentially broadens transitions. As the saturated corners become a significant portion of the head as head width decreases, the edge field dominates the performance of the head. As a result, partial erasure at high densities mainly comes from edge erasure in submicron tracks. The narrower the track, the worse the effective field gradient because of the increase in proportion of the poor writing corners. It is the degraded write field that quickens the onset of partial erasure in narrower tracks. The degradation is also reflected in the medium noise measurement, and eventually confirmed by the track profile measurement.

IV. CONCLUSION

Recording performance of submicron track thin film heads was systematically examined by spin-stand measurements. As head width is reduced, the onset of partial erasure shifts to lower densities, and an excess amount of noise is sensed by the narrow heads. Analysis of track profiles shows that the degradation of performance originates at the edge of a recorded track. It is concluded that for the narrow track heads, partial erasure starts from the track edge and effectively reduces the track width at high recording densities. It is believed that the head corner saturation is partially responsible for the degradation of recording performance for the narrow heads. High moment write heads may be necessary to keep the corners of the pole tips free of saturation.

High-frequency recording is essential for a recording channel with both a high data rate and a high linear recording density, and this study examined the ways in which performances are affected by the switching time of the write current, t_s, and the disk velocity, v. The switching time, defined as $(t_r+t_f)/2$, where t_r and t_f are the rise time and the fall time of the write current, was changed from 5 to 20 ns, while v was changed from 12 to 26 m/s. Co-based thin-film media with a coercivity of about 2.5 kOe and a remanence-thickness product of about 100 G μm were used for recording the data. The flying height of the head was maintained at 50 nm regardless of disk velocity. This study confirmed that the overwrite characteristics are strongly related to the product of t_s and v. Overwrite here was defined as the ratio of the residual fundamental frequency component amplitude of a 21 kFCI signal to the original one after overwriting with a 86 kFCI signal. Suitable overwrite characteristics were obtained when $t_s^* v$ was smaller than πa, where a is the transition parameter derived from the equation proposed by Williams and Comstock.[1] The transition length on the medium was determined primarily by πa when $t_s^* v$ was smaller than πa, but was determined by $t_s^* v$ when $t_s^* v$ was larger than πa. Linear density characteristics and noise characteristics and their relationship to the medium properties will also be addressed in this talk. [S0021-8979(96)46208-2]

Bit-shift performance investigations at different skew angles and for different media orientations

S. B. Hu and B. Liu
Magnetics Technology Centre, National University of Singapore, Singapore 0511

C. S. Lee
Western Digital (S) Pte Ltd., 750-B Chai Chee Road, Singapore 1646

Bit-shift performance was investigated at different skew angles and for media with different orientation. Results indicate that the bit-shift value increases as the skew angle increases for both planar orientated media and near-isotropic media. As the skew angle increases, the off-track capability, described by the bit shift at different off-track distances, decreases and the bit-shift profile becomes asymmetric. Comparison of normalized bit-shift values (normalized according to the bit shift at 0° skew angle) shows that the bit shift of the near-isotropic media is not as sensitive to skew angle variation as the media with strong orientation. © *1996 American Institute of Physics.* [S0021-8979(96)10308-7]

I. INTRODUCTION

Rotary actuators are used in most of today's disk drives for the positioning of read/write heads. The rotary actuator introduces a varying skew angle at different radii. The skew angle, the angle between track direction and slider direction, can vary by as much as 25°–30° in present disk drive design.[1] It has been reported that a nonzero skew angle will make recording performance asymmetric from the track center. Reported results also show that a nonzero skew angle will also induce offset of transitions from the track center and an increase in side reading.[2]

Bit shift, which occurs in closely spaced data bits, affects performance of various detection schemes. Bit-shift analysis measures the timing aperture of a recording system and evaluates the expected error rate. Bit-shift testing and characterization are important parts in recording system design.

Though bit-shift performance at different recording conditions has been studied,[3] a report on the bit-shift performance at different skew angles has not been seen yet. Furthermore, not much work on the relationship between media orientation and bit-shift performance at different skew angles has been addressed, even though the effects of media orientation on transition noise and the signal-to-noise ratio have been reported.[4,5]

This paper presents results of experimental investigations on the bit-shift performance at different skew angles. Special attention is also paid to the impact of the skew angle on the off-track capability and media with different orientations.

II. EXPERIMENT

A. Bit-shift profile and off-track capability

Both track profiles and bit-shift profiles can be used to describe the off-track capability of a given head-disk integration. The bit-shift profile is a plot of the bit shift at different off-track distances, while the track profile is a plot of track average amplitude (TAA) at different off-track distances. The main advantage of bit-shift profile is that it describes the off-track capability from error rate viewpoint, which is of special importance in achieving a reliable disk drive design.

B. Experimental setup

All experimental investigations were conducted with a selected set of transverse pressure contour (TPC) sliders. Testing was carried out at a fixed testing radius (r=1.65 in.) of 3.5 in. disks. The coding scheme used is (1,7) code. Bit-shift is measured at analysis level of 10^{-6}, with a sample level of 10^8.

1. Media

Two types of media were used: near-isotropic media (media *A*) and orientated media (media *B*). All media used are of similar *Hc*, *MrT* values: $Hc=1800\pm50$ Oe and $MrT=2.20\pm0.1$ m emu/cm^2. Here, *Mr* and *T* are the the remanence and media thickness, respectively. Typical *Hc* orientation ratios of the near-isotropic media and the orientated media are 1.01 ± 0.01 and 1.4 ± 0.05, respectively. The *Hc* orientation ratio is the ratio of *Hc* in track direction to that in radial direction: $Hc_{\parallel}/Hc_{\perp}$.

2. Positioning accuracy

To obtain a reliable bit-shift profile, the testing system itself must have high linear positioning accuracy and low hysteresis in positioning operation. A Guzik 1701 MP micropositioning spin stand with air bearing spindle was used in all experiments to be reported. The linear positioning accuracy and positioning hysteresis of such a system are 1.2 and 0.4 μin., respectively.

TABLE I. Spindle speed for 1.5 μin. gap flying height and testing parameter setup.

θ	rpm	Bit cell (ns)	*M*-frps
0°	3077	37.15	13.46
5°	3391	33.69	14.84
10°	4136	27.62	18.1
15°	4895	23.34	21.42
20°	5499	20.7	24.16

 0021-8979/96/79(8)/5649/3/$10.00

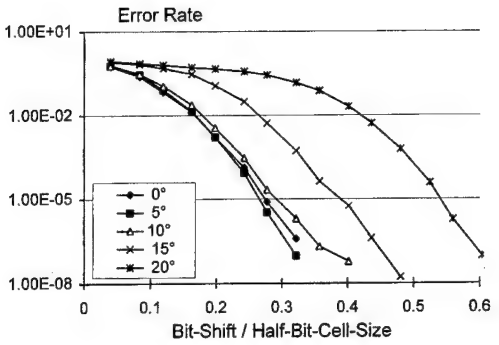

FIG. 1. Bit-shift plots at different skew angles (for media A: the orientated media).

3. Constant flying height

The gap flying height used in all experiment reported in this paper is 1.5 μin. The flying height is measured by the dynamic flying height tester of phase metrics.

The gap flying height of TPC sliders is a function of skew angle. The spindle speed is adjusted so as to achieve 1.5 μin. flying height at different skew angles. The spindle speed, bit cell size and flux reversal rate used for one of the testing HGAs (head-gimbal assembly) is illustrated in Table I.

III. RESULTS AND DISCUSSION

A. Bit-shift plot

Figure 1 illustrates bit-shift plots at different skew angles. Figure 2 shows the relationship between the skew angle and the normalized bit shift at an analysis level of 10^{-6}. The bit shift is normalized so that one unit corresponds to half of the bit cell size. A few degrees of skew angle shift was noticed from the experimental results. The shift value is fixed and is toward the positive direction. Such a shift is believed to be from alignment error in the testing system.

The following two conclusions can be drawn from the obtained results. (1) An increase in skew angle value will increase the bit-shift value at all bit-shift analysis levels investigated and for both positive and negative skew angles.

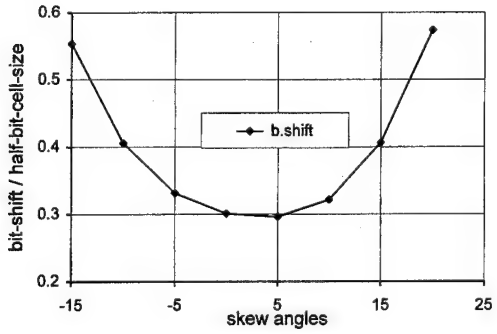

FIG. 2. Normalized bit-shift values at different skew angles (media A: the orientated media).

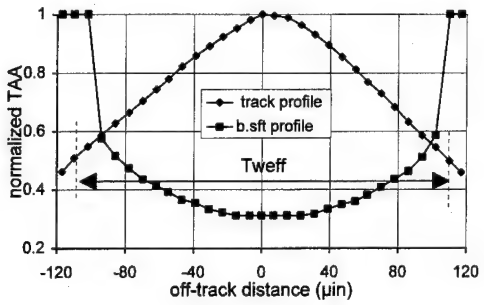

FIG. 3. Comparison between the normalized bit-shift profile and the track profile of the orientated media.

(2) From a bit-shift viewpoint, it is better to restrict skew angle within 15°, as the bit shift will be increased significantly when skew angle value is above 15°.

B. Bit-shift profile and track profile

Figure 3 compares the bit-shift profile and the track profile at a 0° skew angle. The track average amplitude (TAA) at the track center is normalized as one unit. The following can be observed from Fig. 3. (1) Though TAA reduces rapidly as off-track distance increases, the corresponding increase in the bit-shift value is not so significant when the off-track distance is not long. (2) The bit-shift value increases rapidly when the off-track distance is approaching 50% of effective track width (Tweff). Here, the effective track width is the distance measured between the two points corresponding to 50% of the maximum TAA value on the track profile.

C. Bit-shift profiles at different skew angles

Figure 4 gives bit-shift profiles at different skew angles. The following have been noticed in all comparisons conducted between bit-shift profiles obtained at small skew angles (around 0°) and that at high skew angles (above 15°). (1) The bit-shift profile obtained at small skew angles is always below the bit-shift profile obtained at large skew angles if the off-track distance is not so long (say, 90 μin. in Fig. 4). (2) The bit-shift profile becomes asymmetric when skew angle is high.

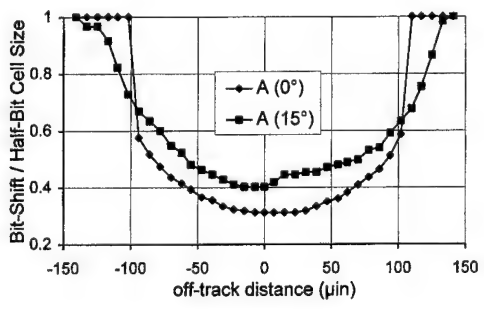

FIG. 4. Normalized bit-shift profile comparison at different skew angles (media A: the orientated media).

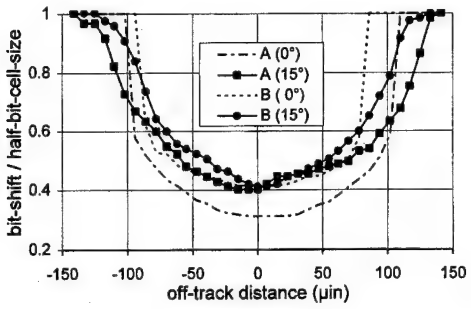

FIG. 5. Comparison of the bit-shift profiles between the near-isotropic media (B) and the orientated media (A) at 0° and 15° skew angles.

D. Bit-shift profile and medium orientation

Bit-shift profiles for the two types of media were measured at different skew angles. Figure 5 compares the bit-shift profiles of the near-isotropic media and the orientated media at both 0° and 15° skew angles. The following observations can be made from Fig. 5. (1) The bit-shift profile becomes asymmetric for both types of media, as the skew angle goes to higher values (15° or above). (2) The bit-shift profile of the near-isotropic media is narrower than that of the orientated media. (3) The normalized bit-shift value of the near-isotropic media (media B) is not as sensitive to skew angle variation as the orientated media (media A).

IV. CONCLUSIONS AND DISCUSSIONS

(1) Both the value of the bit shift and the shape of the bit-shift profile vary when skew angle is changed. Increased skew angle will increase bit-shift value, especially when skew angle is above 15°.

(2) The bit shift increases as the off-track distance increases and the bit-shift profile becomes asymmetric when skew angle is high. However, the increasing rate of the bit shift as the off-track distance increases is smaller than the TAA reducing rate, when the off-track distance is not too long.

(3) The bit-shift value of the near-isotropic media is higher than that of the media with strong orientation, when those media are of comparable *Hc* and *MrT* values.

Track-width dependence of transition jitter

P. Dhagat, E. Glavinas, A. Jander, D. G. Porter, R. S. Indeck, and M. W. Muller
Magnetics and Information Science Center, Department of Electrical Engineering, Washington University, St. Louis, Missouri 63130-4899

A simple model that represents the microstructure of magnetic medium as a rectangular tesselation predicts that the mean-square jitter is inversely proportional to the track width. We test this prediction using different width heads as well as creating different track widths by partially erasing the original track. We also simulate these experiments using a micromagnetic model. Our experimental and simulation results are found to be in agreement with the prediction. © *1996 American Institute of Physics.* [S0021-8979(96)06208-8]

I. INTRODUCTION

Increasing the storage density of magnetic recording media requires both shortening the bit length and narrowing the track width. Density limits are set by noise levels and the inevitable loss of signal associated with the reduction of the storage medium per bit. Transition jitter is a major component of medium noise. We show in this article experimentally and by modeling that, as expected,[1] the transition jitter associated with permanent microstructural medium irregularities[2–4] and with relaxation statistics increases with decreasing track width. This finding emphasizes the importance of exploiting the microstructural permanence in adaptive noise compensation.[5]

In this article we investigate the track-width dependence of jitter. The observed transition jitter is an average, over the track width, of local deviations of the magnetization reversal from the intended transition center. The local deviations are determined by the down track and cross track dimensions of the magnetic units constituting the medium.

The medium may be represented by a brick wall model with bricks representing fixed magnetic microstructural units. As shown in Fig. 1, transitions are locally recorded at the nearest edge of the underlying magnetic unit. The mean-square transition jitter of this model is[6,7]

$$\langle \sigma_t^2 \rangle = \left(\frac{c}{W} \right) (\sigma_s^2), \tag{1}$$

where $(c)/(W)$ is the number of subtransitions, given a medium with transverse coherence length, c, and track width W.

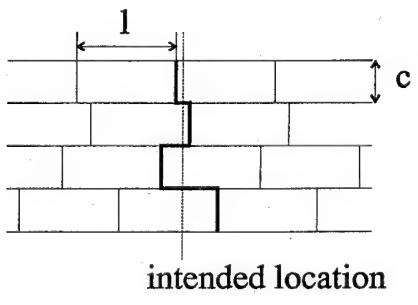

FIG. 1. Brick wall model of a magnetic medium.

σ_t^2 and σ_s^2 represent the variance of transition and subtransition positions, respectively. A detailed derivation of the above is presented in Ref. 7.

II. EXPERIMENT

Our experiments were performed using a precision spin stand with accurate spatial positioning, a variety of thin-film and ferrite heads, and oxide and longitudinal thin-film disks. To establish the track-width dependence of transition jitter we wrote transitions at 100 preselected locations on the medium. Multiple writes at each location ensured minimization of write uncertainty and 128 read acquisitions provided small read uncertainty. We determined the actual position of the transition by fitting each transition output to a standard transition waveform. The position of maximum cross correlation of these waveforms is defined as the transition position. The standard transition waveform was obtained by averaging several read averaged transitions written at different locations. Such ensemble averaging minimized both read/write inaccuracy as well as position dependence of the standard transition waveform.

The displacement of the actual position of the transition from its intended position is defined as jitter. For each of the 100 preselected locations mean jitter is computed (from multiple writes at that location). Histograms of these mean jitter

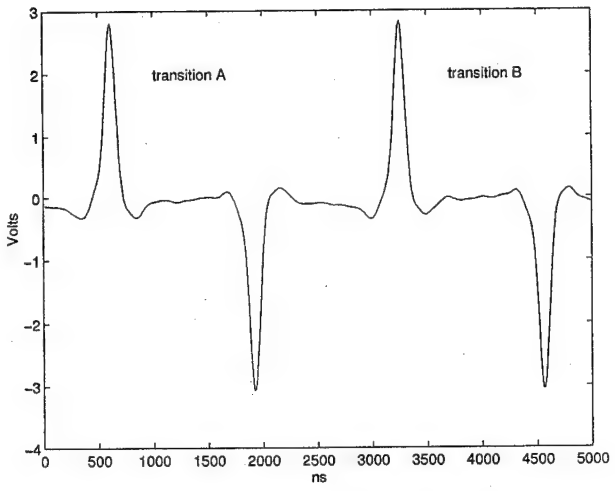

FIG. 3. Consecutive dibits for center-to-center measurements.

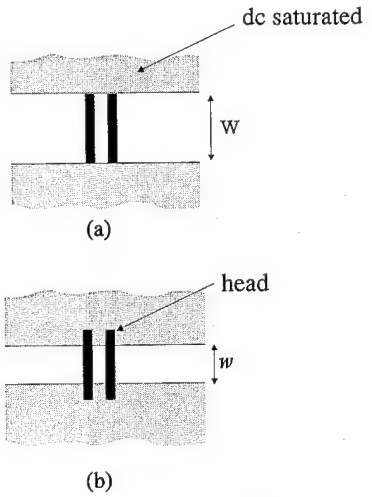

FIG. 5. (a) Original track width W. (b) Partially erased track width w ($w<W$).

values are plotted in Fig. 2. The above approach measures jitter relative to the reference trigger which may vary from write to write due to limitations in the instrumentation. To eliminate the effect of a variable reference trigger we employed a center-to-center measurement technique, measuring the distance between two transitions. We wrote two consecutive dibits (Fig. 3) at randomly selected locations on the medium and determined their position jitter by correlating the first transition (A) and the third transition (B) with a standard transition waveform. The difference between the actual positions of transition (A) and transition (B) gives a measure of the actual distance between them. Jitter is computed as the difference between the actual distance and the intended distance. Presented in Fig. 4 are histograms of jitter values.

We repeated this experiment with heads of the same track-width and number of turns but with different structural parameters (e.g., pole thickness). We found that the standard deviation of jitter was unaffected by these parameters; no systematic error, such as amplitude effects, was seen. We also used a single head (thereby keeping flying height, gap

width, and pole thickness identical from one run to another) to create tracks of different widths by partially erasing a track to various widths (see Fig. 5). Position jitter was determined as before by correlating transition A and transition B with a standard transition waveform. Figure 6 shows histogram plots for different track widths. In order to achieve the accurate placement of the transitions it was imperative to maintain control over tracking and down track timing. Accurate timing was maintained by phase locking an oscillator to a signal on the disk. We measured thermal variations every 10 min, over the span of the experiment. Using the permanent physical microstructure of the underlying medium we infer thermal drifts to be less than 5% of the read track width.

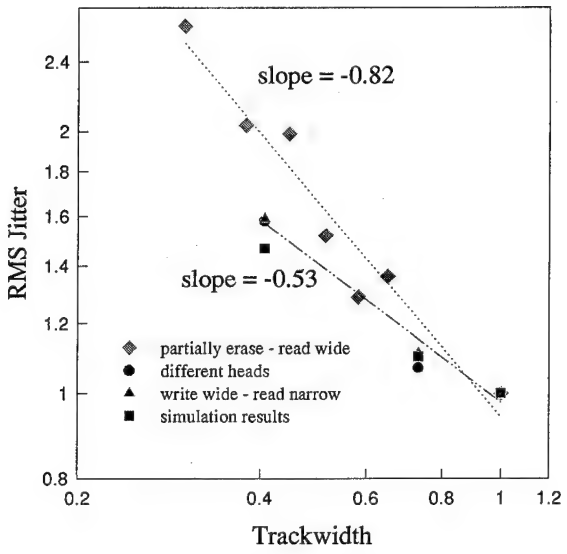

FIG. 8. rms jitter as a function of track width.

III. RESULTS AND DISCUSSION

To augment our recording tests we simulated these experiments using a Voronoi tesselation medium (see Fig. 7). From the histogram plots for each track width we obtain a mean-square value for transition jitter. Equation (1) predicts that ratios of mean-square values plotted against the ratios of corresponding track widths on a log scale follow a slope of $-\frac{1}{2}$. A modification of Eq. (1) predicts more rapid increase of jitter with decreasing track width for partially erased tracks. To account for side writing, edge effects, and erased medium noise we assume the effective track width to be linearly proportional to the signal amplitude and plot in Fig. 8 mean-square ratios versus corresponding effective track width ratios (base track width=12.3 μm) for experimental data. It is found that experimental and simulated results[8] closely follow theoretical predictions, supporting the proposed model of transition jitter.

Transition jitter measurements by Huang *et al.*[9] are also consistent with expectation and show increasing jitter with decreasing track width.

IV. CONCLUSIONS

We have shown that transition jitter increases with decreasing track widths and validated our theoretical predictions with experimental results. These results provide valuable input to real-time pre-compensation schemes which aim at improving signal-to-noise ratio and recording densities by using the repeatability of medium induced effects.

Trilayer media for high track density longitudinal recording

J. Akiyama, Y. Ohinata, T. Hikosaka, T. Taguchi, and Y. Tanaka
Communication and Information Systems Research Laboratories, Toshiba R&D Center, 1 Komukai Toshiba-cho, Saiwai-ku, Kawasaki 210, Japan

This paper introduces a new recording method using a trilayer medium (recording layer/nonmagnetic layer/soft magnetic layer/substrate) to diminish the side written band width (ΔW). Magnetostatic coupling between the soft magnetic layer in the media and the write head poles decreases the side fringing field off the track edges. Off-track overwrite experiments revealed that the trilayer media reduced ΔW by 40%–60% compared to the monolayer medium while maintaining the effective write track width and the linear resolution. © *1996 American Institute of Physics.* [S0021-8979(96)15608-5]

I. INTRODUCTION

In order to achieve high track density in longitudinal recording, aiming at a level of 10 Gbits/in.^{2} or higher, the side written band degradation near the track edges needs to be effectively suppressed. This paper introduces a new trilayer medium structure to diminish the side written band width (ΔW) for conventional ring head writing.

Figure 1 shows the configuration of the new medium. The trilayer structure consists of a recording layer at the top, a nonmagnetic control layer underneath, and a soft magnetic layer at the bottom. Magnetostatic coupling between the write head poles and the soft magnetic layer in the media sharpens the write field distribution along and across the track resulting in a decrease of the side fringing field off the track edges. The nonmagnetic control layer is indispensable for adequately controlling the balance between effective head-to-medium magnetostatic coupling and undesired downward flux leakage from the recorded magnetization to the soft magnetic layer.

The side written band widths were measured using off-track overwrite experiments[1] developed by the authors. The effective write track widths (TW_{eff}) were measured by the conventional off-track profile method. The measured ΔW and TW_{eff} of the trilayer medium (CoPtCr/Ti/CoFeTa) were compared with those of a CoPtCr monolayer medium. The on-track read/write performances including overwrite and linear resolution were also evaluated for both media.

II. EXPERIMENT

A FeTaN metal-in-gap (MIG) head with a high Bs of 1.6 T and coils of 50 turns was used for writing in this experimental study. The widths of top and bottom poles were both 5.5 μm, and the gap length was 0.3 μm. A 4.5-μm-wide MR head with 0.7 μm shield-to-shield gap was used only for evaluating on-track read/write performances. The head flying height was set to be 75 nm at a head-to-medium relative velocity of 7.38 m/s.

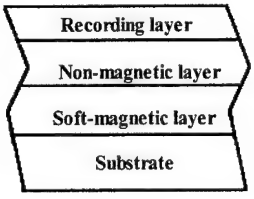

FIG. 1. Schematic view of the trilayer medium.

Two trilayer longitudinal media with different nonmagnetic Ti layer thickness and a monolayer longitudinal medium with almost the same magnetic properties were made by rf sputtering. The magnetic properties of all the media were measured using a vibrating sample magnetometer. The media specifications are shown in Table I.

The off-track overwrite recording was performed to measure the side written band width. Figures 2(a) and 2(b) show the schematic diagram of the off-track overwrite method and the measured off-track overwrite profile, respectively. At first, a signal (sig−1:60 kFCI) was recorded with the MIG head at a fixed position on the previously dc-erased medium. Then the head was displaced in the cross track direction and the old signal was partially erased by another signal (sig−2:42 kFCI) with the same write current as the sig−1 writing. This displacement (x) is the variable of the experiment. The fundamental of the residual sig−1 was read out with a spectrum analyzer (resolution band width: 30 kHz, video band width: 10 Hz) by the same head at the track center where the read sensitivity distribution was uniform. If all the above mentioned procedure is iterated with increasing the displacement (x), the off-track overwrite profile shown in Fig. 2(b) can be obtained. The head position was precisely controlled by a piezoelectric actuator, with an error of less

than 25 nm. Furthermore, for all the media, the sig−1 level at $x=0$ was equal to the noise at the sig−1 frequency, which was about 10 dB larger than the electronic noise and little depended on the displacement. Then, the distance between the origin and the point ($x=x_0$) where the sig−1 begins to increase linearly was defined as the side written band width (ΔW). The error in ΔW was estimated to be less than 0.1 μm.

In addition, the conventional off-track profiles were measured with the MIG head in order to examine the effective write track width (TW_{eff}) of the 60 kFCI signal.

III. RESULTS AND DISCUSSION

A. On-track read/write performances

On-track read/write performances were measured with the MIG write head and MR read head. Figure 3 shows the

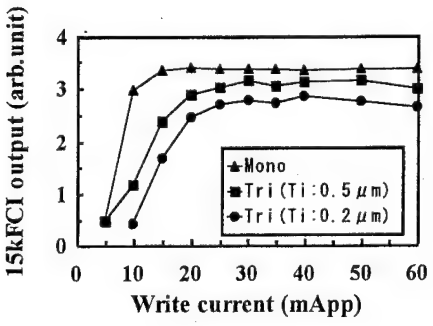

FIG. 3. Write current dependence of 15 kFCI signal output.

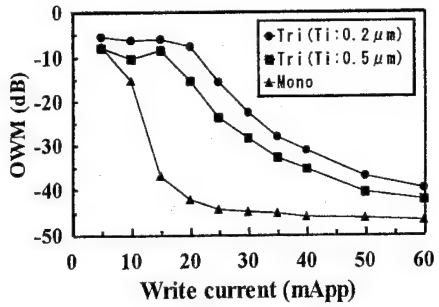

FIG. 4. Write current dependence of OWM. 15 kFCI signal is overwritten by 60 kFCI signal.

write current dependence of the reproduced output of the 15 kFCI signal. The current required to saturate the output increased in order of monolayer medium, trilayer medium B with Ti:0.5 μm and trilayer medium A with Ti:0.2 μm. The saturation output level also decreased in the same order as above. Figure 4 shows the write current dependence of the overwrite modulation (OWM). The OWM was defined as the reduction of the 15 kFCI signal fundamental after overwriting by the 60 kFCI signal. The write current needed to saturate the OWM increased in the order of monolayer medium, trilayer medium B, and trilayer medium A. However, it should be noted that both the trilayer media still had the level of less than −30 dB enough for practical use.

The above-mentioned write efficiency degradation of the trilayer media is thought caused by the decrease of the write field intensity due to the collimation of the head field bubble by the soft magnetic layer.[2]

In order to obtain the saturation output level and the OWM of less than −30 dB, the write currents (*Iw*: shown in Table II) for the subsequent experiments were set to be 20 mA_{pp}, 35 mA_{pp}, and 40 mA_{pp}, for monolayer medium, trilayer medium B, and trilayer medium A, respectively.

Figure 5 shows the measured recording roll-off curves for the sample media. The D_{50}'s were almost the same for the three media. The results showed that there was no significant difference in the linear resolution among the three media, and that the write head could generate enough field gradient to create a sharp transition even for the trilayer media. The results can be supported by the previous work[2] on the shaping of the head field by the soft magnetic layer, explaining that the presence of the soft magnetic layer decreases the write field intensity, but can maintain the write field gradient.

TABLE II. Measured on-track read/write performances.

	Trilayer medium A	Trilayer medium B	Monolayer medium
Write current (mA_{pp})	40	35	20
Normalized output	0.83	0.93	1
D_{50} (kFCI)	76	72	76
OWM (dB)	−31.0	−32.0	−42.5

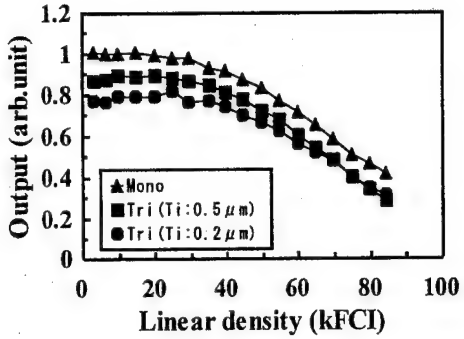

FIG. 5. Measured roll-off curves.

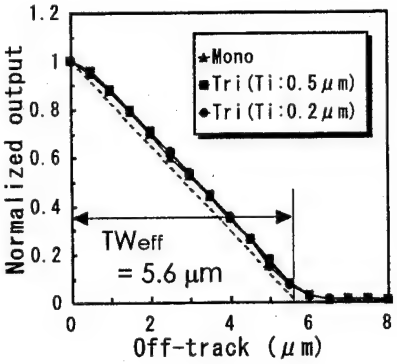

FIG. 7. Off-track profiles.

By the way, the saturation output decrease of the trilayer media can be thought caused by the downward flux leakage from the recorded magnetization to the soft magnetic layer rather than the decrease of write field intensity, because the write head could generate enough field gradient even for the two trilayer media, as above mentioned.

Furthermore, through the experiments, the reproduced wave forms for the trilayer media were extremely stable and no spike noise occurred, even in the presence of an external dc field of a few Oe applied to the soft magnetic layer using a permanent magnet. The results may reveal that the MR head was not sensitive to any magnetic change in the soft magnetic layer because the presence of the relatively thick nonmagnetic layer enough weakened the magnetostatic coupling between the MR head and the soft magnetic layer.

The on-track read/write performances are summarized in Table II.

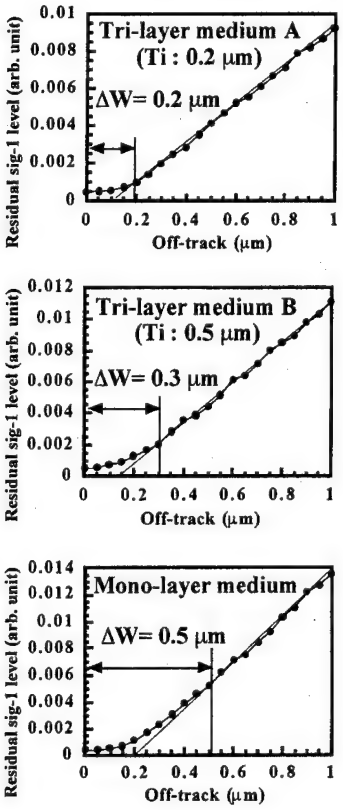

FIG. 6. Off-track overwrite profiles (sig−1:60 kFCI, sig−2:42 kFCI).

B. Side writing performances

Figure 6 shows the off-track overwrite profiles measured with the MIG head. The side written band widths (ΔW) were 0.2 μm for trilayer medium A, 0.3 μm for trilayer medium B, and 0.5 μm for monolayer medium. Both of the trilayer media thus effectively reduced ΔW by 40%–60% compared to the monolayer medium, and ΔW decreased with the decrease in thickness of the nonmagnetic layer of the trilayer medium. The ΔW reduction for the trilayer media is believed to be caused by the sharp fringing field distribution off the track edges due to the magnetostatic coupling between the write poles and the soft magnetic layer in the media. In addition, it is thought that the decrease of the nonmagnetic layer thickness increased the magnetostatic coupling and then more sharply decreased the fringing field resulting in the ΔW decrease.

Figure 7 shows the measured off-track profiles. The effective write track width (TW_{eff}) was defined as the distance between the origin and the point where the straight line through the point (0,1) and parallel to the linear region of the measured curves crosses the horizontal axis in Fig. 7. The results showed that all the three media had almost the same TW_{eff} of 5.6 μm.

IV. CONCLUSIONS

A novel trilayer medium structure was developed, to diminish the side written band width (ΔW). Off-track overwrite experiments revealed that the trilayer media effectively reduced the ΔW by 40%–60% relative to the monolayer medium while maintaining the effective write track width and the linear resolution. This fundamental feature of thenew trilayer medium makes it a strong candidate medium for high track density longitudinal recording.

Experimental analysis of the effects of tape thickness on magnetic recording

A. Friedmann,[a] D. Wei, H. N. Bertram, and J. K. Wolf
Center for Magnetic Recording Research, University of California, San Diego, Mail Code 0401, La Jolla, California 92037

Advances in magnetic tape recording have produced media with magnetic layers as thin as 0.1 μm. In this article, a metal particulate tape with a magnetic layer thickness of ~0.37 μm is compared to a standard thick media tape with a magnetic layer thickness of ~4 μm. Measurements of the isolated pulse are made and shown to compare well with micromagnetic simulations. The replay voltage versus current is measured with a 4 μm track width, shielded magnetoresistive head at various densities. The thin tape shows better high density response at high currents than the thick tape. The simulations show that the transitions are sharper on the thin tape due to both the reduction in thickness, and an improvement in the particle orientation. The better oriented particles yield narrower pulses, thereby improving the high frequency response of the tape. Frequency response measurements are also taken with the magnetoresistive head, which yield a signal to noise ratio of >20 dB at 200 kfci. Last, overwrite performance versus current is compared for the two tapes plus a metal-evaporated (ME) tape with a 0.2 μm thick layer. A significant improvement in overwrite is seen on the ME tape. [S0021-8979(96)10408-3]

I. INTRODUCTION

One historical drawback of high density tape recording has been the thickness of the recording layer. Until recently, the magnetic layer thickness was always greater than the depth of the recorded transitions. This resulted in wider transitions and reduced high frequency response.[1,2] Recently, manufacturers have been able to reduce the magnetic layer thickness of tape to <0.5 μm, to as low as 0.1 μm.[3] In this article we will examine one such tape and compare it to a standard, thick media (SVHS) tape. The thin tape analyzed here is a Fuji double-coated, metal–particulate tape. The double coating refers to a process where first a nonmagnetic layer is deposited on the backing material for smoothness, and then the magnetic layer is added. The experimental results are compared with micromagnetic simulations to better understand the findings, as well as to calibrate the simulations.

II. EXPERIMENTAL SYSTEM

A Honeywell 7600 reel-to-reel recorder was used for the measurements. The recording was done with a 15-turn, thin-film inductive head. The track width was 125 μm, the gap length was 0.3 μm, and the efficiency was 80%. The readback was performed using both an inductive head and a shielded magnetoresistive (MR) head. The inductive readback head had: 200 turns, a gap length of 0.27 μm, a track width of 250 μm, and an efficiency of 72%. The MR head was used for the frequency response measurements while the inductive head was used to measure the isolated pulses. It was necessary to use the inductive head for the isolated pulse measurements because of saturation of the MR head at low frequencies. The MR head was originally designed for disk recording, but a satisfactory mounting arrangement was found for the Honeywell system. The MR head had a shield-to-shield spacing of 0.55 μm and a track width of 4 μm.

The thin tape was a Fuji metal particle (MP) tape with a magnetic layer thickness of ~0.37 μm, a coercivity of 1780 Oe, and a remanence of 3000 G. The thick tape was a 3M SVHS tape with a thickness of about 4 μm, a coercivity of 935 Oe, and a remanence of 1390 G. The tape speed was 7.5 ips for the inductive readback head and 3.75 ips for the MR readback head.

III. MEASUREMENTS AND ANALYSIS

For the measurements that will be presented, a simplified model of tape recording wherein the tape is viewed as having a number of laminae, each at a different depth, will help explain the different response characteristics of the two tapes. Each lamina is assumed to have its own transition with a fixed transition shape and center. The widths and centers of these transitions vary from lamina–lamina. With this model, it has been shown that the demagnetization fields from the back layers of the tape influence the front layers and increase the transition parameter (also referred to as the a parameter), thereby reducing the sharpness of the transition.[2] In addition, the transition width increases for deeper laminae, and their respective centers shift further downtrack. Since the readback head sums the voltages from each layer, this shifting and broadening in the back layers produces asymmetries and widens the overall pulse, yielding a reduction in the high frequency response. From this model, it is clear that reducing the thickness of the magnetic layer will improve the high frequency response if the new thickness is smaller than the depth of recording. In essence, this will limit the demagnetization field and effectively remove the contributions from the deeper layers that broaden the pulse.

 0021-8979/96/79(8)/5658/3/$10.00

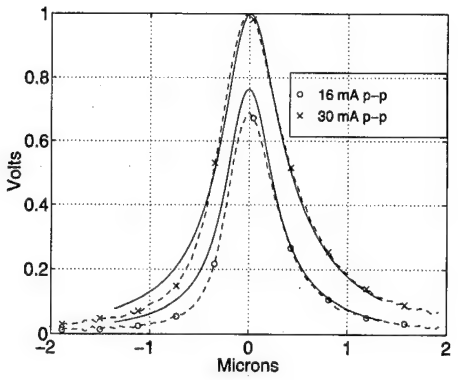

FIG. 1. Measures (dashed line) and simulated (solid line) isolated pulses on SVHS tape for two write currents.

The first measurement presented is a plot of isolated pulses at different write currents. Figures 1 and 2 show measured and simulated isolated pulses written at two currents for the two tapes. The simulation results are plotted in solid lines, while the measured values are given as x's and o's (with a dotted line plot for SVHS). For the measurements, a 10 kHz square wave was recorded on each tape, for each current, at a tape velocity of 7.5 ips. The pulses were then averaged on a Lecroy 9314 sampling digital oscilloscope. The simulation results are from a micromagnetic model developed at CMRR.

The first difference to note is the increase in the peak voltage versus current. This increase is much larger for the two pulses on the SVHS tape (~40%) than for the first two pulses on the MP tape (~20%). Since the readback voltage is directly proportional to the record depth, this implies that the record depth has increased more in the SVHS tape. The depth of recording is approximately equal to the depth at which the recording head field is equal to the coercivity, minus the head-to-tape spacing.[1,4] A good approximation of the record depth is

$$y = g \times \left(\frac{1}{2.95} \times \frac{H_g}{H_c} - 0.15 \right),$$

where y is the depth of recording, g is the gap length, H_g is the deep gap field, and H_c is the coercivity of the tape.[5] The low current isolated pulses were recording at H_g/H_c equal to

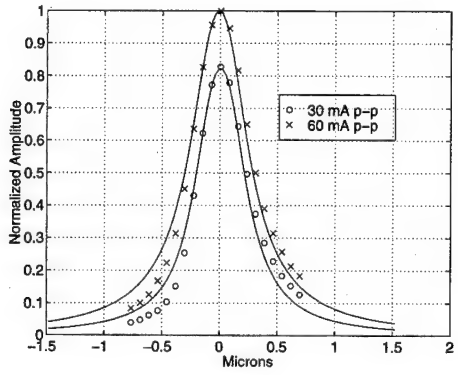

FIG. 2. Measures (x's and o's) and simulated (solid line) isolated pulses on MP tape for two write currents.

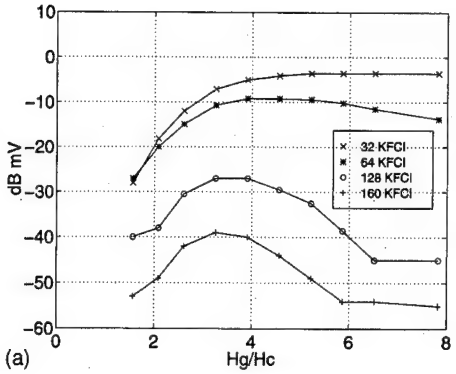

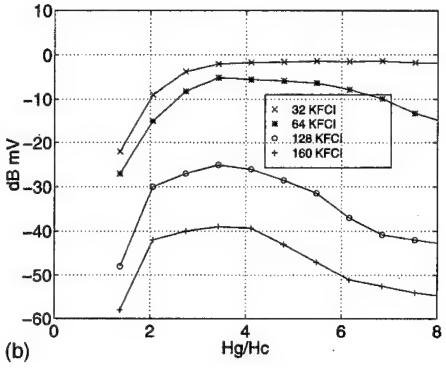

FIG. 3. Voltage vs H/H_c for four densities (a) on SVHS tape and (b) on MP tape.

four for both tapes. Assuming a spacing of 0.125 μm, this yields a record depth of 0.2 μm. For the higher current, the record depth is 0.64 μm. This analysis shows that the MP tape has been recorded through and therefore its output did not increase as much as in the SVHS tape.

Another obvious difference is the width of the pulses. The PW_{50} at 16 mA for the SVHS tape is 11% wider than that of the MP tape at 30 mA, but the PW_{50} of the SVHS increases 38% at 30 mA, while the PW_{50} of the MP (thin) tape increases only 15% from 30 to 60 mA. This is partly due to the recording layer thickness difference, and partly due to particle orientation. To accurately model the MP tape, the particle orientation for the MP tape in the simulation was made more uniform in the longitudinal direction. This translated to less broadening in the MP tape as a function of depth, and consequently, less increase in the PW_{50}.[2]

Figures 3(a) and 3(b) show the effect of increasing write current on the output response of the two tapes for four frequencies. For each plot, the frequency is set and the write current is varied from 0 to 90 mA peak to peak. At each current, a reading is taken from an HP 3586 selective level meter with a bandwidth of 3100 Hz. The MR head was used for the signal reproduction and the tape speed was 3.75 ips. Figures 3(a) and 3(b) show the output as a function of the ratio of the deep gap field (which is proportional to the write current) to the coercivity of the tape. Because the depth of recording varies as a function of this ratio, the plots are essentially normalized to each other. Figure 3(a), the SVHS tape, shows the characteristic output versus current relationship for tape recording. The low frequency output increases

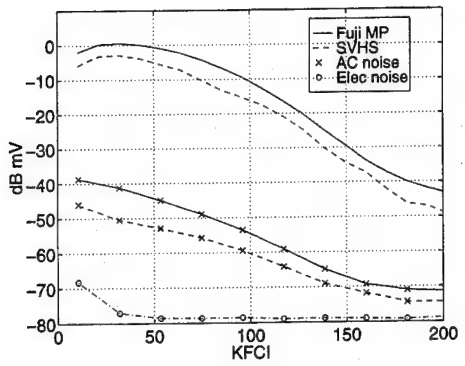

FIG. 4. Frequency response curves for both tapes at two currents. Also shown is the ac-erased noise and the electronics noise.

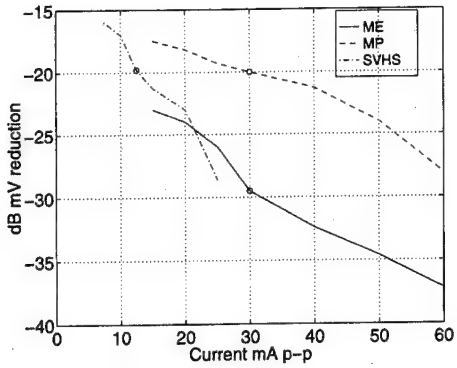

FIG. 5. $4F/1F$ overwrite vs current for SVHS, MP, and ME tape.

as the current increases, and the high frequency output peaks and subsequently declines. The low frequency output increases because as the write current is increased, the depth of recording increases and a stronger field is emitted from the tape. The degradation in high frequency output with increasing current is mainly due to three phenomena. The first is the result of the influence of the deeper layers; the broadening due to the back layers reduces the high frequency output. The second effect is a write process phenomena. The increase in the write current causes a reduction in the gradient of the record head field and results in an increase in the width of the record zone. The increase in the width of the record zone results in a wider pulse and less high frequency response. The third cause is also the result of the write process. As the density is increased, the head field for writing subsequent transitions broadens the previously recorded transitions.[6]

Figure 3(b), the MP tape, shows that the write process is the dominant cause of the degradation of the high frequency response for large currents. The general output characteristics for the MP tape are approximately the same as for the thicker, SVHS tape. The MP tape is recorded through at $\sim H_c/H_g=5.25$, but the high frequency output continues to degrade beyond this point. If the thickness of the magnetic layer was the dominant cause of the high frequency degradation, the output would have leveled off after it had been recorded through. There is improvement, however, which can be seen by comparing the optimum high density output to the output at a ratio of $H_c/H_g=6$ for both tapes. At 160 kfci, this difference is $\sim$16 dB for the SVHS tape and 11 dB for the MP tape.

Figure 4 shows the frequency response of both tapes. The write current was chosen for maximum high frequency response for each tape. The top two curves show the output at the given density to a square wave recording. The middle two curves show the ac-erased noise for the two tapes, and the bottom curve shows the electronics noise. All measurements were taken at a tape speed of 3.75 ips. This plot shows that the signal to noise ratio for the two tapes is about equal. It is interesting to note the high density resolution of the MR head. At 200 kfci, the signal is still $\sim$20 dB above the noise floor. This is impressive for tape recording, considering that the track width is only 4 μm.

The last plot, Fig. 5, shows overwrite characteristics for the tapes, as well as for a metal-evaporated tape. This overwrite test consists of first writing a 25 kfci square wave and measuring the output. Next, a 100 kfci square wave is recorded over the original square wave and the remaining power at 25 kfci is measured. The record current is the same for both frequencies. Since the ratio of the two frequencies is 4:1, this is referred to as $4F/1F$ overwrite. It is important to note that the x axis is the current in mA and that the range was quite different for the SVHS tape. This was also true in Figs. 3(a) and 3(b), but those plots were normalized. The circles represent the currents at which the high frequency output is optimized. The overwrite performance at this current is the same for both the SVHS and the MP tape. In both cases the current would have to be at least double the optimum to reach the 30 dB overwrite seen in the ME tape. The thickness of the recording layer for the ME tape is only 0.2 μm. Micromagnetic simulations of overwrite have shown that overwrite performance is not improved until the thickness of the magnetic layer is less than the gap length of the record head,[7] as is the case with the ME tape. This explains why the thin MP tape did not perform better than the thick SVHS with this write head. Use of newer, thinner, MP tapes should show significant overwrite improvement for narrow gap recording.

For the thin particulate media tested here, there is little improvement in recording characteristics over the thicker media when the record current is optimized for both tapes. Improvement in the signal to noise ratio at high densities was seen in simulations with a 0.1-μm-thick tape,[6] suggesting that the performance will continue to improve as the magnetic layers become thinner and the optimal write current is able to record through the entire layer.

Signals and nonlinearities in thin metal-particle tape

Dan Wei, H. Neal Bertram, and A. Friedmann[a)]
Center for Magnetic Recording Research, University of California at San Diego, La Jolla, California 92093-0401

A new type of metal-particle tape, whose thickness is thinner and whose particles are better oriented than traditional thick particulate media, is simulated and analyzed. Signals at high densities are much larger in the thin tape than in the traditional tape. Nonlinearities at high densities are dominated by transition width increases. Signals and nonlinearities in even thinner media are studied versus record gap length to investigate proper system parameters. © *1996 American Institute of Physics.* [S0021-8979(96)13908-0]

I. INTRODUCTION

In a proposed high-density tape project,[1] the volume density will reach 1 *Terabyte*/in.^{3} and the linear density will be 256 K BPI. Traditional particulate or ME tape media cannot yield sufficiently large signals at such high densities. Recently, new thin metal-particle tape media have been developed.[2] We have simulated these metal-particle (MP) tapes by a three-dimensional micromagnetic simulation model.[3,4]

Square wave signals are simulated at various densities (15–250 KFCI) to calculate the voltage output curves in the thin MP tape tape.[2] The simulated output curve utilizing a magnetoresistance (MR) head for a Fuji dc tape is in very good agreement with the experiment. Nonlinearities at high densities are calculated and analyzed by an analytical formula. Signals and nonlinearities versus record gap lengths are studied.

In Sec. II, system parameters and a simulation model will be introduced. In Sec. III, signals and nonlinearities in thin MP tape media are analyzed.

II. SYSTEM PARAMETERS AND SIMULATION MODEL

Thin MP tape media are simulated with $N\sim2000$ particles. The thickness of the medium is about 5–8 μin. The particle width is about 0.6–0.8 μin. and the particle length is 3–4 μin. We utilize a three-dimensional micromagnetic simulation model for particulate tape media.[3,4] For simplicity, the medium is modeled by a three-dimensional sample of 5:1 ellipsoidal particles. The particle centers are randomly distributed. Particles are very well oriented so that the noninteracting squareness $S_0=0.83$. The cross section of the simulated medium is shown in Fig. 1. The sample size is typically 5 μm in the down-track direction and 8 μin. in width. The packing fraction is about 0.4. The record gap length g is varied from 6–12 μin. and the head-medium spacing d is 2–3 μin. The shield to element spacing in the playback shielded MR head is in the range 4.5–10 μin. Periodic boundary conditions were applied in the width direction.

Magnetostatic interactions dominate the computational time. Due to the spatial random placement of particles, fast Fourier transform (FFT) techniques cannot be used.[3,4] In this article, interactions are approximated by exact interactions from neighbor particles plus a mean-field contribution from nonneighbor particles. The scaled magnetostatic interacting field $\mathbf{h}_m^i$,[3] Eq. (3) acting on i'th particle is calculated approximately as[6]

$$\mathbf{h}_m^i=-\sum_{j,\langle j,i\rangle}^{N}(R_jN_{ij}R_j^T)\cdot\mathbf{m}_j+\mathbf{h}_{\text{mean}}^i. \tag{1}$$

The matrix N_{ij} is a 3×3 dimensionless interaction matrix between i'th and j'th particles. The term $\langle j,i\rangle$ indicates that the j'th particle is a neighbor of the i'th particle (about 30 neighbors are included for each particle). The term $\mathbf{h}_{\text{mean}}^i$ is the mean-field contributions from the nonneighbor particles. In a uniform external field, $\mathbf{h}_{\text{mean}}^i$ is a constant and only a function of the average magnetization. In a spatially nonuniform external field, $\mathbf{h}_{\text{mean}}^i$ depends on the magnetization pattern of the nonneighbor particles. This approximation decreases the memory by 20–30 times and the simulation time by a factor of 8.

The M-H loop was calculated utilizing the above parameters; the interacting coercivity $H_c=9.82M_r$ (or $4\pi M_r/H_c=1.3$)[6] and squareness $S=0.86$ (neglecting interactions, $H_c=4\pi M_r$ and $S=0.83$).[6] The loop fits typical media neglecting a crystalline anisotropy field.

III. RESULTS

Square waves are recorded separately on ac-erased media at various densities. The voltage spectrum is calculated by performing the direct spectral sum of all particles in the recorded magnetization pattern.[3,7] Here, we use a MR head response function $h_s^*(k)$, where the surface field function $h_s(x)$ is given by[8]

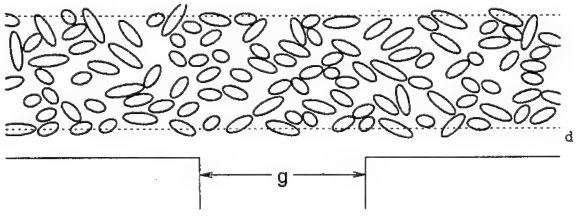

FIG. 1. Cross section of a simulated thin MP tape and the record head.

[a)]Manuscript received November 15, 1995. Kodak student fellow.

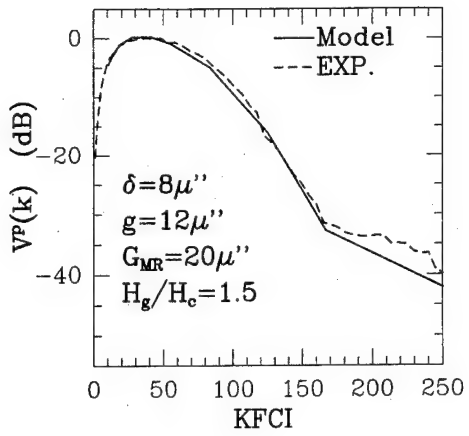

FIG. 2. Simulated and experimental output curve in a Fuji dc tape.

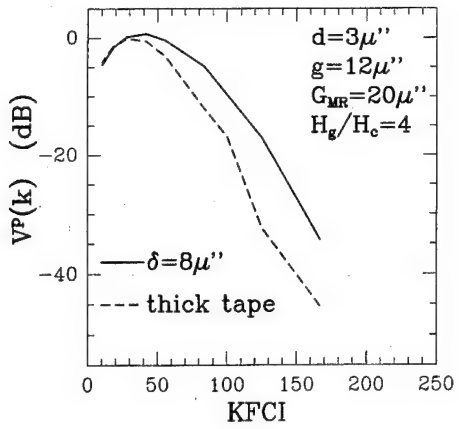

FIG. 3. Output curves for the thick and 200 nm thin MP tapes. All other parameters are fixed for both media.

$$h_s(x)=\frac{1}{2}\left(\frac{1}{1-\alpha}+\frac{C_{\text{nor}}}{\sqrt{(1-x^2)(x^2-\alpha^2)}}\right), \tag{2}$$

where the down-track distance x is normalized by $G_{MR}/2$, half of the shield to shield MR gap length; α is the ratio of MR element thickness t to G_{MR}, usually chosen as 0.1; the constant C_{nor} will normalize the integration of the second part to be one.[8]

The output curve for square wave recording in a tape medium is a function of signal (fundamental peak voltage) versus density. In Fig. 2, a simulated output curve is compared with experiment[5] in a Fuji dc tape. The thickness of the simulated tape medium is chosen to be 8 μin. and the 5:1 ellipsoidal particle length is 4 μin. The record gap length is $g=12$ μin. and the MR head gap length is 20 μin., as in the experiment. The flying height is set to be 3 μin. The experimental deep gap field H_g has a small value of $1.5H_c$. The simulated output curve fits very well with the experiment. The isolated pulse is also studied, and fits very well with the experiment.[9] The recording depth is about 6 μin. Because of the small deep gap field, the transition width increases rapidly versus depth into the medium: the a parameter increases from 1.4 μin. at the surface to 6 μin. at a depth of 3.6 μin. into the tape. If the peak voltage is analyzed by assuming a constant a parameter over the depth, the estimated recording depth will be less than 3.6 μin.

The thin metal-particle tape has a much better high-frequency performance than the traditional thick tape. In Fig. 3, computed output curves in the two media are compared. The thin medium is better oriented. The record gap length g, the flying height d, and the MR gap length G_{MR} have the same values as in Fig. 2. The deep gap field is chosen as $H_g/H_c=4$. The dash curve is the output for traditional thick tape media ($4\pi M_r/H_c=1.6$, $S=0.83$).[2,3] The solid curve is for the Fuji dc tape of similar size particles with smaller thickness $\delta=8$ μin. and better orientation. At extremely low densities ($k<20$ KFCI), signals in two media are almost the same. At the density of 150 KFCI, the voltage for the Fuji dc tape is -29 dB, which is much better than -42 dB for the thick tape. We also calculated the output curve for the same system parameters in a thinner MP tape ($\delta=5$ μin.) and the result is almost the same as the solid curve in Fig. 3.

The recording depth in the thick medium is about 9.6 μin. with $H_g/H_c=4$.[3] For an isolated transition in thick tape,[2] the transition center shifts and the transition width increases with depth. However, the a parameter is virtually a constant versus depth in the thin MP tape with $H_g/H_c=4$. For an isolated transition, the average $\langle a\rangle$ (over depth) for the thick tape is larger than that for the thin tape, but is still much less than the gap length. Therefore, at very low densities, signals in the two media are almost the same.

At high densities, nonlinearity will occur. We have found the transition width will increase with the recording density because of the demagnetizing interactions among neighbor transitions and the spatial extent of the record head field (at previously recorded transitions). We calculate the average transition width $\langle a(k)\rangle$ by fitting the magnetization $m(x)$ for various density k, shown in Fig. 4 for the thick and thin MP tapes. The symbol $\langle\ \rangle$ means averaging over transitions, but also averaging through the depth for the thick tape. The a

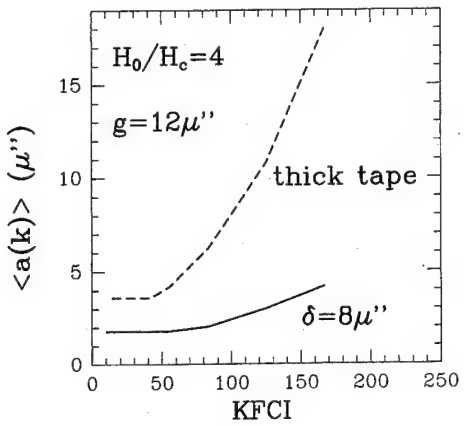

FIG. 4. The transition width of square waves vs density for the thick and thin particulate tape media.

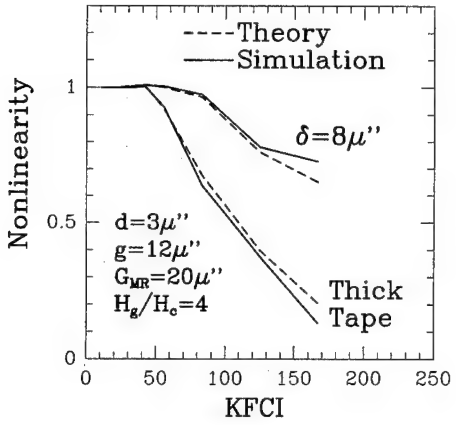

FIG. 5. Nonlinearity curves of the thin and thick particulate tapes. Two solid curves are simulation results, and two dash curves are theoretical estimates.

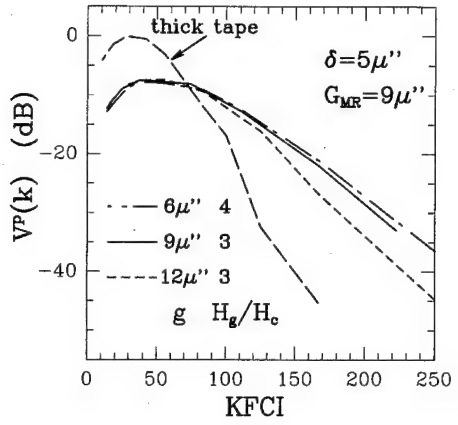

FIG. 7. Output curves with three record gap lengths 6, 9, and 12 μin. in a 130 nm thin MP tape.

parameter is not only larger, but also increases much faster in the thick tape than in the thin tape, which results in the voltage difference at high densities.

Our assessment of nonlinearity at a square wave density k is defined as $V_1(k)/3V_3(k/3)$, where $V_1(k)$ is the fundamental peak with a bit length $B=\pi/k$ and $V_3(k/3)$ is the third harmonic peak with a bit length $3B$.[5] $V_1(k)$ and $V_3(k)$ can be obtained by integrals

$$V_m(k)=\int_0^{B/2} dx\ \sin(mkx)\tanh\frac{2x}{\pi\langle a(k)\rangle}, \tag{3}$$

where the integer $m=1,3,5,\ldots$; and $\langle a(k)\rangle$ is the fitted average transition width versus density plotted in Fig. 4. In Fig. 5, the simulated (solid) and analytical (dash) nonlinearity curves are plotted for the thick and thin particulate tape media. The theoretical nonlinearity curves, calculated by utilizing Eq. (3) and Fig. 4, fit very well with the simulated curves for both media. Therefore, the nonlinearity in tape is due to transition width increase rather than "percolation" as seen in disk recording.[7]

The output and nonlinearity curves in a thinner MP tape media are also studied with three different record gap lengths. The thickness of the media is $\delta=5$ μin. The 5:1 ellipsoidal particle length is $l=3$ μin. The shield-to-shield MR gap length is chosen as $G_{MR}=9$ μin. The I-O curve with $g=6$ μin. is shown in Fig. 6 at two high densities 93 KFCI and 185 KFCI. From Fig. 6, the optimum deep gap fields are chosen as $H_g/H_c=4,3,3$ for $g=6,9,12$ μin., respectively. Note for the thin media, the optimized record current is approximately independent of the density.

In Fig. 7, three output curves for the $\delta=.13$ μm thin tape are plotted with $g=6$ μin. (dash-dot), $g=9$ μin. (solid) and $g=12$ μin. (dash), respectively. The signal curve (long-dash) for the thick tape (the same as in Fig. 3) is plotted for a reference. At a low density of 40 KFCI, the output voltages are almost identical for three different gaps, but are about 7 dB lower than the signal in the thick tape: this result is due to a thickness of $\delta=5$ μin. which is about half of the recording depth in the thick tape. The signals in the thin MP medium are -18 dB, -19 dB, -22 dB at 150 KFCI; and -27.5 dB, -29 dB, -34 dB at 200 KFCI for $g=6,9,12$ μin., respectively. The high-frequency response for the thin tape is about 20 dB better than the thick tape at 150 KFCI.

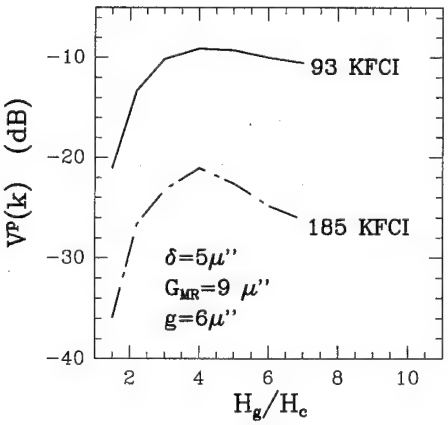

FIG. 6. The I-O curve with $g=6$ μin. in the 130 nm thin MP tape.

Computer simulation of ultrahigh-density perpendicular magnetic recording

K. Yoshida, M. Hara, Y. Hirayama, and Y. Sugita
Central Research Laboratory, Hitachi, Ltd., Tokyo 185, Japan

The possibility of ultrahigh-density recording higher than 10 Gb/in.^{2} with perpendicular magnetic recording is investigated by computer simulation for a ring-type head and single-layer medium combination. A nucleation model is used as a media model because it incorporates a nucleation site, which causes irreversible magnetization switching. Fundamental read–write characteristics are found to be entirely different from those of longitudinal recording. Recorded magnetization strongly depends on head field strength; the maximum magnetization appears around the head field strength of media coercivity, and beyond this the recorded magnetization decreases abruptly. Spacing loss in the recording process also depends on head field strength and recording density. However, saturation recording can be attained even at an ultrahigh recording density of 600 kFCI with a spacing of 30 nm. Also, a higher signal-to-noise ratio than in longitudinal recording can be obtained by introducing weak intergrain exchange interaction with a relatively large grain size in the media film. This suggests that perpendicular magnetic recording is stable in thermal fluctuation. © *1996 American Institute of Physics.* [S0021-8979(96)10508-X]

I. INTRODUCTION

The recording density of hard disk drives is increasing. In the near future, areal recording density is expected to approach up to 10 Gb/in.^{2}. Beyond 10 Gb/in.^{2}, however, longitudinal magnetic recording may encounter serious problems, as a result of residual magnetization that is too low, coercivity that is too high, and strong thermal fluctuation[1] due to thin film thickness. Perpendicular magnetic recording, on the other hand, has the potential to attain an ultrahigh recording density of over 10 Gb/in.^{2} because of its stable recorded mode at a high recording density region.[2] This type of recording has two magnetic head and medium combinations; the first is a single-pole-type head and a double-layered medium (SPT/DL),[3] and the second is a ring-type head and a single-layered medium (RT/SL). The latter combination is better from a practical point of view, although the former is thought to be an ideal combination for perpendicular magnetic recording.

The purpose of this study is to investigate by computer simulation the possibility of ultrahigh-density recording with the RT/SL combination. Zhu and Ye[4] and Che and Bertram[5] performed simulations for perpendicular magnetic recording, however, their studies focused on the SPT/DL combination. In our studies, we simulate the fundamental read–write characteristics of perpendicular magnetic recording, and compare them with longitudinal recording. The possibility of an ultrahigh-density recording with perpendicular magnetic recording of the RT/SL combination is discussed.

II. CALCULATION METHOD

In computer simulations of magnetic recording, the recording media usually consist of a closely packed regular array of hexagonal prisms. However, magnetization curves calculated with this model never agree with experimental results. The calculated switching fields (H_{sw}) are always larger than those of the experiments, resulting in a higher coercivity and squareness. Thus, for the calculation and experiment to agree, a much lower anisotropy field (H_k) or stronger exchange interaction constant has to be used. To solve this problem, we used the nucleation model, proposed by Chang and Zhu[6] for magnetization reversal simulation of Ba–ferrite platelet particles. In this model, each grain is divided into smaller subgrains. The subgrain with the lowest anisotropy field (H_{kn}) is located on the outermost side, as shown in Fig. 1, and functions as a nucleation site. Based on the model, the switching field (H_{sw}) and perpendicular coercivity decreased considerably, although the effects depend on grain size and the number of subgrains.

The following calculation conditions were chosen for the simulation; the saturation magnetization (M_s) was 440 emu/cm^3; the anisotropy field (H_k) of the normal subgrain was 5750 Oe, and that of the nucleation site (H_{kn}) was 500 Oe. The average H_k was 5000 Oe. The exchange interaction constant acting within one grain and the constants acting between the neighboring grains are defined as A_i and A_b, respectively. A_i was set at 0.3×10^{-6} erg/cm and A_b was varied from 0 to 0.3×10^{-6} erg/cm. The value of A_i was the most effective in decreasing H_{sw} and squareness. The diameter of the grain was 30 nm and each grain was divided into seven subgrains with a diameter of 10 nm. The dimensions of the medium were 1.2 μm in length (track direction) and 0.26 μm in width (track width direction), and the thickness was 50 nm. The boundary condition for the track width direction was periodic. The surface charges of the track direction side were erased. The head field was calculated by the Lindholm equation. The head field (H_h) means a vertical

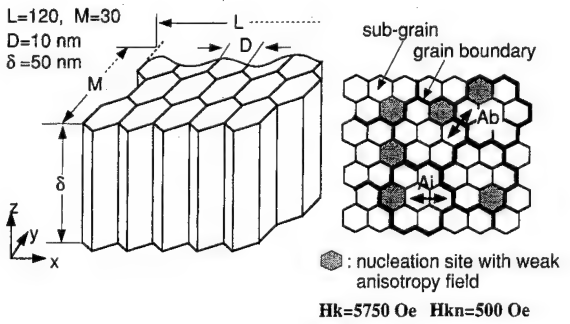

FIG. 1. Media model (nucleation model).

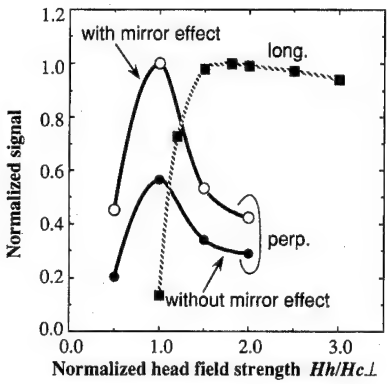

FIG. 2. Dependence of signal output on head field strength.

field strength at the middle of the media. The track width was 1.0 μm and the gap length 0.3 μm. The interaction between the head and media was calculated by the mirror effect.

III. RESULTS

A. Head field strength dependence

We investigated the dependence of the signal output on the head field strength at the middle of a medium. Figure 2 shows the calculated results. The recording density was 170 kFCI and the spacing was 5 nm. The unshaded circles indicate results with the mirror effect and the shaded circles indicate results without the mirror effect. For comparison, we included the results for longitudinal recording, indicated by a broken line. The maximum output for perpendicular recording with the mirror effect and that of longitudinal recording were equated. For perpendicular recording the signal has maximum output around the head field strength (H_h) of media coercivity ($H_{c_\perp}$), but it decreases abruptly with a stronger field than the $H_{c_\perp}$. This is different from the characteristics of longitudinal recording in which the maximum signal output appears at twice the field strength of the media coercivity, and the amplitude changes little in stronger fields. The output of the signal with the mirror effect is about twice that without the mirror effect, meaning that the interaction between the recording head and the media facilitates magnetic recording, although the mirror effect may overestimate the interaction.

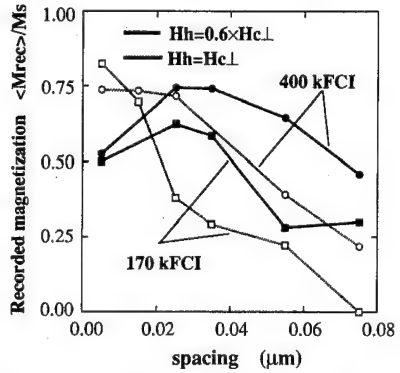

FIG. 3. Dependence of recorded magnetization on head-medium spacing.

TABLE I. Dependence of magnetic properties on intergrain exchange interaction strength.

A_b ($\times 10^6$ erg/cm)	$H_{c_\perp}$ (Oe)	Squareness	Switching field (Oe)
0	3400	0.60	3500
0.1	2750	0.63	3800
0.2	2200	0.62	3800
0.3	1300	0.52	4000

B. Spacing dependence

The spacing loss of perpendicular magnetic recording for the RT/SL combination is an important issue. Several experiments have suggested that the spacing loss, especially in the recording process, is very large and the spacing loss coefficient K is over 100 dB.[7] This is one reason for the necessity of proximate recording. Figure 3 shows the recorded magnetization (M_{rec}) dependence at 170 and 400 kFCI on the spacing. Here, M_{rec} means the magnetization averaged over a recorded bit area. The head field strength is $1.0H_{c_\perp}$ and $0.6H_{c_\perp}$. The spacing dependence strongly relies on head field strength and recording density. The M_{rec} larger than $0.6M_s$ can be obtained by adjusting a head field strength for the recording density of 170 kFCI and of 400 kFCI in a spacing region narrower than 30 nm. But, the spacing loss increases abruptly over a spacing of 30 nm, especially for $1.0H_{c_\perp}$. The spacing loss for 400 kFCI is smaller than for 170 kFCI. This strong dependence of M_{rec} on head field strength and spacing is a serious problem for practical use. This dependence may result from an insufficient head field gradient of the z component at the trailing edge of a ring-type head.

C. Effect of exchange interaction

In longitudinal recording, reducing exchange interaction is necessary to decrease media noise. Reducing exchange interaction may also be effective in attaining a high signal-to-noise ratio in perpendicular recording, however, this has not been confirmed. In this section, we examine the effects of exchange interaction on signal output and media noise.

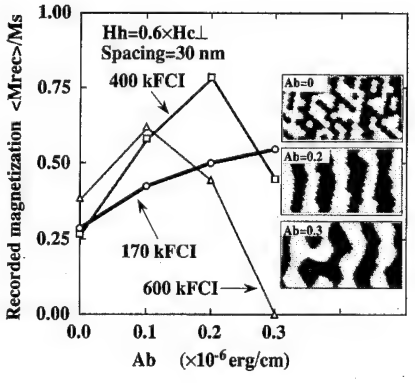

FIG. 4. Relationships between intergrain exchange interaction and recorded magnetization.

TABLE II. Comparison of signal-to-noise ratios of perpendicular recording and longitudinal recording at ultrahigh density.

	M_s	H_k	A_b	H_c	Thickness	Grain size	Relative SN (dB)		
	(emu/cc)	(Oe)	($\times 10^{-6}$ erg/cm)	(Oe)	(nm)	(nm)	400 kFCI	600 kFCI	KuV/kT
Perp 1	440	5000	0.2	2200	50	30	+5.5	···	~800
Perp 2	440	5000	0.1	2750	50	30	+4	+1	~800
Long.	360	8320	0	4000	20	10	0	···	~50

Intergrain exchange interaction (A_b) was varied from 0 to 0.3×10^{-6} erg/cm. Along with the changes in the exchange strength, the coercivity changed as shown in Table I. Figures 4 and 5 show the relationships between A_b and recorded magnetization, and A_b and media noise, respectively. The insets in Fig. 4 show recorded magnetization patterns at 400 kFCI. At any linear recording density, the introduction of a weak A_b such as 0.1 and 0.2×10^{-6} erg/cm increases the recorded magnetization. The introduction of a stronger interaction, such as 0.3×10^{-6} erg/cm, decreases the recorded magnetization, especially at high recording densities of 400 and 600 kFCI. The weak interaction also tends to reduce media noise, and strong interaction abruptly increases the media noise for 400 and 600 kFCI. This suggests that moderate intergrain exchange interaction is favorable for attaining a high signal-to-noise ratio.

Signal-to-noise ratios (SNRs) of perpendicular magnetic recording and longitudinal recording at recording densities of 400 and 600 kFCI are compared in Table II. The spacing is assumed to be 30 nm. The SNRs of perpendicular recording with weak exchange interaction are much higher than those of longitudinal recording, despite the larger grain size of the perpendicular media. Also, the ratio of anisotropy energy to thermal energy (kT; k is the Boltzmann constant and T is temperature) is about 800, which is much larger than that of longitudinal media. This means that perpendicular recording is very stable in thermal fluctuation.

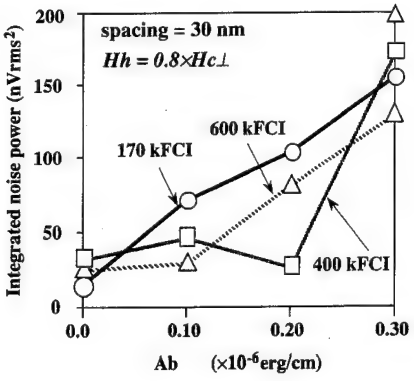

FIG. 5. Dependence of media noise power on intergrain exchange interaction.

IV. CONCLUSION

Read–write characteristics for perpendicular magnetic recording for a ring-type head and single-layer medium combination were investigated using computer simulation. The following results were obtained.

(1) Recorded magnetization strongly depended on head field strength and spacing between head surface and media surface. However, magnetic recording could be attained at an ultrahigh-density of 600 kFCI by carefully adjusting the recording head field and writing at a proximate spacing of 30 nm.

(2) A high SNR ratio could be obtained with a medium having a grain size of 30 nm and a weak intergrain exchange interaction. Thus, perpendicular magnetic recording is stable in thermal fluctuation.

Barkhausen jumps during domain wall motion in thin magneto-optical films

S. Gadetsky and M. Mansuripur
Optical Sciences Center, University of Arizona, Tucson, Arizona 85721

A method with high spatial resolution is developed to study wall motion in thin magnetic films with perpendicular anisotropy. Barkhausen jumps during domain wall motion in amorphous TbFeCo films and polycrystalline Co/Pd multilayer films have been observed. The average distance between strong pinning sites in Co/Pd was found to be around 0.3–0.4 μm. Maximum pinning times as long as several seconds were observed. Magnitudes of major jumps in TbFeCo were around 0.7 μm.
 [S0021-8979(96)05908-0]

I. INTRODUCTION

Jaggedness of a recorded domain causes additional noise during magneto-optical (MO) readout. The jaggedness is produced by Barkhausen jumps during domain wall motion within a nonuniform medium containing pinning sites.[1] When a domain wall climbs out of one pinning site and falls into an adjacent trap, it produces a Barkhausen jump. The wall can get over the energy barrier due to an energy supply from an external magnetic field,[2] due to increased surface tension of the wall itself,[3] by thermal activation,[4] and through certain tunneling mechanisms.[5] The average wall velocity depends on the average distance between pinning sites and also on the average time it takes the wall to overcome pinning. Therefore, experimental measurements of average wall velocity [6–8] generally produce the ratio of average Barkhausen jump distance to average pinning time, rather than the values of each parameter individually.

In this article we study domain wall motion in Co/Pd multilayers and in amorphous TbFeCo thin films using a focused laser beam in a magneto-optical Kerr loop tracer.

II. EXPERIMENT

Co/Pd multilayers were sputtered in an argon environment onto Si(111) substrates coated with 85 nm of SiN sublayer. Individual layer thicknesses of Co and Pd were 1.6 and 6.3 Å, respectively. In this study we used samples having 10 and 20 Co/Pd pairs of layers; we will refer to these films as Co/Pd-80 Å and Co/Pd-160 Å, respectively. The TbFeCo film was also fabricated by sputtering in an argon environment onto a Si substrate. The film had a TM-rich composition and was approximately 100 nm thick.

The experimental setup for this study is described in detail in Ref. 9. The motion of domain walls was monitored with a 780 nm diode laser whose beam was focused onto an approximately 2 μm diam spot (1/e intensity radius $\approx$1 μm). The reflected beam was picked up by a differential detector. When the domain wall was moving under the focused spot, the differential output signal was sampled by a computer at equal time intervals. The estimated spatial resolution in measuring the position of a given domain wall was about 50 nm.

Figure 1(a) shows a jagged domain wall whose profile is described by the function $x(y)$, and is assumed to be moving with an average velocity v from right to left. The average distance between the wall and the Y axis will be denoted by x_0. The circle with radius R_0 represents the focused laser spot, which is assumed to have a Gaussian intensity profile with a 1/e radius of R_0. The apparent Kerr rotation angle α measured at an arbitrary position x_0 of the wall is given by

$$\alpha/\alpha_{\max}=2\int_0^{x_0}\exp(-x^2/R_0^2)dx/(\sqrt{\pi}R_0), \tag{1}$$

where $\alpha_{\max}$ is the Kerr rotation angle of the saturated sample. Figure 1(b) shows the theoretical dependence of $\alpha/\alpha_{\max}$ on $x_0=vt$, obtained from Eq. (1). Here v is the wall velocity and t is the time relative to the instant at which the wall crosses the center of the focused spot. In our experiments R_0 was about 1 μm (measured directly using the knife-edge method). Figure 1(b) has been used throughout this article to determine domain wall velocities.

Figure 2 shows domain structures in two different Co/Pd multilayer films. In (a) the domain structure within the Co/Pd-80 Å film is seen to be solid and free from mazelike patterns. On a micrometer scale (the size of the focused spot) the wall is fairly straight, thus justifying the approach taken in arriving at Eq. (1). [Our TbFeCo film also possesses a domain structure similar to that shown in Fig. 2(a).] In the Co/Pd-160 Å film, the mazelike domain structure of Fig. 2(b) is observed. Thus, Eq. (1) is not applicable to this film.

III. RESULTS AND DISCUSSION

A. Wall motion in Co/Pd-80 Å film

Figure 3 shows the differential signals during the passage of a domain wall under the focused spot. The shape of the curve indicates that the wall motion is not smooth, but rather consists of jumps separated by pinnings at certain locations. The average number of large jumps is typically five or six, indicating that the distance between strong pinning sites is around 0.3–0.4 μm. With the magnetic field of 1.02 kOe applied in this experiment, pinning times as long as several s were observed. During a jump the wall velocity is greater than the average wall velocity. The ratio of maximum velocity (V_{max}) to average velocity (V_{ave}) of the wall in Fig. 3(a) is about six. Between strong pinning sites there exist weaker sites that cause short delays in the wall motion. Figure 3(b) is an enlarged view of the encircled region in Fig. 3(a). Figure 3(a) shows a number of different pinning times and different magnitudes of jumps.

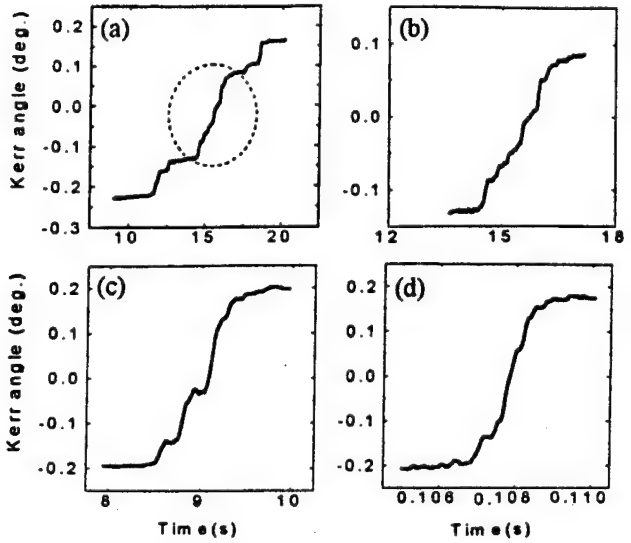

FIG. 3. Differential signals obtained during the passage of a wall under a focused spot in the Co/Pd-80 Å film under an external magnetic field. (a) $H=1.02$ kOe. (b) Enlarged view of the encircled region in (a). (c) $H=1.05$ kOe. (d) $H=1.25$ kOe.

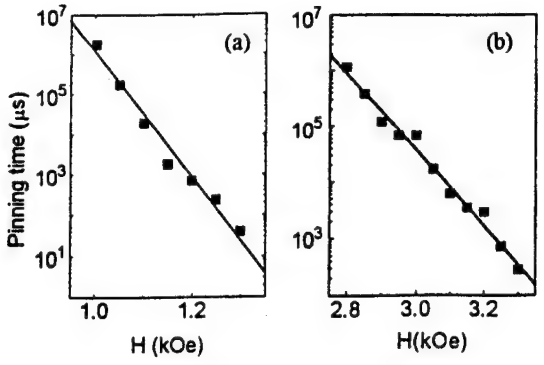

FIG. 4. Maximum domain wall pinning time vs the strength of the magnetic field. (a) in the Co/Pd-80 Å film; (b) in the TbFeCo film.

At higher magnetic fields the wall velocity increases and the wall passes under the focused spot in shorter times [see Figs. 3(c) and 3(d)]. The pinning times become shorter at higher fields, and there are fewer large jumps. Figure 4(a) shows the magnetic-field dependence of the maximum pinning time experienced by the wall. Clearly there is an exponential decrease of the pinning time with the increasing magnetic field. Figure 4(b) shows the similar behavior of the TbFeCo sample which will be discussed later in the article.

Both V_{max} and V_{ave} increase exponentially with H in the range of 1.0–1.3 kOe, as shown in Fig. 5(a). The slope of V_{ave} on a logarithmic scale is slightly larger than that of V_{max}, indicating that the ratio of V_{max} to V_{ave} must decrease with the increasing magnetic field [see Fig. 5(b)].

B. Wall motion in amorphous TbFeCo film

Figure 6 shows the differential signals obtained during the passage of a domain wall under the focused spot in TbFeCo film. As in the Co/Pd-80 Å film, the motion consists of jumps separated by pinnings at certain locations. Unlike the Co/Pd-80 Å film, however, there are fewer strong pinning sites within the illuminated area. In Fig. 6(a), where the applied field is $H=2.8$ kOe, we observe only three major jumps, implying that the average distance between strong pinning sites is about 0.7 μm. Between strong pinning sites

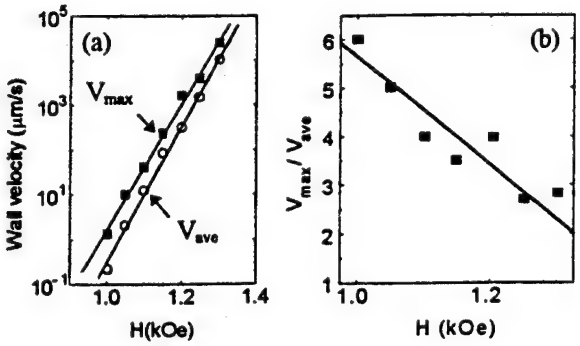

FIG. 5. (a) Maximum and average wall velocities in Co/Pd-80 Å film vs the applied magnetic field. (b) Ratio of the velocities.

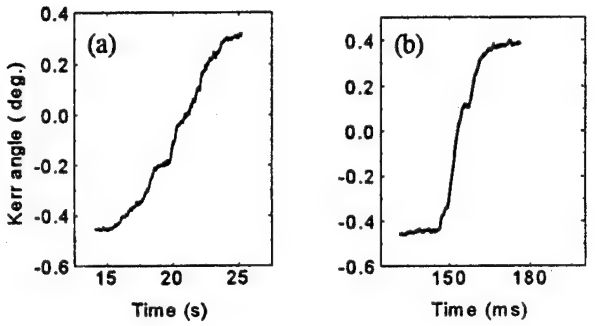

FIG. 6. Differential signals during the passage of a domain wall under the focused spot in TbFeCo film in the presence of an external magnetic field. (a) $H=2.8$ kOe. (b) $H=3.2$ kOe.

there exist weak sites which block the wall motion for short periods of time. In the TbFeCo film during and in between major jumps, the wall experiences rather strong pinning from weak sites as compared with the Co/Pd-80 Å film. This leads to a lower V_{max} during the major jumps in TbFeCo. At the higher magnetic field of 3.2 kOe, shown in Fig. 6(b), the wall velocity increases while the pinning times decrease.

Figure 4(b) shows the magnetic-field dependence of the maximum pinning time experienced by the wall in TbFeCo film; clearly, there is an exponential decrease of the pinning time with the increasing field. The slope of this curve is smaller than that in Fig. 4(a), which corresponds to Co/Pd-80 Å. Within a 300 Oe range of magnetic fields, the pinning time changes by four orders of magnitude in Co/Pd-80 Å, whereas it changes by only two orders in TbFeCo.

In the TbFeCo film, V_{max} and V_{ave} increase exponentially with H in the range of 2.8–3.3 kOe [see Fig. 7(a)]. On a logarithmic scale the slope of V_{ave} is slightly larger than that of V_{max}, indicating that the ratio V_{max}/V_{ave} must decrease with the increasing field [see Fig. 7(b)]. The slopes of both V_{ave} and V_{max} for TbFeCo shown in Fig. 7(a) are much smaller than those of Co/Pd-80 Å shown in Fig. 5(a). This implies significantly lower wall mobilities for the TbFeCo sample. The highest V_{max}/V_{ave} in TbFeCo is about 2.5,

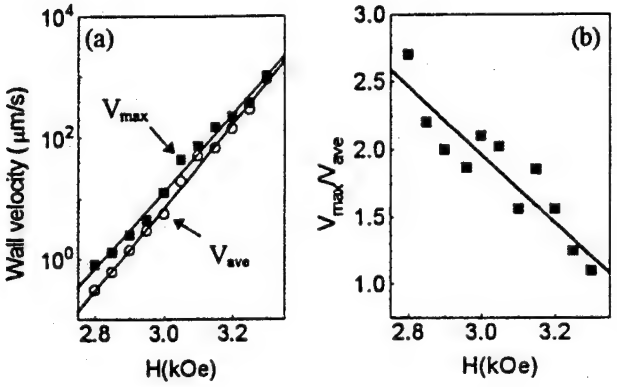

FIG. 7. (a) Maximum and average wall velocities in TbFeCo film vs the applied magnetic field. (b) Ratio of the velocities.

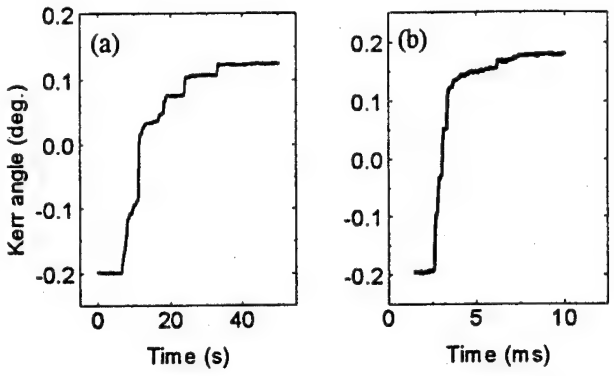

FIG. 8. Differential signals during the passage of a domain structure under the focused spot in Co/Pd-160 Å film in the presence of an external magnetic field. (a) $H=2.25$ kOe. (b) $H=3.1$ kOe.

whereas that in Co/Pd-80 Å is about 6. (These ratios are evaluated at similar values of V_{ave}, namely, at 0.3 and 0.2 μm/s, respectively.) We conclude that V_{ave} in Co/Pd is controlled primarily by pinnings at randomly distributed, strong pinning sites. In contrast, TbFeCo has more frequent pinnings and the pinning strength is distributed more uniformly.

C. Wall motion in Co/Pd-160 Å film

As mentioned earlier, we cannot apply Eq. (1) to determine wall velocity in this sample, which has the complicated domain structure shown in Fig. 2(b). Therefore, in this section we provide only general considerations on wall motion in this film. Figure 8 shows the differential readout signal during the passage of a domain structure under the focused spot. The plots consist of jumps separated by wall pinnings at certain points. Both plots are asymmetric, having a smaller slope at the end of the process (where the signal level is close to $+0.2°$) rather than in the beginning. The pinning times also become longer towards the end of the process. Moreover, at the lower field shown in Fig. 8(a), the region under the focused spot remains partially unreversed after the passage of the domain structure. (To see this, note that a maximum Kerr angle of 0.12° is achieved compared to the saturation value of 0.2°.) In the case of the higher magnetic field, shown in Fig. 8(b), the final signal is close to the saturation level, indicating that the illuminated area is fully reversed after the passage of the domain structure.

Simulation of magneto-optic readout signal spectrum using digitized mark and beam patterns (abstract)

S. Jo and J. W. Sohn
Department of Electronic Engineering, Soong Sil University, Seoul 156-743, Korea

S. K. Lee and S. G. Kim
Materials Design Laboratory, Korea Institute of Science and Technology, Seoul 136-791, Korea

This paper describes a simple and convenient simulation method, which uses analytical models[1] for mark and beam patterns. The readout signal of optical disk system is obtained by two-dimensional convolution of Gaussian intensity beam pattern and elliptical mark pattern. Then, signal spectrum is obtained by executing a fast Fourier transform algorithm after adding quantitative MO noise sources within bandwidth. For simulation, the two-dimensional distributions of mark reflectivity and beam intensity were digitized, which enabled us to use easily available algorithm routines in digital signal processing. The resolution of the beam and mark patterns can easily be adjusted by changing the number of bits representing the patterns. Also, various noise sources in the MO disk system can be selectively added using random function generator. Simulated signal spectra were compared with experimental results.[2] The parameters used were as follows: laser beam width was 780 nm, NA was 0.55, signal frequency was 9.4 MHz, duty ratio was 38%, and minimum mark dimension was 0.6 μm by 0.75 μm. Simulated C/N ratio was 50 dB, which was very close to the experimental value of 52 dB. [S0021-8979(96)46308-9]

Prediction of the limitations placed on magnetoresistive head servo systems by track edge writing for various pole tip geometries

R. Davidson[a] and R. Simmons

The typical configuration for inductive write/magnetoresistive read heads used in hard disk applications involves a shared pole (shield) between the write transducer and the read transducer. The shared pole forms the leading pole of the write portion of the head. The write track width is primarily determined by the width of the trailing pole, however, the leading pole geometry has an important influence on track-edge writing effects and, therefore, on embedded servo system performance. This effect is simulated for shared pole, trimmed pole, and, for comparison, conventional inductive head pole geometries. The merits of each geometry and impact of side writing on servo is discussed. © *1996 American Institute of Physics.* [S0021-8979(96)28108-2]

I. INTRODUCTION

The continuous increase in areal density required by industry demands narrower tracks and magnetoresistive (MR) heads. Narrower tracks increase the importance of track edge effects in the design of recording systems. The use of MR heads introduces new physics to the readback process. The MR readback element responds to the flux from the track directly in contrast to the inductive case where it is the partial derivative of the flux taken in the down-the-track direction that is transduced. The result is that the MR head responds to the track-edge charge created during the write process,[1] an edge effect one does not have to consider with inductive heads.

The goal of this work is to analyze the dependency of track-edge writing on pole geometry and the effect that the track-edge charge has on servo gain linearity and position error signal (PES) noise. The patterns of track-edge charge created in the write process vary for each pole geometry; the effect this has on the servo system gain depends on the servo detector method. Two detection schemes are discussed, area integrate and peak-peak amplitude demodulation. For the purpose of this analysis, media noise is assumed to be proportional to $1-m^2$.[2] All predictions are based upon a three-dimensional (3D) self-consistent recording model.

II. MACROMAGNETIC MODELING

The simulation consists of a 3D macromagnetic media model and nonlinear finite element model (FEM) 3D head field models.[3] The macromagnetics of unoriented thin film media is simulated with a new vector Preisach hysteresis model.[4] The hysteresis model uses a biaxial switching function in place of the classic square loop switching function normally associated with the Preisach model. The advantage of this approach is speed since micromagnetic detail can be treated in terms of the aggregate or macromagnetic response.

Three pole geometries were considered including the most common implementation of the write portion of a MR head, the shared pole geometry, as shown in Fig. 1. The corresponding head fields, including saturation effects, were computed for the midplane of the medium, which is 75 nm from the poletips in this case. The head fields are then used to self-consistently compute the resulting magnetization pattern as the head (field) is translated down the track. To compute a representative servo magnetization pattern, dibits were recorded for each of the three pole geometries. The MR output is proportional to the flux from the media and, therefore,

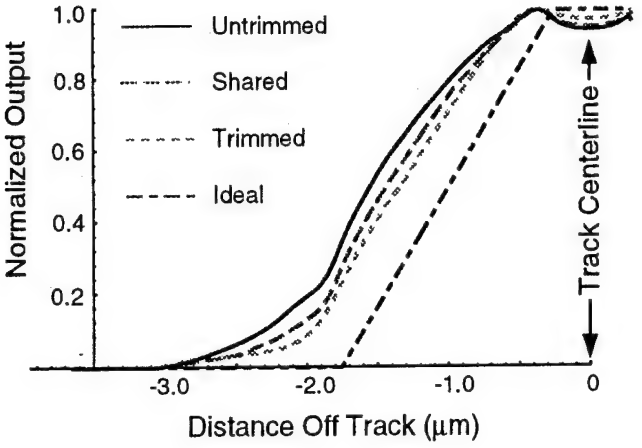

FIG. 2. Area integrated PES for various poletip geometries.

to the equivalent magnetic charge density, ρ_m, associated the written magnetization patterns.

In the case of a servo demodulation scheme using area integration of the servo burst, the signal from the MR head is proportional to the integral of the magnitude of ρ_m from the beginning of the servo field to the end. In this simulation the integral is over one dibit. The PES signal read from the dibit, i.e., the readback signal versus position across the track, would then be the correlation of down-the-track integral of $|\rho_m|$ and the 3D MR head sensitivity function. To avoid the complication of the spatial variation of the MR sensitivity functions, a simple rectangular response function is assumed, the width being 0.75 of the 2 μm trailing write pole width. This approach is appropriate for a DSMR or spinvalve head and can be applied, with modifications, to a SAL MR head.[6] The ideal case would yield a PES that is the correlation of two rectangular functions, one equal to the pole width for the write and the other to the MR width for the read. In this analysis, any deviation from this ideal straight line response would be considered PES gain nonlinearity as shown in Fig. 2.

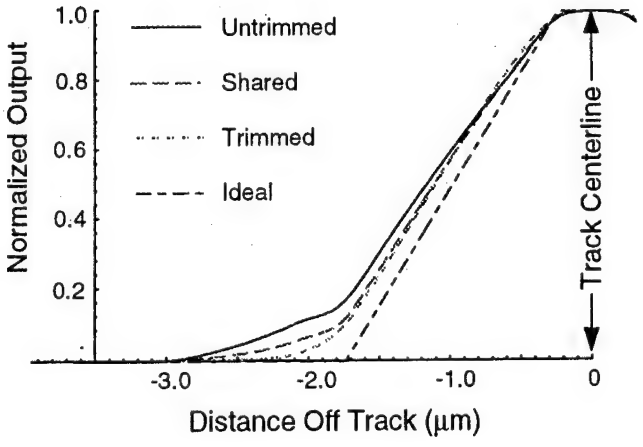

FIG. 3. Peak detected PES for various poletip geometries.

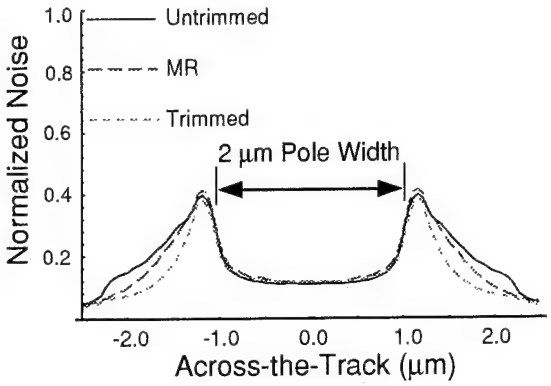

FIG. 4. Integrated noise proportional to $1-m^2$.

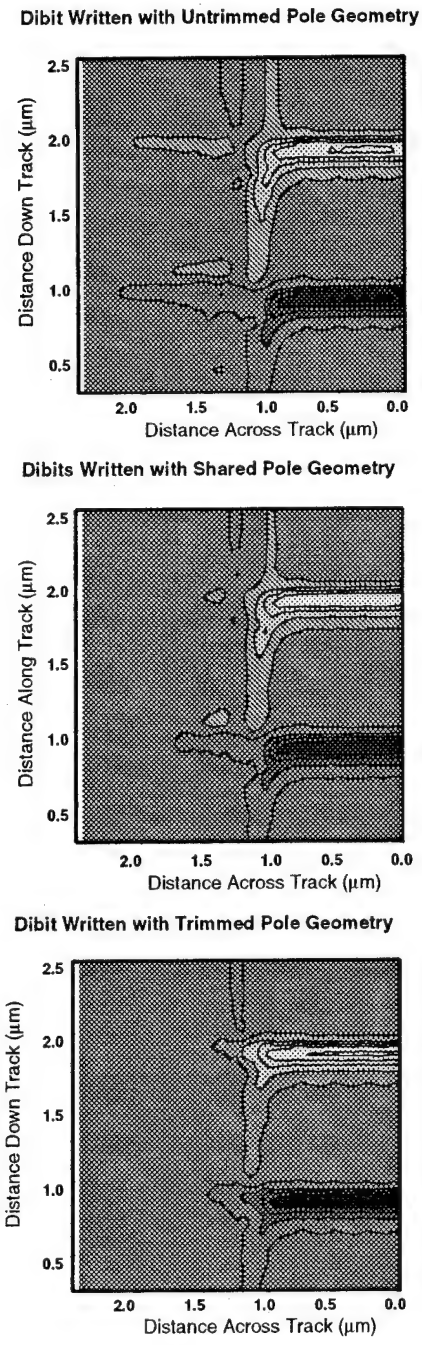

FIG. 5. Resulting ρ_m for various poletip geometries.

In the case of a servo demodulation scheme which uses peak-to-peak output, the down-the-track peak-to-peak value of ρ_m for the dibit is used. The PES is computed as in the previous case, and the results are shown in Fig. 3. Deviation from the ideal appears as nonlinear gain variations to the servo system.

In addition to PES nonlinearity, PES noise must be considered. The fluctuation of the magnetization at the track edge contributes to the noise on PES. The total PES noise must be included in the off-track error budget. To determine this, the normalized noise function, $\text{noise}(x,y,z)=1-m^2$, where $m=M(x,y,z)/M_{\text{sat}}$, is computed. Finally, noise (x,y,z) is integrated down the track to yield the total noise across-the-track corresponding to the written transitions as shown in Fig. 4.

III. RESULTS AND DISCUSSION

The head fields differ mainly in the spatial distribution of the edge fields due to the pole geometry differences, the gap length and head/medium separation being held constant. The difference in the edge fields can most easily be seen in H_z, the across-the-track component. For the trimmed pole configuration, the peak in the H_z component occurs at the same distance from the track edge for the leading as for the trailing pole. For the shared pole case, there is only a H_z component for the trailing pole at the same distance from the track edge as for the trimmed pole case. The untrimmed pole case, however, has a much wider distribution in H_z, the peak in H_z for the leading pole being offset from the trailing pole by the geometric difference in the leading to trailing pole widths.

In Fig. 5, the spatial distributions of ρ_m corresponding to the written magnetization patterns for each geometry are shown. The variation in writing beyond the edge of the dibit and the charge along the edge of the dibit are visible in the contour plots. The slow decay to the side of the track and the spike at the track edge visible in the untrimmed case would contribute significant nonlinearity in the servo gain as the head is moved onto the track using the area integrate servo detection scheme. For example, the change in the output per unit track width would increase sharply when the edge of the read head is in the neighborhood of 1.9 μm in Fig. 2, i.e., high gain. However, as the head is moved further onto the track, to 1.0 μm, the increase in output per unit track width is much less. For the area integrate scheme, the trimmed pole geometry is best. In the case of peak-to-peak detection, note that the track edge charge does not contribute, but the slow decay to the side is still present. The nonlinearity would only occur when the read head is almost completely off the servo field, so the relative impact to the system design would be a narrower range for the servo.

IV. CONCLUSIONS

Leading pole geometry has an important effect on side writing. High track density MR designs must take this into account. Trimmed poles are best at reducing side writing and peak-to-peak servo demodulation is more immune to side-writing. Partially trimmed poles for MR heads need to be evaluated. It is sufficient to consider the macromagnetics of the recording system to see this.

Autotuning of a servowriter head positioning system with minimum positioning error

Y. H. Huang, S. Weerasooriya, and T. S. Low
Magnetics Technology Center, Faculty of Engineering, National University of Singapore, 10 Kent Ridge Crescent, Singapore 0511, Singapore

This paper proposes a servopositioning system of a servowriter with autotuning capability. The position feedback is obtained through an interferometry-based laser positioning system. The retroreflector is mounted directly on the disk drive arm for hard coupling. The dynamics of the actuator are now included in the servopositioning loop. Since drive dynamics vary from drive to drive, a fixed controller may not provide optimal settling performance for a series of drives. In the proposed control method, the actuator dynamics are identified by injecting a pseudorandom binary sequence into a coarsely tuned feedback servoloop. The resulting frequency domain identification results are used to fine tune the compensator to enable faster settling and better following. Using this information in the servodesign, settling times of 9 ms and a following accuracy of 1 μin. seem achievable using existing hardware. © *1996 American Institute of Physics.*
[S0021-8979(96)10608-6]

The primary concern in designing a servowriter is head positioning accuracy. In the hard disk drive industry at present, the physical head position accuracy required when servowriting is typically 1% of the track pitch. With a track density of 10 000 TPI, the position accuracy requirement in servowriting is translated to less than 1 μin.

With such stringent position accuracy requirements in servowriting, a precision position sensing scheme is imperative.[1–6] Laser-interferometry-based position measurement is the most widely used technique today. In this technique, a glass prism called a retroreflector is attached to a moving part of the actuator system. Depending on how the retroreflector is attached there are two head positioning techniques that have been successfully used: (1) servowriting using the heads of the head disk assembly (HDA) pushed by an external stage, and (2) servowriting using the HDA's own heads with a retroreflector attached to the actuator.[1]

The main disadvantage of the first method is that the dynamic effects of having the actuator driven by the push pin are not compensated for by the servoloop.

In the second method, the highest confidence in head positioning results.[1] The position of the arm is now inside the servoloop. With future hard disk drive's track density climbing to above 10 000 TPI, actuator dynamics and thermal deformation of the actuator structure can no longer be ignored in servopositioning, therefore this method seems to have a better chance of survival in the long term.

However, as a result of including the drive dynamics in the servoloop in the second method, a controller that is tuned for one drive may not achieve the same performance for another drive. One parameter which primarily affects the closed-loop system performance is the acceleration constant of the Amplifier/VCM Actuator Structure (AAS). From the control system point of view, the change in AAS is equivalent to the change in the dc gain of the plant, which has the effect of moving the position of the closed-loop dominant poles.[2]

In this paper, the effects of variations in the AAS of individual drive on track to track seek is investigated. In order to achieve fast settling and accurate following, it is desirable to autotune the servoloop on a drive by drive basis so that the closed-loop dominant pole locations are maintained at the specified position in the z plane. This is the motivation of the research performed in this paper. The test stand for the proposed servopositioning control system is illustrated in Fig. 1. The system consists of a laser position measurement system, a VCM current driver, a spindle motor speed controller, a 3.5 in. disk-drive assembly, and an IBM-compatible PC.

The block diagram of the servoloop with the rigid body plant model of the VCM actuator is given in Fig. 2.[8] The specifications of interest are settling time and overshoot in time responses. As servowriters mainly operate on one-half or one-quarter track seek mode, the filter $F(z)$ in the block diagram is a discrete time linear IIR filter which can facilitate the required closed-loop operation. The digital-to-analog-converter DAC gain and the laser position transducer gain K_t are specified by the laser measurement electronics. The amplifier gain K_a is selected by the transconductance of the voice coil motor driver. The rigid body model of the VCM actuator/retroreflector structure is a double integrator with an acceleration constant K_m. The last block K_d is determined by the relative position of the retroreflector on the actuator.

The AAS of the system in Fig. 2 can be defined as a series gains of K_a, K_m, and K_d. It is equivalent to the dc gain of the rigid body model of the amplifier/VCM actuator structure. It is seen that AAS changes with the moment of inertia to the pivot of the actuator/retroreflector structure, as well as with the force constant of the VCM. Because these parameters vary from drive to drive, the optimal controller may not be obtained without prior knowledge of the AAS of the particular drive. Therefore, system identification is introduced to provide information on fine tuning of the controller.

The target of the system identification is the VCM actuator/retroreflector structure of the new drive being servowritten. From the system identification, the AAS of the drive can be reliably obtained. Pseudorandom binary sequences (PRBS) detection have long been used in system

 0021-8979/96/79(8)/5674/3/$10.00

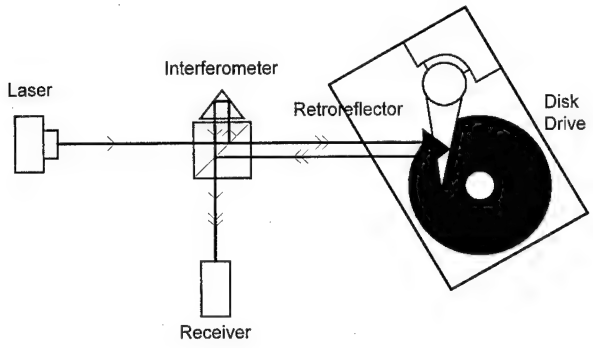

FIG. 1. Head-disk assembly with laser positioning system.

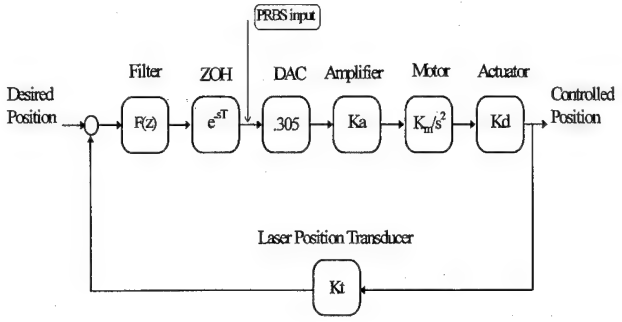

FIG. 2. System block diagram of servowriter positioning system.

identification problems in place of white noise.[4] PRBS signals are simple to generate in the present hardware/software platform. This method is an effective alternative to swept-sine identification which is normally used for such applications.

The identification is done under closed loop. The test signal is injected after the filter output; see Fig. 2. The corresponding controller output and actuator position are captured and used as the input–output pair for system identification. The frequency response of the plant transfer function is then calculated by comparing the spectrum of the input–output data. The reader is referred to Ref. 4 for details of this method. Once the plant transfer function frequency response is available, both the rigid body and flexible body model of the plant can be estimated. This is illustrated bellow.

Let $\{\omega_i, G(j\omega_i)\}$ be the experimental frequency response data of the plant. We would like to fit the experimental data with a polynomial rational transfer function $P(s)$,

$$P(s)=\sum_{i=0}^{m} b_i s^{m-i} \Big/ \left(s^n+\sum_{i=1}^{n} a_i s^{n-i} \right), \tag{1}$$

where $b_i,\ldots,b_m$ and $a_0,\ldots,a_n$ are real coefficients, m and n are the estimated order of the numerator and denominator, respectively. We wish to find the above-mentioned parameters $m,n,b_i,\ldots,b_m$ and $a_0,\ldots,a_n$ so that for each particular frequency ω,

$$\sum_{i=0}^{m} b_i(j\omega)^{m-i} \Big/ \left((j\omega)^n+\sum_{i=1}^{n} a_i(j\omega)^{n-i} \right) = G(j\omega) \quad \text{for all } \omega=\omega_i. \tag{2}$$

However, Eq. (2) is the ideal case which is either unachievable or too costly to achieve with the computing resource given. A practical solution can be to select the coefficients of Eq. (1) such that the tolerance for Eq. (2) to hold is in some way minimized.

Rewrite Eq. (2) as

$$\sum_{i=0}^{m} b_i(j\omega)^{m-i}-G(j\omega)\sum_{i=1}^{n} a_i(j\omega)^{n-i}=(j\omega)^n G(j\omega). \tag{3}$$

The identification task now becomes minimizing

$$\left\| \left\{ \sum_{i=0}^{m} b_i(j\omega)^{m-i}-G(j\omega)\sum_{i=1}^{n} a_i(j\omega)^{n-i} \right\} -(j\omega)^n G(j\omega) \right\| \quad \text{for all } \omega=\omega_i. \tag{4}$$

Selecting the rms norm the above equation transforms into a standard least-square minimization problem.[5]

In the proposed system, a fourth-order model in the form below is used to represent the system identified,

$$\frac{k}{s^2}\,\frac{b_1 s+a_0}{s^2+a_1 s+a_0}. \tag{5}$$

The above model can be considered as a double integrator model plus one high frequency resonance mode. The AAS of the nominal plant is therefore equivalent to k in Eq. (5).

In the s plane, the model shown in Eq. (5) has two poles at the origin and two zero-pole pairs near the imaginary axis. The controller design is then to select the proper controller zero/pole locations as well as the appropriate gain to obtain desired closed-loop performances. This is illustrated in Sec. III B.

With the nominal model of the plant, a linear second-order IIR filter is designed in time using MATLAB.[2,3] The controller is a combination of a PI and a lead compensator. The transfer function of the filter is

$$\frac{C(s)}{E(s)}=K\,\frac{s+z_1}{s}\,\frac{s+z_2}{s+p_1}, \tag{6}$$

where the zeros z_1 and z_2, and pole p_1 are so selected that the root locus of the control system has the desired shape. The gain K in Eq. (6) is chosen so that the dominant closed-loop poles are placed at the desired position on the root locus.

The ideal closed-loop dominant poles are the key factors in determining the system time responses. At the preliminary stage of design, the controller chooses its controller gain according to the AAS of the nominal plant model. For a drive with an AAS different from the nominal value, such selected controller gain will not give the same time response as desired. However, with the identified AAS of each drive from Sec. III A, the controller gain can be adjusted so that the dominant poles of the closed-loop system with the new drive are the same as that with the nominal one.

The discrete time IIR filter in Fig. 2 can be derived from the continuous time controller model demonstrated below.

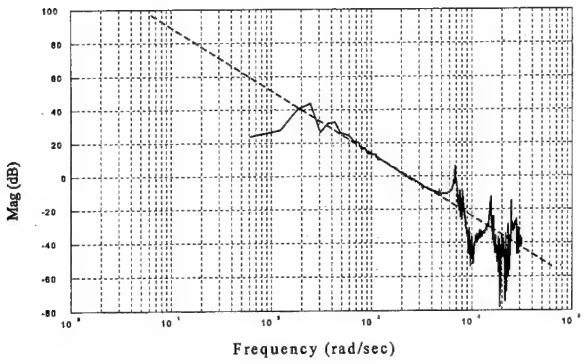

FIG. 3. Frequency response plot of identification.

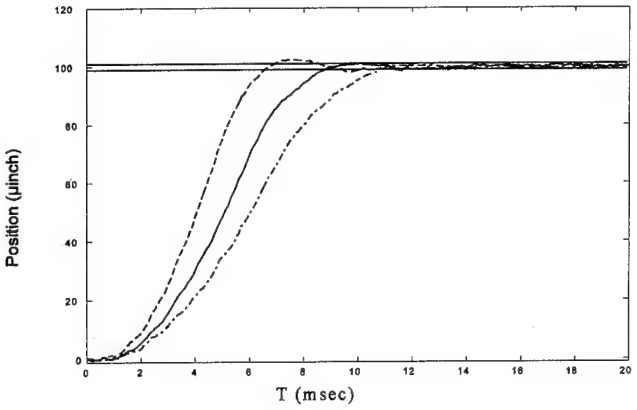

FIG. 4. A 100 μin. move of the servosystem.

Assuming a sampling interval of T, the backward rectangular rule is used to discretize the model by substituting

$$s=(1-z^{-1})/T. \tag{7}$$

As a result, the IIR filter equation of the digital controller is obtained as[8]

$$\frac{C(z)}{E(z)}=\frac{K_{x0}+K_{x1}z^{-1}+K_{x2}z^{-2}}{1+K_{y1}z^{-1}+K_{y2}z^{-2}}, \tag{8}$$

where

$$\begin{aligned} K_{x0}&=K(1+Tz_1)(1+Tz_2)/(1+Tp_1),\\ K_{x1}&=-K(2+Tz_1+Tz_2)/(1+Tp_1),\\ K_{x2}&=K/(1+Tp_1),\\ K_{y1}&=-2-Tp_1,\\ K_{y2}&=1//(1+Tp_1). \end{aligned} \tag{9}$$

Before servowriting a new drive, a maximal length PRBS signal of 1023 time points is first applied to the servoloop. Figure 3 shows the frequency responses of both the identified plant and the estimated rigid body model. The dashed line is the estimated value of the rigid body model, while the solid line represents the experimental values. Due to system nonlinearities such as the significant effect of pivot friction in disk drives of 3.5 in. and below, the low frequency responses (below 100 Hz) deviate significantly from the rigid body model of the plant. The rigid body model of the plant matches the experimental data only in the midfrequency range.

With the identified system model, the AAS of the new plant is compared with that of the nominal value used in the preliminary design stage. The controller gain and reference input are then adjusted accordingly to give the desired performance of the closed-loop system.

Figure 4 shows a 100 μin. move of the closed-loop system with 1% error tolerance lines. A profiled reference input is used instead of a step input in order to suppress the excitation of the high frequency components of the system. Equal acceleration commands in opposite directions are applied in the two halves of the reference input. The amplitude of the acceleration is adjusted proportionally to the AAS of the plant.

The same control is applied to three drive sets of different AAS gains. The dashed line shows the case where the previous controller gain is large. An undesirable larger overshoot is observed. The dot-dashed line shows the case where the previous controller gain is small. The system seems overdamped and an improvement in settling time is expected. The solid line gives a time response of the tuned system. Compared with the two cases before controller tuning, the tuned system has the fast settling time while the overshoot is sufficiently suppressed.

Note that although other system dynamics like resonance mode and low frequency nonlinearity are available from the system identification, only the gain is used in tuning the controller. The first resonance mode identified, however, aids mainly in the preliminary design stages in selecting the controller. Future development on direct on-line tuning of a higher order system model can be achieved without modifications of the system identification scheme.

Magnetically induced super-resolution performance for a center aperture detection scheme in a double layered magneto-optical storage is discussed. In order to make a readout layer thinner for better media lifetime, the effect of Ta and Pt additive elements in a readout layer GdFeCo on recording performance is systematically studied. Ta is found to be most effective in making it possible to reduce the readout layer thickness for an acceptable recording performance. For the mark length of 0.5 μm, the thickness can be reduced to 60 nm with Ta (1.9 at. %) from 80 nm without Ta for carrier-to-noise ratio (CNR)$\geq$42 dB.
[S0021-8979(96)10708-2]

INTRODUCTION

Magnetically induced super-resolution (MSR), through which marks smaller than a diffraction limited size can be read, is one of the schemes for future high-density magneto-optical recording.[1] There are several proposals for MSR. One of them is a so-called "center aperture detection scheme (CAD)," which consists of an exchange coupled double layer. A readout layer has the magnetic anisotropy which changes from in-plane to perpendicular at higher temperatures.[2] Inside a heated laser beam spot of reading, the magnetization direction tends to be along the film normal because the perpendicular magnetic anisotropy becomes predominant, whereas outside the spot the magnetization is in-plane. Therefore, only the perpendicular component of the magnetization in the locally heated center region can be detected as signal.

Previous work[3] on the relation between magnetic properties and readout characteristics of MSR with a GdFeCo readout layer showed that the readout layer thickness larger than 80 nm was necessary for CNR higher than 35 dB at 0.4 μm mark length. Thicker magnetic layer requires higher writing power due to larger heat capacity. Therefore, the writing power must be lowered for practical applications in order to avoid the degradation of a media lifetime. One way to overcome this drawback is to make a readout layer thickness smaller. (However, it should not be too thin, since one should avoid the readout signal from the magnetization of a recording layer.) Through the exchange coupling, the direction of the magnetization near the interface between the recording and readout layers is not completely in-plane, but has a component along the film normal. It gradually changes in going from the interface through the readout layer thickness direction. Because of this gradual change, the thickness of more than at least 80 nm was found to be necessary to keep the polar Kerr rotation of GdFeCo at room temperature small enough so that little signal can be detected. It is believed that a steep change of the direction in the readout layer is essential for high performance MSR.

The present study discusses the effect of additives in a readout layer on performance so that one can decrease a readout layer thickness.

EXPERIMENT

Thin films of SiN(80 nm)/GdFeCoM(d)/TbFeCo(50 nm)/SiN(30 nm)/Al(20 nm) (M=Ta, Pt) were sputter deposited on polycarbonate (PC) substrates with a track pitch of 1.6 μm. GdFeCoM layers were deposited by co-sputtering of Gd and FeCo targets. Chips of additive, M, were placed on a Gd target. The deposition rate was 0.2 nm/s and the Ar pressure was 0.7 Pa. SiN films were deposited by reactive sputter deposition of Si in (Ar+N_2) gases, where the total gas pressure was kept 0.76 Pa. The compositions of GdFeCoM were (a) $(Gd_{94}Ta_6)_{32}(Fe_{60}Co_{40})_{68}$, (b) $(Gd_{88}Ta_{12})_{31}(Fe_{60}Co_{40})_{69}$, (c) $(Gd_{94}Pt_6)_{32}(Fe_{60}Co_{40})_{68}$, and their Curie temperatures, T_c, were about 370, 350, and 380 °C for (a), (b), and (c), respectively. The composition of recording layer was fixed for the above samples, which was $Tb_{19}(Fe_{87}Co_{13})_{81}$ with T_c of 270 °C. A sample with nondoped $Gd_{27}(Fe_{50}Co_{50})_{73}$ readout layer was also prepared as reference.

Writing and reading performances were examined using an optical tester with λ=780 nm, NA=0.55, and linear velocity 7.5 m/s.

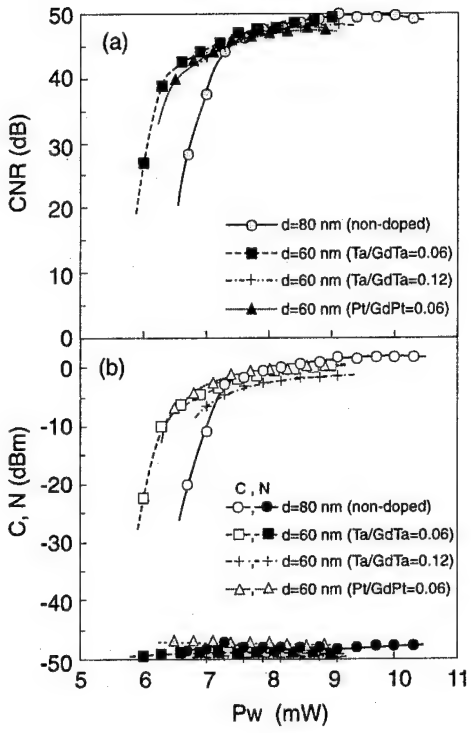

FIG. 1. Writing power dependence of (a) CNR and (b) C and N levels for mark length of 0.76 μm at 7.5 m/s.

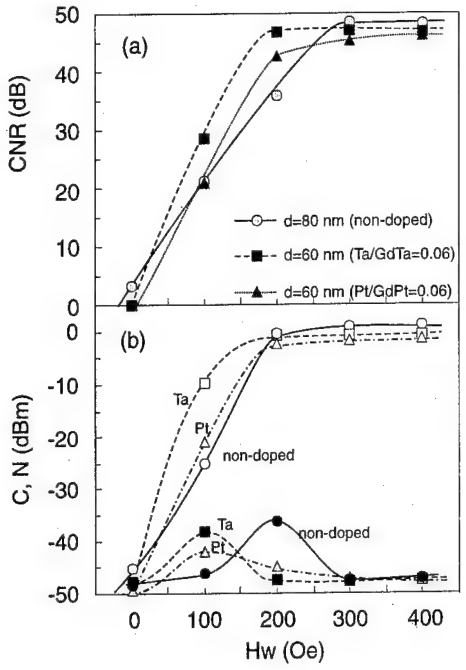

FIG. 2. Writing field dependence of (a) CNR and (b) C and N levels for mark length of 0.76 μm at 7.5 m/s.

RESULTS AND DISCUSSION

Figure 1(a) shows the writing power dependence of CNR, where the mark length is 0.76 μm, the readout power is 2.5 mW, and the writing magnetic field is 500 Oe. Figure 1(b) is the carrier and noise levels as a function of the writing power. The samples with a 60-nm-thick readout layer show nearly the same CNR in a range from 7.5 to 9 mW as that with a 80-nm-thick nondoped one. A slight difference between the nondoped and doped samples in a low writing power region is believed to be due to a difference in thermal capacity through the thickness difference. The writing powers corresponding to minima of a second harmonic amplitude of carrier for the doped samples were lower than that for nondoped one by about 1 mW. [The actual powers were 9.7, 8.7, 8.5, and 8.6 mW for nondoped of d=80 nm, (a) of d=60 nm, (b) of d=60 nm, and (c) of d=60 nm, respectively.] A slight difference of CNR between Ta and Pt in a low power region is due to a lager noise of the Pt additive one, as shown in Fig. 1(b).

Figure 2(a) shows the writing field dependence of CNR, where the mark length is 0.76 μm and readout power is 2.5 mW. Figure 2(b) is the result of carrier and noise. When the thickness of the readout layer decreases, and when the Curie temperature of the readout layer also decreases with the additives, the writing process becomes less influenced by the magnetization of the readout layer. Therefore, the field dependence is improved, as given in Fig. 2(a). The saturation writing field for the doped samples is smaller than that of nondoped one. The effect of the additive is more clearly seen in Fig. 2(b), where the peaks of the noise level for the doped samples are smaller by 100 Oe than that of the nondoped one.

Figures 3(a) and 3(b) show the readout power dependences of CNR and carrier and noise, respectively for 0.5 μm marks. The sample with a Ta-doped 60-nm-thick readout layer (a) exhibits nearly the same CNR as that for nondoped one with a 80-nm-thick readout layer in a range from 2 to 4

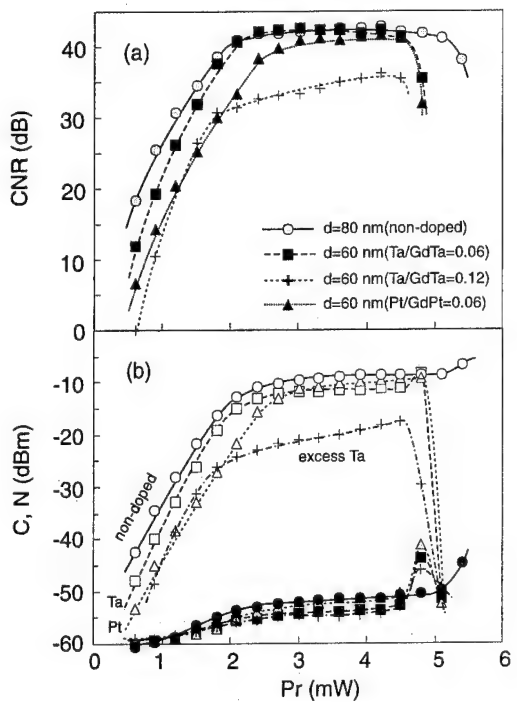

FIG. 3. Readout power dependence of (a) CNR and (b) C and N levels for mark length of 0.5 μm at 7.5 m/s. Excess Ta means Ta/GdTa=0.12.

mW of the readout power. The readout power margin (CNR>40 dB) for the Ta doped sample is about 2 mW, which is quite reasonable for practical use. The CNR of the Pt doped sample (c) is less by a few dB than those with and without Ta. An excess amount of Ta doping to the readout layer (b) reduces CNR as shown in Fig. 3(a). The Ta doped samples show lower noise level than other samples, as shown in Fig. 3(b).

The present result indicates that there might be a further possibility for reducing a readout layer thickness. In order to examine how thin the thickness can be made for acceptable performance, another experiment was performed. A sample with a 40-nm-thick readout layer (Ta/GdTa=0.06) was tested. Although the writing power sensitivity was improved by 1 mW under the same condition as indicated in Fig. 1, the CNR value was 37 dB for 0.5 μm marks. Thus, this result implies that there is a limit for reducing a readout layer thickness, which is around 50 nm for the composition of Ta/GdTa=0.06.

As to the effect of the exchange constant, A, and the perpendicular magnetic anisotropy, Ku, on the reduction of a readout layer, it is conjectured that a smaller A and Ku are favorable, since a sharper transition of the magnetization direction near the interface of the two layers takes place for smaller A and Ku.[4] The present result is consistent with this argument, where the sample with Ta has smaller A and Ku than those for nondoped one. A preliminary calculation was made to examine the effect of A and Ku on the spin distribution for two cases:

(i) reduction of A by 1/2, and
(ii) reduction of Ku by $1 \cdot 10^5$ ergs/cm^3.

For both the cases the spin distribution was found to become equally sharper. It is not clear, however, at this moment what are the optimum values of A and Ku for best CNR performance at small mark size. The change of Ku with temperature is also strongly related to MSR performance. A detail study on the effect of A and Ku relating to MSR performance is in progress.

CONCLUSION

The present study has demonstrated that the readout layer can be made as thin as 60 nm for acceptable performance with adding Ta. It is found that the writing power can also be made lower by 1 mW as compared to the case for the nondoped sample. Improvement of the writing field dependence of CNR was demonstrated, which results from a lower Curie temperature of the Ta-doped readout layer.

We study exchange coupling in rare-earth/transition-metal multilayers in which one layer has perpendicular magnetization and a second layer has in-plane magnetization at room temperature. The exchange coupling between these layers is mediated by a thinner intermediate layer, and we investigate the dependence of the exchange on the magnetic properties of this intermediate layer from room temperature through the compensation and Curie temperatures of the layers. The structures of interest consist of a 400 Å TbFeCo layer with perpendicular magnetization, a 400 Å GdFeCo layer with in-plane magnetization, and a GdFe intermediate layer of variable composition and thickness. The results indicate that the structures are well-described by either a two-layer or a three-layer coherent rotation model (depending on intermediate-layer thickness) and that the influence of the intermediate layer is a function of its anisotropy energy, its thickness, and the identity of its dominant atomic moment. © *1996 American Institute of Physics.*

INTRODUCTION

Ferrimagnetic amorphous alloys of the rare-earth and transition-metal groups are the media of choice in today's magneto-optical storage technology. Sequential layering of such alloys permits additional control of their magnetic behavior through interlayer exchange coupling. As the intrinsic properties of the constituent layers are strongly temperature dependent, the exchange coupling exhibits unique dynamic effects when such structures are rapidly heated and cooled. An elegant example of such effects has been demonstrated in recent years through the concept of magnetic super-resolution (MSR).[1–5]

In one MSR scheme, Murakami *et al.*[4] used two layers, one (the storage layer, SL) having perpendicular magnetization and the other (the readout layer, RL) having in-plane magnetization at room temperature. The temperature response of this system depends strongly on the exchange interactions between the RL and the SL. Recent results by Nishimura *et al.*[5] suggest that better control of the exchange process can be achieved by using an intermediate layer (IL). This motivated us to understand the exchange interactions between the RL and SL as a function of the composition and thickness of the IL.

EXPERIMENTAL TECHNIQUES

RE–TM alloys are sputtered onto glass substrates in a system equipped with six magnetron sources and a rotating sample turntable. The system's base pressure is around 6×10^{-8} Torr and films are grown in a 3 mT argon atmosphere. Deposition takes place at the chamber's ambient temperature (estimated to be 70–80 °C) with no bias voltage applied to the substrates. SiN underlayers and overcoats are grown during the same pumpdown by reactive sputtering.

Magneto-optical Kern effect (MOKE) measurements are conducted in a 20 kG electromagnet equipped with a heating stage and a MOKE setup consisting of a He–Ne laser and a Wollaston prism/differential detector combination. Measurements are conducted from both sides of the trilayer samples to obtain hysteresis loops for both RL (glass interface) and SL (air interface) at the same temperature. A combined vibrating-sample magnetometer/torque system is employed to measure saturation magnetizations in the films as a function of temperature.

RESULTS AND DISCUSSION

In Fig. 1, representative MOKE loops for the RL in a bilayer structure as well as those of the single RL and SL are shown for various sample temperatures (expressed as a frac-

tion of the RL compensation temperature). The SL composition $[Tb_{24}(Fe_{70}Co_{30})_{76}]$ is TM-dominated and exhibits room-temperature compensation and 100% remanence hysteresis loops through its Curie temperature of about 400 °C. The RL composition $[Gd_{31}(Fe_{60}Co_{40})_{69}]$ is RE-dominated and has in-plane magnetization for all temperatures below 0.8 T/T_{comp}. It has a T_{comp} value of about 225 °C and a Curie temperature above 400 °C. The exchange coupling between the two layers manifests itself as a bias field which displaces the hysteresis curve of the RL from the H, θ origin. When the field sweep exceeds the SL coercivity, the MOKE signal from the RL traces out an inverted loop whose zero crossings give the magnitude of the exchange bias field H_b. Above T_{comp} the films are strongly exchange coupled for all applied field values.

The exchange bias represents the value of the applied field at which the Zeeman energy per unit area ($E_j = \mathbf{H}_{applied} \cdot \mathbf{M}_j t_j$ for each layer j) favoring rotation of net moments in all layers toward the applied field direction balances the energy of the interface domain wall that accommodates nonparallel TM moment alignment in the various layers. This domain wall is a 180° head-on wall whose energy is considered to be equivalent to that of a 180° Bloch wall, $\sigma_w = 4(AK_{eff})^{1/2}$, in which A is the exchange stiffness constant and $K_{eff} = (K_u - 2\pi M_s^2)$ is the effective uniaxial anisotropy energy of the layer in which the wall resides. The thickness of a Bloch wall is given by $\delta = \pi(A/K_{eff})^{1/2}$; for typical values of A and K_{eff}, a lower bound for δ is about 100 Å for our films.

This work dealt with samples in which either the composition of 100 Å intermediate layers or the thickness of $Gd_{30}Fe_{70}$ intermediate layers was varied. Plots of H_b versus reduced temperature for both sets of samples [Figs. 2(a) and 2(b)] show the increase in H_b with temperature observed in Fig. 1. The results of Figs. 2(a) and 2(b) can be categorized into two classes, one in which the IL thickness is comparable to δ and one in which it is larger.

For the case in which the IL thickness is less than about 100 Å, the situation is equivalent to the bilayer case considered by Esho,[6] for which the exchange bias is described by

$$H_b = \sigma_w / 2M_s t. \tag{1}$$

Here σ_w is the energy per unit area of the domain wall between the two layers and M_s and t are the saturation magnetization and thickness of the layer which feels the exchange bias (the RL). The H_b results of Fig. 2(a) can be understood by considering that the domain wall is energetically favored to lie in the layer with the lowest value of (AK_{eff}). IL compositions $Gd_{35}Fe_{65}$ and $Gd_{30}Fe_{70}$ both have higher K_{eff} values than the RL, so energy considerations suggest that the wall will tend to reside in the RL for these samples. Consequently, σ_w is the same in both cases, so the H_b behavior is similar. The observed H_b data can be fit using a value of $\sigma_w = 0.1$ erg/cm^2, as shown in Fig. 2(c). Since the $Gd_{25}Fe_{75}$ IL is TM-dominated we observe a higher H_b, for which experimental results are shown in Fig. 2(a) and fit in Fig. 2(c) using an effective value of $\sigma_w = 0.4$ erg/cm^2.

The second category of trilayers includes those in which the IL thickness is larger than δ. In this case, the experimental H_b results shown in Fig. 3, which plots exchange bias at a given temperature versus IL thickness, are consistent with a three-layer coherent rotation model. In the three-layer model, we express the energy of the generic trilayer of Fig. 4(b) as the sum of six terms describing the Zeeman, exchange, anisotropy, and magnetostatic energies of the IL and the RL. The full energy expression is

$$\frac{E}{\text{area}} = -M_{s,r} H t_r (1 - \cos\theta_r) + \sigma_{w,r} \sin^2\left(\frac{\theta_r - \theta_i}{2}\right) + K_{\text{eff},r} t_r \sin^2\theta_r - M_{s,i} H t_i (1 - \cos\theta_i) + \sigma_{w,i} \sin^2\left(\frac{\theta_i}{2}\right) + K_{\text{eff},i} t_i \sin^2\theta_i, \tag{2}$$

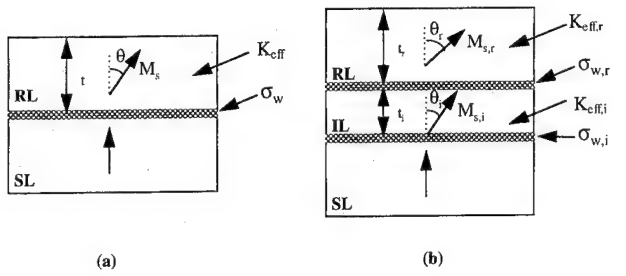

FIG. 4. Geometries for (a) two-layer and (b) three-layer coherent rotation models.

where the subscripts i and r indicate values for the IL and the RL, respectively. The bias field is found by minimizing the energy with respect to both angles θ_i and θ_r, setting θ_r equal to $\pi/2$, and eliminating θ_i. This yields an equation that is fourth order in H_b. We recover the prior solution for H_b [Eq. (1)]. as well as a new solution which allows for an arbitrary direction of IL magnetization; the exchange bias is then described by

$$H_b = \frac{\sigma_{w,i}\sigma_{w,r}}{2t_i(M_{s,i}\sigma_{w,r} - 4K_{\mathrm{eff},i}t_r M_{s,r})}. \tag{3}$$

This equation has an explicit $1/t_i$ dependence, but it should be noted that $K_{\mathrm{eff},i}$ is also a function of t_i.

Figure 2(d) shows simulated data using Eq. (3) to find H_b for triple-layer films. The model indicates that the temperature dependence of H_b stems from the individual temperature dependencies of $M_{s,i}$ and $K_{\mathrm{eff},i}$ of the IL; both of these vanish at the Curie temperature, so the model predicts that H_b will go to infinity at the IL's T_C (190–205 °C depending on composition). However, the H_b curve appears to be insensitive to the Curie temperature of the IL. Magnetostatic coupling can be ruled out because of the different dominant submoments in the SL and RL. Thus it is apparent that coupling persists beyond the temperature at which the IL is expected to become paramagnetic, in contrast to the "switching off" of exchange that is proposed in Ref. 5.

The model also predicts a monotonic decrease in exchange bias as a function of IL thickness, while Fig. 3 indicates that the exchange bias increases in the thickness range from 100 to 150 Å before decreasing with further thickness increases. The physical interpretation is that there is some threshold thickness of the IL at which it begins to behave as a coherent magnetic layer bounded by two domain walls. This critical thickness corresponds to a balance between the energetic cost of building two 90° domain walls (one in the high-anisotropy IL) and the energetic benefit of allowing the IL to assume its lower-energy state of in-plane magnetization. This means that the three-layer model is valid only above a certain threshold IL thickness, so the $1/t_i$ dependence of the exchange bias is observed only above this thickness.

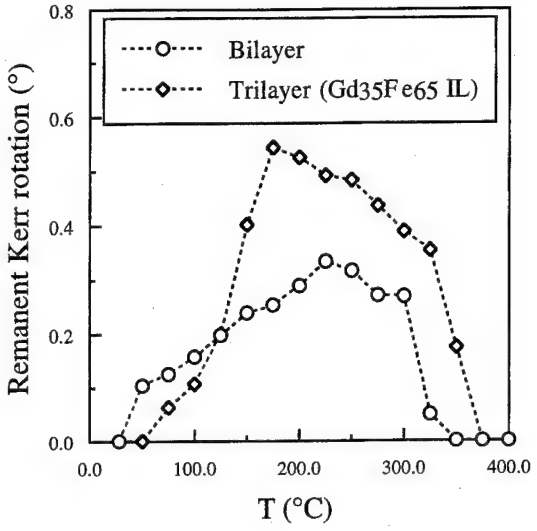

FIG. 5. Comparison of temperature response of bilayer and trilayer structures.

Since the shifting of the magnetization curve of the RL causes a finite remanence (related to the magnetization direction of the SL) at zero field, and since this shifting increases with temperature, the films exhibit the temperature-dependent remanent Kerr rotation that is necessary for MSR. As shown in Fig. 5, the influence of the IL is to sharpen the temperature response of the remanent Kerr rotation in comparison with that of the two-layer system.

CONCLUSION

We observe exchange coupling in RE–TM bilayers in which one layer has in-plane magnetization and a second layer has perpendicular magnetization at room temperature, and we investigate the influence of an intermediate layer on the strength of the exchange coupling between the two layers.

Transition from in-plane to perpendicular magnetization caused by temperature changes have been investigated for double-layer (GdFeCo/TbFeCo) and triple-layer (GdFeCo/GdFe/TbFeCo) magneto-optical recording films. The transition in the GdFeCo layer occurs mainly as a result of change in the demagnetizing energy of the GdFeCo layer having compensation temperature. Such transition occurs more rapidly in the triple-layer film than that in the double-layer film. Micromagnetic calculation showed that in the double-layer film the interface wall penetrates deeply into the GdFeCo readout layer, while in the triple-layer film the wall is almost completely confined within the GdFe intermediate layer having a large Ms and a low T_c. The triple-layer film is found to improve the characteristics of magnetically induced super resolution (MSR). © *1996 American Institute of Physics.* [S0021-8979(96)15708-1]

Magnetically induced super resolution (MSR) is a promising technology for achieving super high-density magneto-optical recording media.[1] Recently, a new type of MSR double layer film has been proposed.[2,3] In the film, the magnetization orientation of the readout layer changes from in-plane to perpendicular with the raise of the temperature, and hence the marks in the most heated area can be detected while the adjacent marks are masked. However in such double-layer film, it is difficult to achieve sharp transition from in-plane to perpendicular magnetization, resulting in insufficient MSR characteristics.

The present authors adopted a magnetic triple-layer film instead of the double-layer film and allowed a sharper transition from in-plane to perpendicular magnetization, and then succeeded to improve the MSR characteristics.[4,5]

In this paper we investigate the mechanism of the transition from in-plane to perpendicular magnetization, and clarify the effect of the intermediate layer on the magnetization transition both by micromagnetic calculation and by magnetic and magneto-optic measurements.

Magnetic layers were deposited by dc co-sputtering from elemental targets on glass or polycarbonate substrates. GdFeCo (readout) and GdFe (intermediate) layers were rare-earth (RE) rich alloys. TbFeCo (memory) layers were $3d$ transition metal (TM) rich alloys.

Saturation magnetization Ms was obtained by using a vibrating-sample magnetometer and mean-field theory. The Kerr rotation θk and the anisotropy field Hk were measured from Kerr hysteresis loops, which were measured from the substrate (GdFeCo) side for the wavelength of 830 nm. All of the magnetic layers were sandwiched between SiN layers, and samples have a reflectivity of 19%. The uniaxial perpendicular anisotropy constants Ku of respective layers were obtained from the expression $Ku-2\pi Ms^2=-MsHk/2$.

In magnetic thin films the orientation of the magnetization is determined by the effective perpendicular anisotropy constant K given by

$$K=Ku-2\pi Ms^2, \tag{1}$$

where $2\pi Ms^2$ is demagnetizing energy. When K is negative, the magnetic film exhibits in-plane magnetization. On the other hand, when K is positive, the magnetic film exhibits perpendicular magnetization.

In both single and double layer films, the effective perpendicular anisotropy K changes its sign from negative to positive at a certain temperature, resulting in a transition from in-plane to perpendicular magnetization [Fig. 1(a)]. When the GdFeCo layer is coupled with the TbFeCo layer,

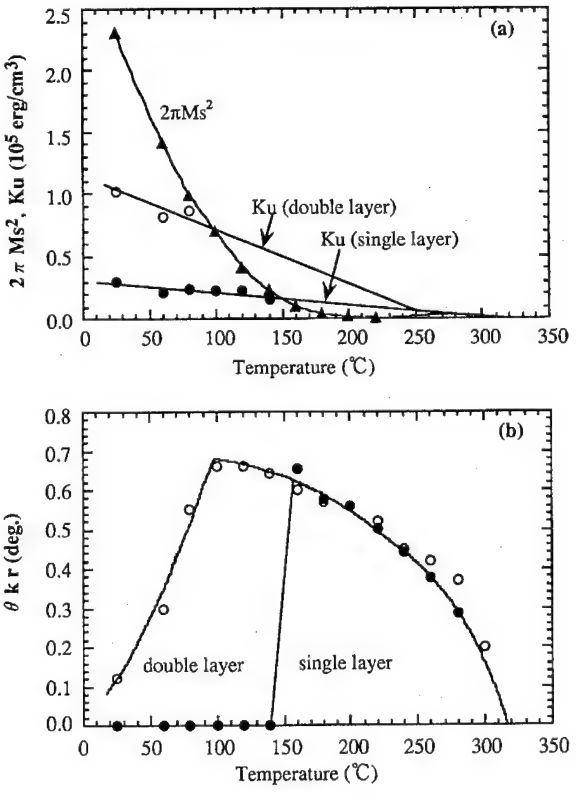

FIG. 1. Temperature dependence of magnetic and magneto-optical properties for single layer $Gd_{28}(Fe_{60}Co_{40})_{72}$ (80 nm) and double layer $Gd_{28}(Fe_{60}Co_{40})_{72}$ (50 nm)/$Tb_{20}(Fe_{80}Co_{20})_{80}$ (30 nm). (a) $2\pi Ms^2$ and Ku for $Gd_{28}(Fe_{60}Co_{40})_{72}$, which has a compensation temperature of 220 °C and Tc of 320 °C. (b) Remanent Kerr rotation θkr.

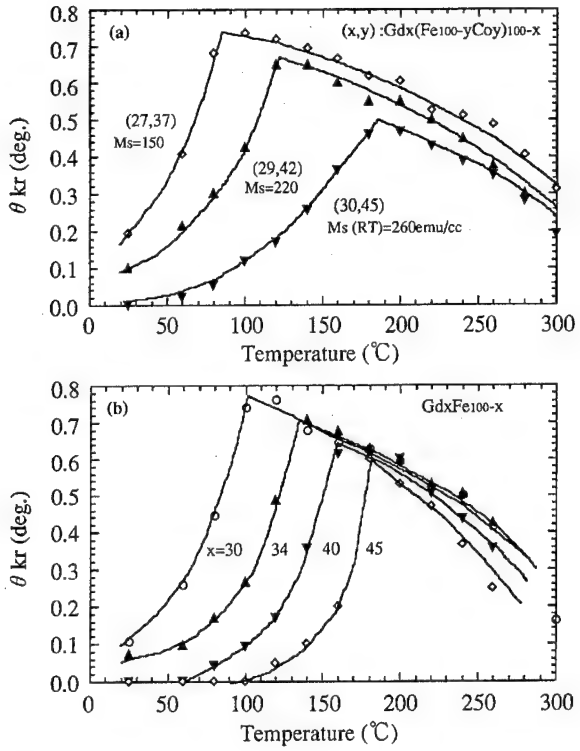

FIG. 2. Temperature dependence of θkr for (a) double layer: $Gd_x(Fe_{100-y}Co_y)_{100-x}$ (50 nm)/$Tb_{20}(Fe_{80}Co_{20})_{80}$ (30 nm), where Tc of the GdFeCo layers was adjusted to 320 °C by controlling Co content and (b) triple layer: $Gd_{28}(Fe_{60}Co_{40})_{72}$ (40 nm)/Gd_xFe_{100-x} (10 nm)/ $Tb_{20}(Fe_{80}Co_{20})_{80}$ (30 nm).

Ku is apparently increased due to the large perpendicular anisotropy of the TbFeCo layer. As a result, the transition occurs at lower temperature [Fig. 1(b)]. It should be noted here that, in double-layer films, the transition does not occur suddenly at a temperature but does occur gradually over a wide range of temperature.

In double-layer films, as the Gd content becomes higher, the transition point shifts to higher temperatures due to larger demagnetizing energy [Fig. 2(a)]. Although θkr at room

temperature (RT) can be made almost zero by increasing the Gd content up to 30 at. %, the transition takes place more gradually and θkr does not reach its saturation value even at 180 °C. This is because, as we will describe in a later section, the interface wall appearing around the boundary between the two layers considerably penetrates into the GdFeCo layer.

For the ideal MSR media, the penetration of the interface wall is not desired and furthermore the transition should occur suddenly at an appropriate temperature. Therefore, we controlled the behavior of the interface wall by inserting an intermediate layer between the readout and memory layers. For high speed recording,[4] the lower part (intermediate layer side) of the GdFeCo layer was removed to maintain the total thickness of magnetic layers constantly. We adopted the intermediate layers of GdFe having a low Curie temperature (T_c) and a large Ms as shown in Fig. 3.

Figure 2(b) shows that the transition temperature in triple-layer films becomes higher as the higher Gd content of the intermediate layer. A more important point is that in the case of higher Gd content, the triple-layer films show a sudden transition, namely, a very steep slope of θkr while attaining zero θkr at RT.

To analyze the effect of the intermediate layer on magnetization transition, we calculated the profile of the magnetization direction using the noncontinuous model.[6] In this model, the total free energy per unit area E is expressed as a function of the magnetization direction $\Phi=(\phi_1,\phi_2,,,\phi_N)$ of N homogeneously magnetized sheets

$$E(\Phi)=\sum_{i=1}^{N-1}\frac{2A_i}{d_i}[1-\cos(\phi_{i+1}-\phi_i)] + \sum_{i=1}^{N}[d_i(Ku_i-2\pi Ms_i^2)\sin^2\phi_i], \quad (2)$$

where A_i is the exchange stiffness of the coupling between the nth and the $(n+1)$th sheet, and d_i and ϕ_i are the sheet thickness (0.5 nm) and angle of the magnetization with respect to the film's normal direction [Fig. 4(a)], respectively. The equilibrium magnetization orientation is obtained by minimizing E with respect to Φ.

Kerr rotation θk can also be obtained by Kerr enhancement calculation with ϕ and refractive index $n^{\pm}$ derived from

$$n^{\pm}(T)=n_0\pm\delta n\times\cos(\phi)\times m^{\mathrm{TM}}(T)/m^{\mathrm{TM}}(\mathrm{RT}), \quad (3)$$

where n_0 is the average of refractive index for right circularly polarized light n^+ and for left circularly polarized light n^-, and δn is the difference between n^+ and n^-, and $m^{\mathrm{TM}}(T)$ and $m^{\mathrm{TM}}(\mathrm{RT})$ are magnitudes of TM magnetic moment at the temperature and RT, respectively.

We applied these micromagnetic calculations to double and triple layer films both of which have almost zero θkr at RT. The calculated results show that the interface wall of the double-layer film significantly penetrates into the GdFeCo layer which has a small effective magnetic anisotropy [Fig. 4(b)]. As the temperature increases, the interface wall spreads into the GdFeCo layer, and as a result, the transition from in-plane to perpendicular magnetization does not occur suddenly.

On the other hand, in the case of triple-layer film, the interface wall is almost confined within the intermediate layer, and the direction of the magnetization in the GdFeCo layer is almost completely in-plane at low temperatures [Fig. 4(c)]. This can be attributed to the strong effective in-plane anisotropy of the intermediate layer. When the temperature is increased, the transition of the GdFeCo layer to perpendicular magnetization occurs very rapidly. This seems to be attributed to the rapid decrease of the effective in-plane anisotropy of the intermediate layer below and near the Curie temperature. Figure 5 shows that the calculation results are in good agreement with experimental results. The triple-layer film is seen to exhibit very rapid transition around 140 °C.

The triple-layer media was confirmed to achieve CN ratio at least 4 dB higher than the double-layer media for a mark length of 0.40 μm using a conventional optical unit with a wavelength of 780 nm and numerical aperture of 0.55.

Transition from in-plane to perpendicular magnetization of GdFeCo layers occurs as a result of the changes in the sign of the effective perpendicular anisotropy. In the triple-layer films, the transition occurs more rapidly than double-layer films. A micromagnetic calculation showed that the interface wall is almost completely confined within the intermediate layer while, in the case of the double-layer films, the wall penetrates into the GdFeCo layer. The triple-layered films make it possible to improve the MSR characteristics.

Magnetic parameter control for high-density quadrivalued MO recording (invited) (abstract)

N. Ohta, K. Shimazaki, M. Yoshihiro, N. Nagai, and S. Ohnuki
Engineering Research Laboratory, Hitachi Maxell Ltd., 6-20-1 Kinunodai, Yawara-mura, Tsukuba-gun, Ibaraki, 300-24 Japan

To increase recording density of MO media, several schemes have been proposed. Among them, magnetic multivalued (MMV) recording is one of the most promising methods. We have first realized the quadrivalued MMV media using a field modulation method.[1] Such media is composed of an exchange coupled TbFeCo/PtCo bilayer. By switching the external field in four levels, the separated signal corresponding to the each field is obtained as a four leveled output. For the acutal device application for high-density and high-speed recording, it is necessary to reduce the external field as small as possible. In the previous experiment, about ±900 Oe was necessary to record the whole levels. For such MMV media, the quadrivalued signal response depends on the magnetic characteristics of the TbFeCo/PtCo bilayer, which is so called dual write state.[1] The higher field level on the MMV media is defined by the threshold field of the dual write state. It is found that the threshold field is controllable to tune the magnetic parameter, especially the exchange coupling force between the TbFeCo and PtCo. As a result, the reduction of the recording field less than 350 Oe is realized on a new media. Using such tuned media, high-density quadrivalued recording is experimentally carried out. [S0021-8979(96)46408-5]

Patterning of glass or plastic substrates in the form of shallow square patches is a promising method of increasing the storage density for magneto-optical disks. The sidewalls of the patches pin the reverse-magnetized domains that develop in these samples. Confinement of domains within the patch boundaries during thermomagnetic recording has also been demonstrated. We have measured polarization conversion of the incident light on the sidewalls of the patches; a method to reduce the amount of such polarization conversion is proposed in this article. © *1996 American Institute of Physics.* [S0021-8979(96)06008-5]

I. INTRODUCTION

To keep pace with present hard magnetic drives, magneto-optical (MO) recording technology must increase recording density to 10 Gb/in.^{2}. Such densities imply recorded domain diameters of the order of 0.25 μm. From a micromagnetic point of view, such domains are stable in the current MO media, which are based on amorphous rare-earth transition metal alloys.[1] The problem is how to write and read back such small domains considering the fact that, even for the blue light, the focused spot at the disk surface is about twice the size of the desired domains. Reading of small marks may be possible with a three-beam scheme[2] in conjunction with partial response signaling.[3] As for writing and erasure, patterning of disk substrates[4,5] promises to confine reverse-magnetized domains within areas that are as small as (or even smaller than) the focused laser spot.

Figure 1 presents the main idea behind the confinement of domains on patterned disks. The circle with a radius of 0.4 μm represents the Airy disk for the laser spot with a wavelength of 400 nm, focused through an objective lens with NA=0.6. The disk substrate is patterned by 0.25×0.25 μm^2 shallow square patches in the form of a checkerboard. When the laser beam is focused at the center of a patch it nucleates a reverse domain which subsequently expands (under the influence of an externally applied magnetic field) towards the patch borders. The sidewalls of the patch prevent the domain wall from crossing the patch boundary. This confinement is caused by the increased coercivity of the MO film at the sidewalls. The increased coercivity is probably rooted in the tilt of the easy axis of magnetization on the sidewalls, as well as in the reduced film thickness there.[6] Thus, this technique should allow the writing of magnetic domains smaller than the laser spot. Another advantage of patterned substrates is that the laser beam does not interfere with previously recorded domains since the patch sidewalls prevent the expansion or contraction of existing domains in the neighborhood of the focused spot.

In this article we provide experimental evidence for the strong pinning of domain walls on the sidewalls of shallow patches. Thermomagnetic recording performed on several patterned samples indicates that recorded domains can form within the confines of patches that have a height (or depth) as low as 10 nm. Scanning optical microscopy has been used to identify the source of noise introduced during readout of patterned samples.

II. EXPERIMENT

Corning 7059 glass substrates were patterned using a photolithographic method.[4] The patterns in the photoresist layer were produced by exposure to optical interference fringes in two orthogonal directions. 2.5×2.5 μm^2, 1×1 μm^2, and 0.5×0.5 μm^2 square patches having height (or depth) of 10, 20, or 30 nm were produced by argon–ion etching through the developed photoresist mask.[7,8] The samples used in our study are listed in Table I. The resulting surface features are shown in two typical atomic force micrographs in Fig. 2. If the exposed photoresist is underdeveloped, wells appear in the photoresist film, which, upon ion etching, are replicated into the glass substrate [see Fig. 2(a)]. On the other hand, if the exposed photoresist is overdeveloped, isolated islands remain on the glass substrate [see Fig. 2(b)]. A thin film stack was subsequently deposited on these substrates as follows: substrate/SiN(10 nm)/TbFeCo(either 25 nm or 50 nm)/SiN(80 nm). The MO layer in this stack was an amorphous Tb-rich TbFeCo film having a saturation moment Ms=190 emu/cm^3 and a coercivity Hc=3 kOe at T=300 K (see Table I).

Figure 3 is a schematic diagram of our custom-built microscope for domain observations, Kerr loop tracing (with a resolution approaching one wavelength of the light), wall motion studies, and scanning optical microscopy. Domain structures were observed in this polarized-light microscope

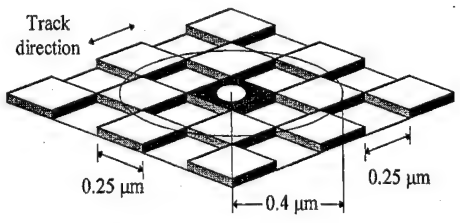

FIG. 1. Schematic diagram showing a checkerboard pattern of 0.25×0.25 μm^2 square patches on a disk substrate. The 0.8 μm diam circle represents the Airy disk of the focused laser spot, produced with a 0.6 NA objective lens at a wavelength of 400 nm. The small white circle in the middle represents a domain nucleus.

TABLE I. Characteristics of the samples used in experiments.

Sample	Patch size (μm^2)	Patch height (nm)	TbFeCo thickness (nm)	Etched areas
A	2.5×2.5	30	50	Low
B	1×1	20	50	Low
C	1×1	10	50	Low and high
D	0.5×0.5	10	25	Low and high

using a 100× oil immersion objective. The observations were recorded with a TV camera and a PC-based frame grabber that allowed image processing for noise reduction.[9] An electromagnet, having a maximum field capability of 9 kOe and a rise time of 50 ms, was mounted under the microscope's XY stage to provide the necessary fields for domain nucleation and wall motion studies, for thermomagnetic recording, and for loop tracing. The microscope was supplemented with a laser diode operating at $\lambda=780$ nm. The laser beam was focused onto the sample by the microscope's objective lens. The reflected beam was picked up by a differential detection module (polarizing-beam splitter and two photodiodes). The difference and sum signals from the detectors were sampled by an A/D board and were sent to the computer for further processing.

For Kerr loop tracing with submicron resolution, the sampling of detector outputs was synchronized with the sweeping magnetic field. For every value of the magnetic field, the differential and sum signals were sampled and an apparent Kerr rotation angle was calculated. (Faraday rotation in the objective lens was taken into account when the final Kerr angle was determined.) Kerr hysteresis loops obtained with this loop tracer will be discussed later in the article.

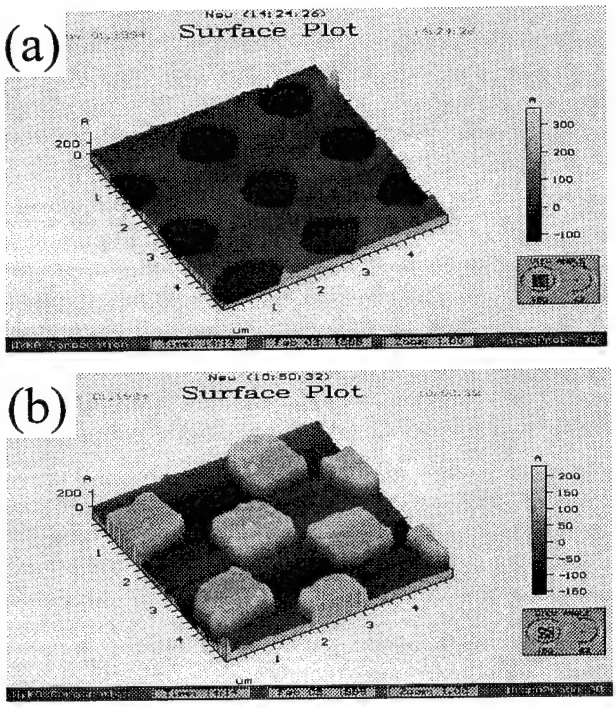

FIG. 2. AFM pictures of 1×1 μm^2 patches on Corning 7059 glass substrates obtained by a photolithographic process and argon–ion milling. (a) Lowered patches having a depth of 10 nm. (b) Raised patches having a height of 20 nm.

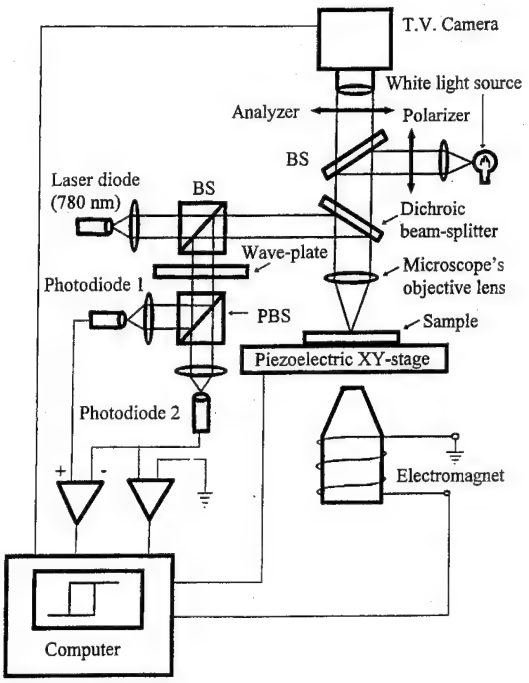

FIG. 3. Experimental setup used in observations of domain nucleation and wall propagation, scanning optical microscopy, and micro-Kerr loop tracing.

To study the peculiarities of domain wall motion with a spatial resolution of better than 50 nm, the magnetic field was brought up to a constant level that allowed a single domain wall to move under the laser spot. The differential output signal was then sampled at equal time intervals (maximum sampling rate=10^5/s) and plotted as a function of time. This method allows observation of small Barkhausen jumps during wall motion.[10]

For scanning optical microscopy, the polarized-light microscope was equipped with a piezo stage. The piezo stage was computer controlled, its steps being synchronized with the sampling instances of the differential and sum signals from the photodetectors. A two-dimensional plot of the sum signal would represent a reflectivity map of the sample. The corresponding plot of the differential signal would yield a map of the polarization rotation angles occurring at the sample's surface.

III. EXPERIMENTAL RESULTS AND DISCUSSION

A. Scanning optical microscopy of patterned samples

Figure 4 shows scanning photomicrographs of patterned samples that were saturated prior to scanning (i.e., there was no magnetic structure within the scanned area). The micrographs were obtained using the differential signal from the detector module. The gray level represents the degree of rotation of polarization. In Figs. 4(a) and 4(b), where the patch size is 2.5×2.5 μm^2 and the patch height is 30 nm (sample A), black corresponds to a minimum rotation of −3.0° and white corresponds to a maximum rotation of +3.0°. Figure

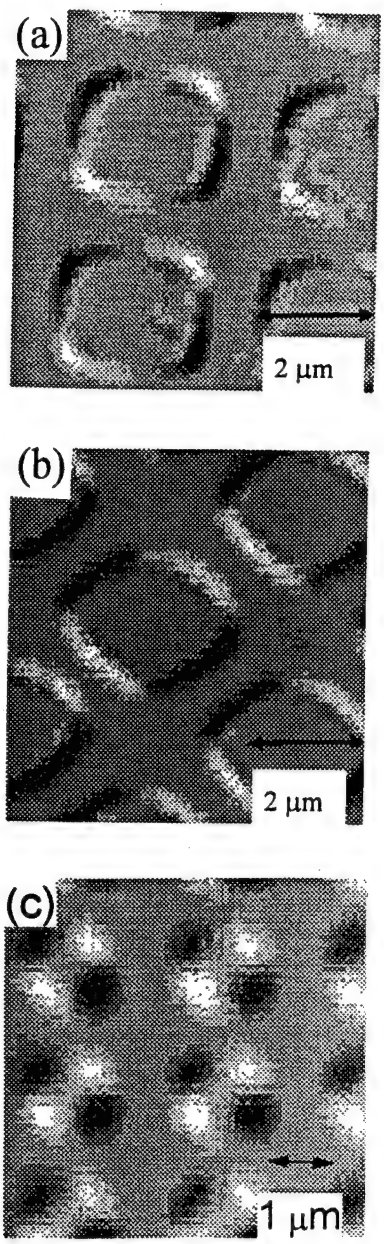

FIG. 4. Scanning photomicrographs of patterned samples. The samples were saturated in a strong magnetic field prior to scanning. The differential signal picked up during scanning (and used to produce these images) was proportional to the angle of rotation of polarization. The incident polarization was linear along the Y axis. (a) 2.5×2.5 μm^2 patches having a height of 30 nm. (b) Same sample as in (a) but rotated 45° around the Z axis. (c) 1×1 μm^2 patches having a height of 10 nm.

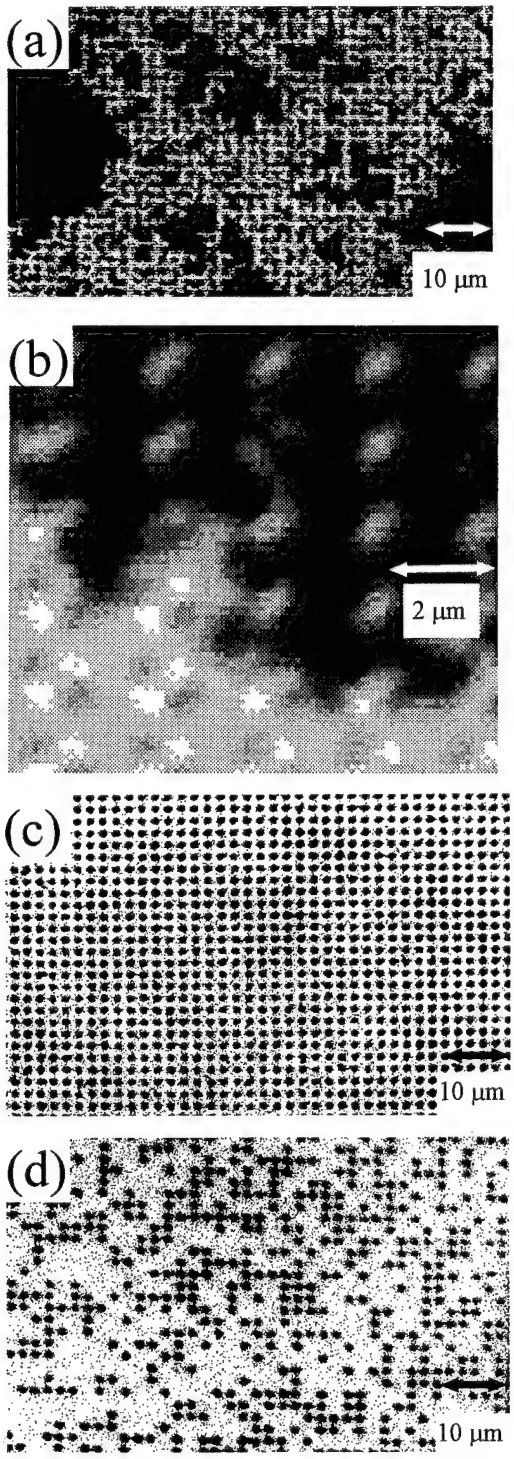

FIG. 5. Domain structure developing under a bias magnetic field in a TbFeCo film on a patterned substrate having 10 nm high, 1×1 μm^2 patches: (a) at $H=2.8$ kOe; (b) scanned photomicrograph showing a close-up of a small region in (a); (c) at $H=3.4$ kOe; (d) at $H=4.5$ kOe.

4(a) indicates that the patch borders cause a fairly significant rotation of polarization. Specifically, the sidewalls of the patches aligned at ±45° to the direction of incident polarization (which is along the Y axis) produce the strongest rotations. If the orientation of the sidewall relative to the incident polarization is +45° (upper left and lower right corners of each patch) the sidewalls produce negative rotation. For −45° orientation (lower left and upper right corners of each patch) the sense of rotation is positive. The observed rotations are caused by different reflectivities for the p and s components of polarization, where s is perpendicular and p is parallel to the sidewall. If the incident polarization happens to be either parallel or perpendicular to the sidewall, then there would be no rotations at all. The patches in Fig. 4(a) are visible in this differential scanning micrograph essentially because they have rounded corners (at ±45° to the incident polarization). If we rotate the sample by 45°, then

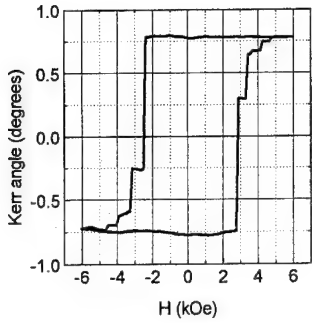

FIG. 6. Micro-Kerr loop measured on the sample of Fig. 5 using a loop tracer with a 2 μm diam focused spot.

the sidewalls themselves become oriented at $\pm 45°$ to the incident polarization, which is the case presented in Fig. 4(b). In Fig. 4(c), where the patches are 1×1 μm^2 and the patch height is only 10 nm (sample C), the minimum rotation angle (black) is $-0.3°$ and the maximum rotation angle (white) is $+0.3°$. The order of magnitude reduction in the polarization rotation angles in the case of Fig. 4(c) as compared to those in Figs. 4(a) and 4(b) indicates that polarization rotation on the sidewalls dramatically decreases with a reduction of the patch height.

B. Magnetic domain structures in patterned samples

Figure 5 shows domain structures developing in the patterned sample C [i.e., the sample with the surface topography of Fig. 2(b)] under a bias magnetic field. At first the magnetic reversal occurs due to nucleation followed by wall motion in the connected areas of the sample, namely in the region between the patches, as shown in the polarized-light micrograph of Fig. 5(a). The scanning optical micrograph of Fig. 5(b) shows how the domain structure bends its way around the patches, leaving behind unreversed islands. In this picture, the advancing domains are black, while the four corners of individual patches appear as two pairs of bright and dark spots. The surviving domains appear as elongated bright spots oriented at 45° to the X axis. This apparent elongation of the domain is an illusion caused by the surrounding pairs of bright and dark spots arising from the patch corners: the dark spots compress the domain image in one direction, while the bright spots stretch it in the perpendicular direction. At a certain magnetic field the entire region in-between the patches becomes saturated, while within the patches magnetization remains unreversed [see Fig. 5(c)]. Apparently, the patch sidewalls prevent domain walls from entering the patches. At higher magnetic fields the domains confined within the patches begin to collapse either by domain wall penetration through the sidewalls or by nucleation of reverse domains from within the patches [see Fig. 5(d)].

Figure 6 shows a micro-Kerr loop, measured in sample C, using a 2 μm diam probe laser beam ($1/e$ intensity radius ≈ 1 μm). The beam covers a region that contains only a few patches (a minimum of one and a maximum of four), thus allowing us to obtain information about individual patch reversals. The sharp drop in the Kerr signal in the vicinity of 2.8 kOe corresponds to magnetization reversal in the connected regions between the patches. The three jumps that follow the first one at magnetic fields between 2.8 and 4.8 kOe correspond to individual reversals within the three patches that are apparently illuminated by the focused beam in this experiment. The different heights of the jumps are due to uneven illumination of the patches.

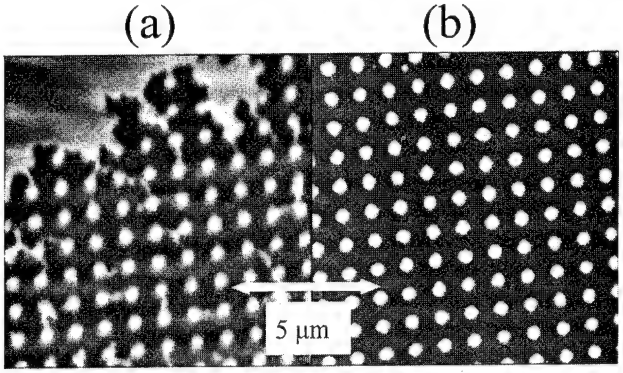

FIG. 7. (a) Magnetic force microscope image of domain structure developing under a bias magnetic field in a TbFeCo film on a patterned substrate having 10 nm high, 0.5×0.5 μm^2 patches. (b) Atomic force micrograph of the same region of the sample.

The domain structure under a bias magnetic field in sample D, which has 0.5×0.5 μm^2 patches, is shown in Fig. 7(a). Since optical microscopy fails to resolve domain features on such a small scale, we employed an atomic force microscope (AFM) and a magnetic force microscope (MFM) for these observations. In Fig. 7(a) the MFM picture shows domains expanding in the connected areas between the patches. [The AFM picture of Fig. 7(b) shows the same region of the sample where the patches are white and the space between them is black.] In a good portion of the MFM picture, the black domain structure has developed in the connected areas of the sample, but it has not penetrated through the patch borders.

Figure 8 shows a micro-Kerr loop, measured for sample D, using a 2 μm diam probe beam. The first jump of the Kerr signal in the vicinity of $H=2.6$ kOe corresponds to fast domain expansion in the connected areas between the patches.

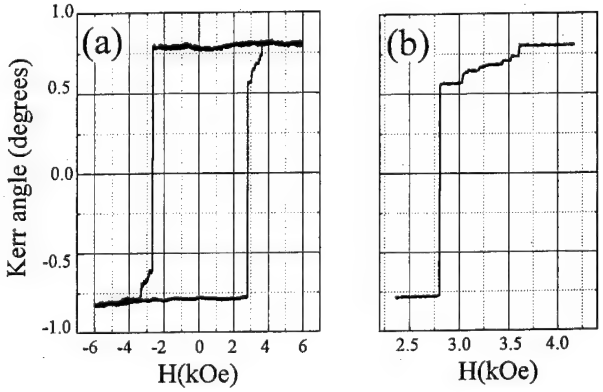

FIG. 8. (a) Micro-Kerr loop measured on the sample of Fig. 7 using a loop tracer with a 2 μm diam focused spot. (b) Enlarged view of the section of the loop between $H=2.5$ and $H=4.0$ kOe.

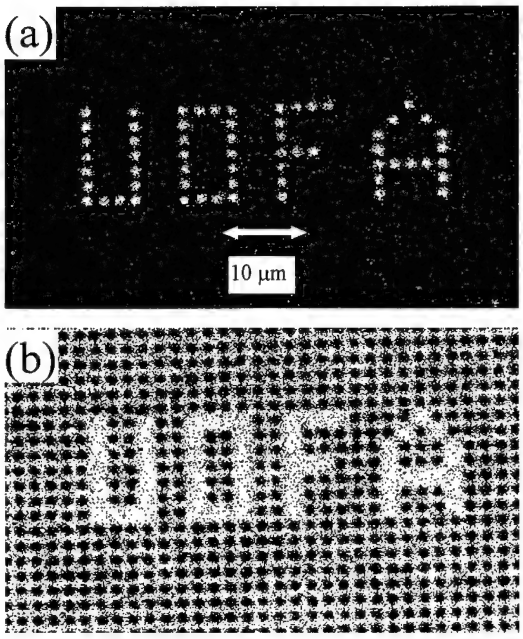

FIG. 9. (a) Domains written on 1×1 μm^2 patches having a height of 20 nm at $H=1.3$ kOe using 200 ns, 10 mW laser pulses. (b) Domains erased at $H=1$ kOe by 200 ns, 10 mW laser pulses from a sample having 10 nm high, 1×1 μm^2 patches.

The next five jumps between $H=2.6$ and $H=3.6$ kOe correspond to individual patch reversals. As before, different magnitudes of the jumps are caused by uneven illumination of the patches within the focused beam.

These observations of magnetization reversal on patterned substrates indicate that the patch sidewalls prevent domain walls from entering the patches. At room temperature the strength of this sidewall pinning varies from a maximum of 1 kOe in the 0.5×0.5 μm^2 patches to a maximum of 2 kOe in the 1×1 μm^2 patches (both patches having a height of 10 nm). This difference may be due to the better quality of the 1×1 μm^2 patches fabricated with our photolithographic process. One conclusion that we may draw from this study is that pinning on the sidewalls should also occur when a domain nucleates inside a patch and proceeds to expand towards the sidewalls. It must therefore be possible to confine such domains within the patch borders.

C. Thermomagnetic recording and erasure experiments on patterned samples

Figure 9 shows results of thermomagnetic recording and erasure on patterned samples. The 780 nm laser beam was directed through a 1.25 NA immersion oil objective onto individual patches and, with the aid of an externally applied magnetic field, effected the writing and/or erasing of domains. The domains in Fig. 9(a) were written inside the patches of the initially saturated sample B under a reverse field of 1.3 kOe using a 10 mW, 200 ns laser pulse. Good confinement of domains within individual patches is observed. In Fig. 9(b), the application of 10 mW, 200 ns laser pulses has produced erasure of selected domains on sample

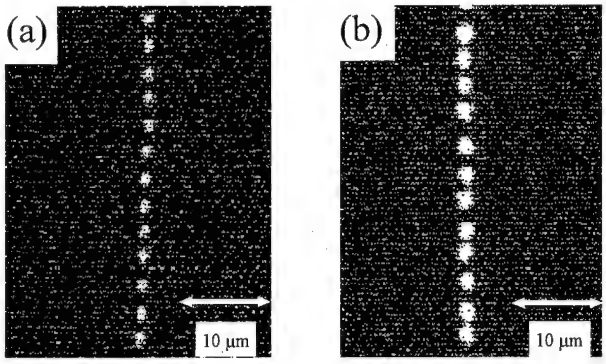

FIG. 10. (a) Domains written on 1×1 μm^2 patches having a height of 20 nm at $H=1.3$ kOe using 200 ns, 10 mW laser pulses. (b) Domains written on a flat area of the same sample under identical recording conditions.

C, which was described earlier in conjunction with Fig. 5; the pattern of domains before erasure of selected patches may be seen in Fig. 5(c).

Figure 10(a) shows domains written on 1×1 μm^2, 20 nm high patches (sample B) under a reverse field of 1.3 kOe, using 10 mW, 200 ns laser pulses. Compare this with Fig.

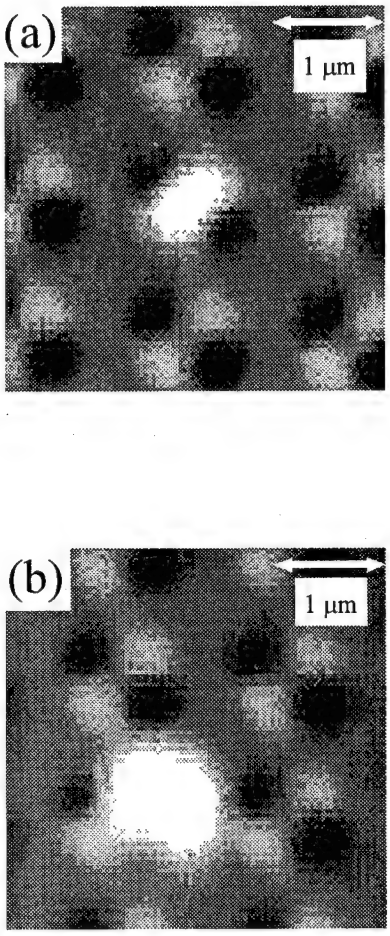

FIG. 11. (a) Scanning photomicrograph of a domain recorded on a 1×1 μm^2 patch. The focused beam was aimed at the center of the patch during recording. (b) Same as (a) but the beam was intentionally offset from the patch center.

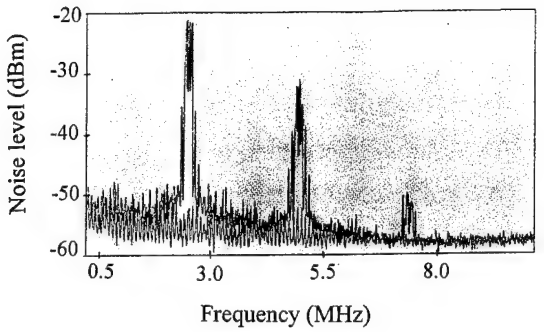

FIG. 12. Noise spectra measured on the flat region (bottom trace) and patterned region (top trace) of the sample having 1×1 μm^2, 10 nm high patches. The sample was fully saturated in a strong magnetic field prior to these measurements. The sample's linear velocity during these measurements was 5 m/s.

10(b), which shows domains written under identical conditions on the flat area outside the patterned region of the same sample. The domains on the flat region are much larger, thus implying confinement on the part of domains written onto the patches.

Figure 11(a) shows a domain written on a 1×1 μm^2 patch on sample C using the same conditions as those described earlier in conjunction with Figs. 9 and 10. This scanning optical micrograph shows that the recorded domain is located symmetrically with respect to the two pairs of bright and dark spots corresponding to the patch corners. The size of the domain is similar to those shown in Fig. 5(b). If we intentionally miss a patch during thermomagnetic writing, as we did in the case of Fig. 11(b), the resulting domain becomes considerably larger, reminding us, once again, of the lack of confinement.

The noise spectrum measured in a dynamic tester[11] on sample C is shown in Fig. 12. The sample was magnetically saturated before the measurement. The peaks at 2.5, 5.0, and 7.5 MHz correspond to the first three harmonics of the 2 μm period pattern at the measurement velocity of 5 m/s. Shown below the spectrum of the patterned region is the noise spectrum obtained from the flat region of the same sample. Note that the additional wideband noise introduced by the patches is about 5 dB. This noise is believed to have arisen from the induced roughness on the substrate by our primitive photolithographic and ion-etching processes. Improvements in the patterning process should reduce this component of the media noise. The various harmonics of the periodic pattern appearing in the differential channel output are caused by polarization rotation at patch corners, as discussed earlier. To prevent the signal of the patches from appearing alongside the MO signal in the differential channel output, one must fabricate perfectly square patches whose sides are aligned strictly parallel and perpendicular to the direction of polarization of the incident beam.

IV. CONCLUSIONS

Kerr loop tracing on micrometer-sized regions and scanning optical microscopy with polarization detection have been employed to study magnetization reversal on patterned substrates. Pinning of domain walls in TbFeCo films by the sidewalls of shallow patches on patterned glass substrates has been demonstrated. Also, thermomagnetically written domains have been shown to be successfully confined within the patches. The angle of rotation of polarization, caused by different reflectivities of the patch corners for p- and s-polarized light was measured, and a method to eliminate this undesirable signal was proposed.

Comparison of the magneto-optical figure of merit of NdFeCo and TbFeCo alloys

W. A. Challener
Basic Materials Laboratory, 3M, St. Paul, Minnesota 55144

Due to the magneto-optical (MO) activity of light rare earths, NdFeCo alloys have been suggested as candidates for use in future high density MO media designed for use at shorter wavelengths. We have measured the MO indices of refraction and computed the maximum Kerr rotation figure of merit as a function of wavelength from 400 to 900 nm for a wide range of NdFeCo and TbFeCo alloys. Only a marginal gain in MO media performance is expected by incorporating NdFeCo into optimized TbFeCo thin film stacks. © *1996 American Institute of Physics.* [S0021-8979(96)10908-5]

INTRODUCTION

Magneto-optic (MO) materials suitable for future high density MO media will be designed for use with shorter wavelength lasers. Rare-earth–transition-metal (RE–TM) alloys in general and TbFeCo in particular have been found quite suitable for use in media designed to operate at red and near-IR wavelengths. These alloys can be tailored to exhibit perpendicular anisotropy, high coercivity, and Curie temperatures that are suitable for the recording powers available with current semiconductor lasers. While the MO signal is not particularly large, an optimized thin film stack typically exhibits about 20% reflectance and 1° Kerr rotation. This together with the amorphous nature of the MO film, which eliminates grain boundary noise, generally provides an excellent signal-to-noise ratio. In addition, TbFeCo can be sputtered from an alloy target, making it more easily manufactured than a nanolayered MO material such as PtCo.

Concern has been expressed in the MO community about ways to increase the MO signal, especially at shorter wavelengths. As a result, a variety of materials[1–5] have been proposed as replacements for TbFeCo, or as "enhancement layers." The latter typically lack certain desirable properties such as perpendicular anisotropy and/or high room temperature coercivity, and so must be laminated with another material like TbFeCo to obtain a suitable recording medium.

An enhanced Kerr rotation has been reported for NdFeCo alloys.[6–10] It was initially suggested that a Nd spin–polarized $4f$ band was within about 2 eV of the Fermi level, closer than that of the heavy rare earths, and could therefore contribute to the increase in Kerr rotation.[7,11] Subsequent electronic structure calculations,[12] however, indicated that transitions from Fe d states at the Fermi level to Nd f states about 3.85 eV above the Fermi level are primarily responsible for the MO activity. This information is not sufficient, however, to determine if NdFeCo alloys can be used in optimized thin film stacks to give a larger signal in MO media than that which can be obtained with TbFeCo alloys.[13] The correct figure of merit (FOM) for comparing different MO materials is not the Kerr rotation of the thick film, but rather the potential Kerr coefficient[14,15] or maximum Kerr rotation.[16] These FOMs can only be calculated by first completely determining the MO refractive indices of the materials. The maximum Kerr rotation FOM is[13]

$$\mathrm{FOM}=\frac{1-R}{2\sqrt{R}}\sqrt{\left(\frac{1}{n^2}+\frac{1}{K^2}\right)(\Delta n^2+\Delta K^2)}, \tag{1}$$

where R is the reflectance of the film stack, and the refractive index of the MO layer is $(n\pm\Delta n)+i(K\pm\Delta K)$ where the "+" and "−" signs refer to right and left circular polarizations, respectively. The potential Kerr coefficient FOM in other publications[14,17] may be directly compared to the maximum Kerr rotation FOM in this article after multiplying by $(360°/2\pi)(1-R/\sqrt{R})=102.5°$ for $R=0.2$.

EXPERIMENT

Samples with a variety of NdFeCo and TbFeCo compositions were dc magnetron sputtered in Ar gas at a pressure of 2.5 mTorr from elemental targets in a vacuum chamber with a base pressure of 1.5×10^{-7} Torr. Silicon wafers and glass microscope slides were used as substrates. They were mounted on a planetary and its speed of revolution could be controlled to obtain either complete mixing or nanolayering. The typical sample consisted of 180–200 Å of SiC, 150–200 Å RE–TM deposited in an alloylike film, and 180–200 Å SiC. Film thicknesses were measured by a stylus profilometer. The SiC was used as an environmental barrier to oxidation of the MO. Separate glass slides of SiC alone were also prepared for optical characterization.

The composition of the samples was measured by XRF on the Si wafers. Reflectance and transmittance measurements were made from both the air-incident and substrate-incident side of the thin films on the glass slides from 400 to 900 nm to determine the average value of the index of refraction.[18] The MO indices of refraction were calculated from polar Kerr rotation and ellipticity, measured from 400 to 900 nm from the air-incident side only to minimize effects of Faraday rotation in the glass substrate. Room temperature magnetization was measured on a vibrating-sample magnetometer.

Three optimized film stacks were also deposited. The first of these was a standard quadrilayer consisting of 60 Å YO_x/200 Å TbFeCoTa/400 Å YO_x/ and 1000 Å AlCr. In the other two film stacks the MO layer was replaced by a trilayer film stack with 50 Å TbFeCoTa on either side of a 100 Å NdFeCo layer to obtain perpendicular anisotropy and 100%

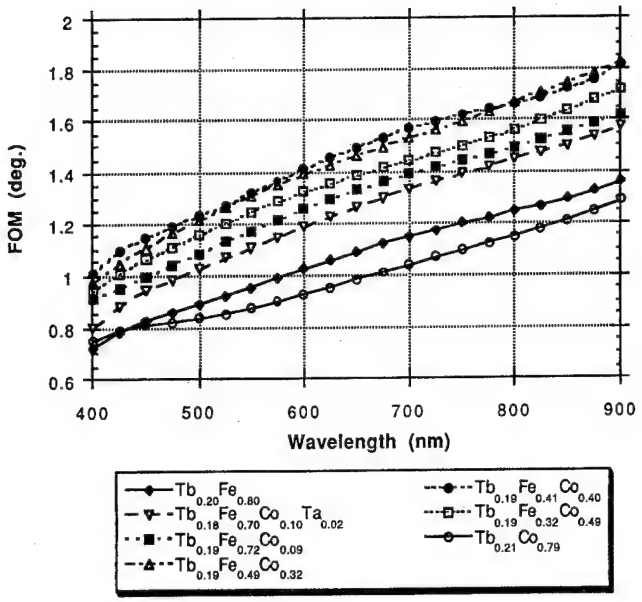

FIG. 1. Figure of merit vs wavelength for various TbFeCo alloys.

remanence for the MO trilayer. For these two film stacks, the NdFeCo layers were deposited in a nanolayered structure to enhance perpendicular anisotropy.[19]

RESULTS AND DISCUSSION

The wavelength dependence of the maximum Kerr rotation FOM for a film stack with 20% reflectance is shown for several $Tb_{0.2}(FeCo)_{0.8}$ alloys in Fig. 1. The standard deviation in the measurements from random error is less than ± 0.05. Systematic error in the film thickness or optical measurements is more difficult to assess, but is probably no larger than the random error. The FOM decreases monotonically with decreasing wavelength, as found previously.[13,17] The maximum FOM occurs for an Fe/Co ratio close to 1, which also corresponds to maximum room temperature magnetization. $Tb_{0.18}Fe_{0.70}Co_{0.10}Ta_{0.02}$, used in current MO media, has a FOM of 0.8° at 400 nm.

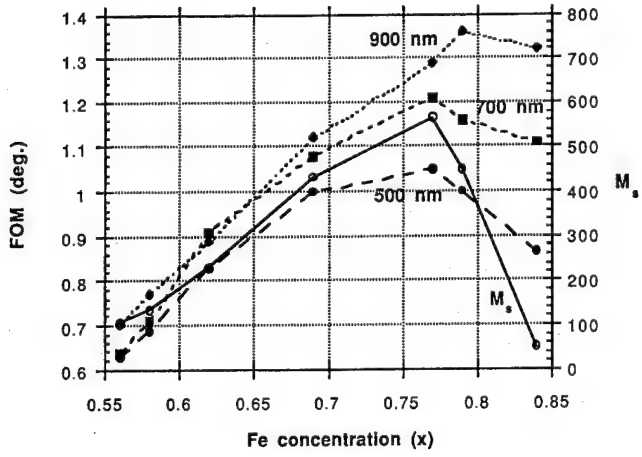

FIG. 2. Figure of merit and M_s vs composition for various $Nd_{1-x}Fe_x$ alloys.

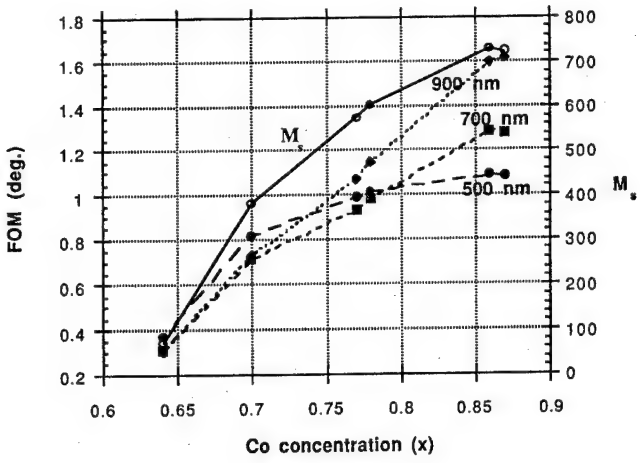

FIG. 3. Figure of merit and M_s vs composition for various $Nd_{1-x}Co_x$ alloys.

The FOM and room temperature M_s for NdFe alloys are graphed as a function of Fe concentration in Fig. 2 and for NdCo alloys as a function of Co concentration in Fig. 3. The FOM for all NdFe and NdCo alloys are generally smaller than that of $Tb_{0.19}Fe_{0.41}Co_{0.40}$ at essentially all wavelengths, although at wavelengths below 550 nm there are NdFe and NdCo compositions with FOMs larger than the standard MO media alloy of TbFeCoTa. The FOM and room temperature magnetization for NdFe are directly correlated and are maximized for Fe concentrations slightly less than 80%. The FOM and room temperature magnetization for NdCo alloys both increase with increasing Co concentration. The Curie points of $Nd_{0.14}Fe_{0.56}$ and $Nd_{0.36}Co_{0.64}$ are only slightly above room temperature, resulting in small FOMs.

FOMs significantly larger than those of TbFeCo can be obtained with NdFeCo alloys. The FOMs versus wavelength for $Nd_{0.2}(FeCo)_{0.8}$ alloys are shown in Fig. 4, and for $Nd(Fe_{0.5}Co_{0.5})$ alloys are shown in Fig. 5. As before, room temperature magnetization is found to be directly correlated with FOM. The FOM for some of these alloys is larger at all

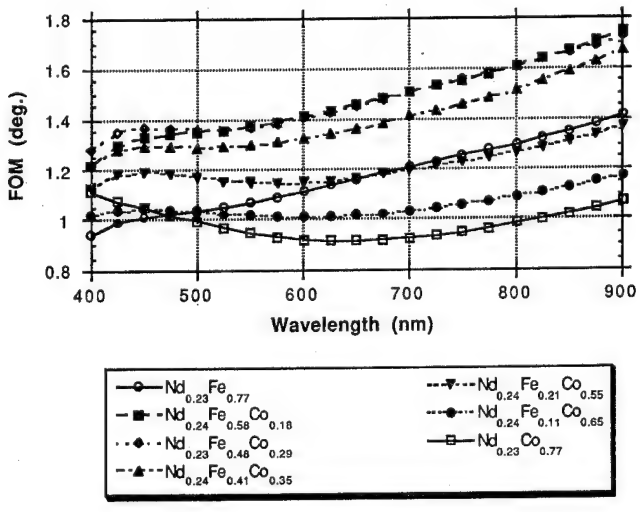

FIG. 4. Figure of merit vs wavelength for various NdFeCo alloys.

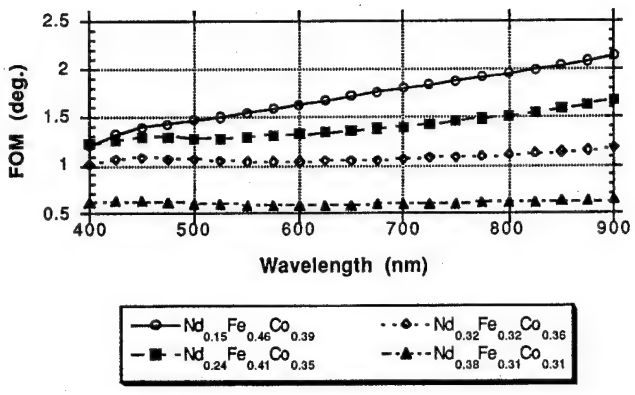

FIG. 5. Figure of merit vs wavelength for various NdFeCo alloys.

visible wavelengths than that of the best TbFeCo alloy. At 515 nm the largest FOM for a NdFeCo alloy is 1.5°, compared to 1.25° for TbFeCo. Alloys with 20% Nd exhibit a peak in the FOM for an Fe/Co ratio of about 2. Alloys with Fe/Co≈1 show a monotonic decrease in FOM with increasing Nd concentration.

Using the measured indices of refraction for TbFeCoTa, a substrate-incident thin film stack optimized for maximum effective Kerr rotation at 515 nm was designed and deposited. It had a total reflectance of 26% (including the 4% front surface reflectance of the glass substrate) and an effective Kerr rotation of 0.75°. The disparity from the predicted value of 1.04° in Fig. 2 is due to three factors. The FOM in Fig. 2 is calculated for a 20% inside surface reflectance, but for this sample the inside surface reflectance is actually 24%, which accounts for a reduction in the FOM of 0.87 according to Eq. (1). Absorption losses in the AlCr reflector account for a reduction of 0.90 and in the dielectric of 0.91 as determined by computer modeling.

Two additional samples were deposited using the same thin film stack design, but in which the center 100 Å of TbFeCoTa was replaced by $Nd_{0.23}Fe_{0.54}Co_{0.23}$ in one case, with a FOM of 1.36° at 515 nm, and $Nd_{0.15}Fe_{0.46}Co_{0.39}$ in the other case with a FOM of 1.47°. The first sample had a measured total reflectance of 26% and an effective Kerr rotation of 0.80° at 515 nm. The FOM for this trilayer stack can be no larger than the simple average of the FOMs of the two alloys, or 1.2° for a 20% reflectance stack. This is 7% larger than the measured value after including the previously discussed correction factors. The second sample had a measured total reflectance of 24% and effective Kerr rotation of 0.94° at 515 nm. In this case, the expected FOM average at 20% reflectance is 1.26°. The reflectance correction factor is 0.94, so the measured value is only 3% smaller than the expected value.

CONCLUSION

TbFeCo has proven over the years to be an excellent MO material for optical recording, and it will require strong incentives to incorporate new materials into future MO thin film stacks. Although it has been suspected that TbFeCo is not capable of providing the MO signal required at shorter wavelengths, the FOM results demonstrate that at 400 nm a fully optimized thin film stack, using the standard TbFeCoTa composition, with 20% reflectance will have an adequate Kerr rotation of 0.8°. Even with a nonideal absorbing dielectric and reflector, a thin film stack with 0.75° effective Kerr rotation and 24% reflectance at 515 nm has been made. From a MO signal standpoint, TbFeCo should be adequate for any future visible wavelength MO media.

Nevertheless, an appropriate choice of NdFeCo alloy will indeed enhance the MO signal for an optimized film stack at all visible and near-IR wavelengths over that obtainable with the standard TbFeCo composition. The main drawback with NdFeCo is that its magnetic properties (anisotropy, coercivity) by itself are not suitable for MO media, and therefore it must be laminated with TbFeCo in order to obtain a suitable thin film stack. Lamination not only increases the complexity of the manufacturing process, but also significantly reduces the enhancement effect. In particular, an optimized MO trilayer stack at 515 nm would exhibit an MO signal increase of only 1.5 dB over that of an optimized TbFeCo film stack.

Effect of sputtering condition on dynamic characteristics and microstructures of magneto-optical 5.25 in. SiN/TbFeCo/SiN/Al disks for 532 nm recording media

M. D. Ro, B. I. Cho, M. J. Kim, S. S. Kim, Y. M. Ahn, K. G. Lee, and B. L. Gill
Optical Storage Media Laboratory, Samsung Advanced Institute of Technology, P.O. Box 111, Suwon 440-600, Korea

A systematic study of the effect of sputtering conditions, for each layer of the magneto-optical SiN 500 Å/TbFeCo 200 Å/SiN 200 Å/Al 600 Å disks, such as power and Ar gas flow rate on the noise levels (NL) and carrier-to-noise ratio (CNR) was performed for the 532 nm high density storage media in this work. The NL dropped to its minimum value of −71.3 dB as the sputtering power for the first SiN increased from 0.5 to 1.5 kW. With a further increase in sputtering power to 2.5 kW, it sharply increased to −64.5 dB. This was ascribed to the smooth and dense surface of the first layer at 1.5 kW, as was observed in the atomic forces microscopy images. The spherical, isotropic, fine grains with a diameter of about 0.2–0.7 μm at 1.5 kW were found, while the longitudinal, directional granular features with a length of 2.5 μm were seen at 2.5 kW. The highest CNR of 46.3 dB was observed at 0.6 kW with a constant sputtering Ar gas flow rate of 25 sccm for the magneto-optical layer. The sputtering conditions for other layers are as follows: 1.5 kW with sputter Ar/N_2 gas flow rate of 30 sccm/11 sccm for the first and third SiN layer, and 0.6 kW with 25 sccm of Ar for the Al reflection layer. This is due to the smooth surface morphologies of the magneto-optical layer at this optimum sputtering pressure, as previously reported in similar research. To obtain a high readout signal, the phase compensation for the elliptic laser beam has been considered. © *1996 American Institute of Physics.* [S0021-8979(96)11008-X]

I. INTRODUCTION

Transition-metal-rich Tb–Fe–Co amorphous thin film alloys have received considerable attention from technological and scientific points of view for the following reasons: (1) the high perpendicular magnetic anisotropy and high coercivity make it possible to greatly enhance areal storage density,[1] compared to that of the longitudinal magnetic recording media; (2) the strong magneto-optical response produces good dynamic characteristics such as high carrier levels. Recently, a comparably increased information storage capacity of the magnetic recording media due to persistent research and development motivated the use of short wavelength lasers for writing and reading in the magneto-optical media.[2–4] However, the readout carrier-to-noise ratio (CNR) is known to decrease due to a deteriorated Kerr rotation angle at the short wavelengths. It has been reported that the static magnetic properties of Tb–Fe–Co thin films are influenced to a large extent by the sputtering parameters of the magneto-optical layer.[5,6] To further explore this possibility and increase the CNR, extensive and systematic research to correlate main sputtering parameters (power and gas flow rate) for the SiN, TbFeCo, Al layers with dynamic characteristics [C.L. noise level (NL), CNR] of 5.25 in. SiN 500 Å/TbFeCo 200 Å/SiN 200 Å/Al600 Å disks for the high density media using a green laser (wavelength, λ=532 nm) was conducted in this work. This study was partially focused on reducing the NL for the maximum CNR by determining optimal sputtering conditions through investigating the relationships between morphology of the first SiN film and the NL. The film structure and surface mophology were examined by transmission electron microscopy and atomic force microscopy, respectively. The dynamic characteristics of the magneto-optical disks using glass substrates with a narrow track pitch of 1.0 μm were measured by an optical pickup system which was made by the authors' institution.[7]

II. EXPERIMENT

The thin film layers consisting of the magneto-optical 5.25 in. SiN 500 Å/TbFeCo 200 Å/SiN 200Å/Al 600 Å disk were magnetron rf-dc sputter side deposited onto the pregrooved photopolymer (2P) glass substrates with a narrow track pitch of 1.0 μm using a continuous in-line sputtering system (model—Balzers SDS-130). The magneto-optical and reflection films were sputtered from hot isostatic pressed $Tb_{20.7}Fe_{71}Co_{8.3}$ alloy and Al targets with a diameter of 8 in. The chemical composition of the magneto-optical films was analyzed with an inductively coupled plasma (ICP) and was almost the same as that of target. A good uniformity of both thin film layer thickness and magneto-optical properties in disks was confirmed. For the dielectric and antioxidation SiN films, an elemental Si target was reactively sputtered with N_2 gas mixed with Ar gas. Sputtering for the first SiN layer was carried out at the different powers. For morphological study, the first SiN films with a thickness of 500 Å were deposited on the rock salt for a transmission electron microscopy (TEM) operating at 300 kV, and were deposited on a Si wafer for a contact-type atomic force microscopy (AFM) with a 4 μm piezo cantilever. The AFM was also used for measuring film thickness. The Kerr rotation angle and coercivity of the four layered films were measured at 532 nm at the room temperature with a Kerr spectrometer. The reflectivity was measured with an UV-VIS scanning spectrophotometer (model UV-2101PC). The dynamic characteristics were measured at the following conditions: constant angular

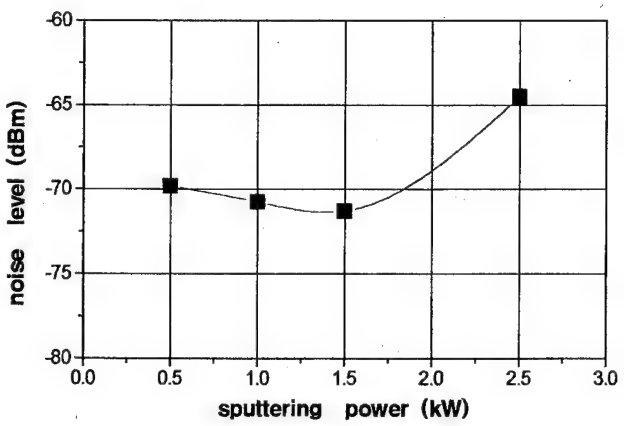

FIG. 1. Noise level of the magneto-optical 5.25 in. SiN 500 Å/TbFeCo 200 Å/SiN 200 Å/Al 600 Å disks as a function of sputtering power for the first SiN thin film layer.

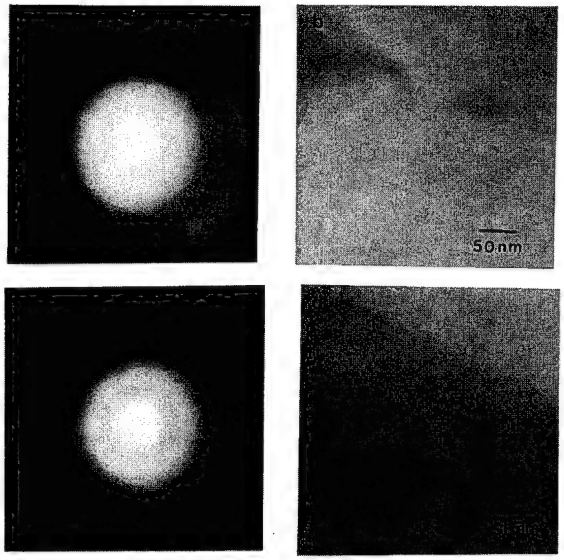

FIG. 2. TEM diffraction patterns and bright field images of the as-deposited SiN films at different sputtering powers: (a), (b) 1.5 kW and (c), (d) 2.5 kW, respectively.

velocity—1800 rpm, frequency—6.27 MHz, writing power ≤4.5 mW, reading power—1.2 mW, erasing power—5.0 mW, and duty—37.5%. For the high information storage density, the mark edge recording method has been adopted.

III. RESULTS AND DISCUSSION

The NL of the magneto-optical 5.25 in. SiN 500 Å/TbFeCo 200 Å/SiN 200 Å/Al 600 Å disks was measured as a function of sputtering power for the first SiN thin film layer and is plotted in Fig. 1. Sputtering conditions for the SiN, TbFeCo, and Al layers are shown in Table I. Experimental results show that variation in the sputtering power resulted in a significant change in the NL, as similarly suggested in previous investigations.[8,9] The NL decreased to its minimum value of −71.3 dB as the sputtering power increased from 0.5 to 1.5 kW. With a further increase in sputtering power to 2.5 kW, it sharply increased to −64.5 dB. Transmission electron microscopy (TEM) diffraction patterns confirmed the typical amorphous structures of the first SiN film as shown in Fig. 2(a) for 1.5 kW and Fig. 2(c) for 2.5 kW, respectively. No big difference in TEM bright field images [Figs. 2(b) and 2(d)] was observed at two different sputtering powers. Considering an important effect of the sputtering power on atomic arrangements in the SiN film surface, a further examination of film surface morphology was conducted with a contact-type AFM. The experimental results showed that the surface consists of spherical, isotropic, fine grains with a diameter of ~0.7 μm when the film with a thickness of 500 Å [Fig. 3(a)] was sputter deposited at 1.5 kW. As the film thickness increased to 2700 Å at the same power level, the structures became dense with fine grains with a diameter of ~0.2 μm as shown in [Fig. 3(b)]. At 2.5 kW, however, the longitudinal, directional, granular features with a length of 2.5 μm were observed for both 500- and 2500-Å-thick films [Figs. 3(c) and 3(d), respectively]. Therefore, it appeared that the desirable lowest NL at 1.5 kW was ascribed to the relatively dense and smooth surface morphologies of the first SiN film layer, compared to those at 2.5 kW. In the second set of experiments, the dynamic characteristics such as CL, NL, and CNR were measured as a function of sputtering power for the $Tb_{20.7}Fe_{71}Co_{8.3}$ film at a constant sputtering Ar gas flow rate of 25 sccm [Fig. 4]. The sputtering conditions for the first and third SiN layer and Al layer are listed in Table II. At 0.6 kW, the maximum CL (−22.2 dB) and minimum NL (−68.5 dB) resulted in the highest CNR of 46.3 dB. Figure 5 also shows the dynamic characteristics of disks as a function of Ar gas flow rate for the magneto-optical layer at 0.6 kW. The same sputtering conditions as in the above experiment were used for the first and third SiN, and Al reflection layers. As the Ar gas flow rate increased from 15 to 25 sccm, the noise level greatly

TABLE I. Sputtering conditions for the third SiN, TbFeCo, and Al film layers with variation in sputtering power for the first SiN layer.

Layer	Sputtering power (kW)	Ar gas flow rate (sccm)
First SiN	0.5–2.5	···
TbFeCo	0.6	25
Third SiN	1.5	···
Al	0.6	25

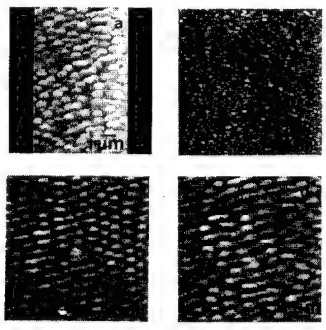

FIG. 3. AFM surface morphologies of the as-deposited first SiN films with variation in sputtering power and film thickness: (a) 1.5 kW, 500 Å, (b) 1.5 kW, 2700 Å, (c) 2.5 kW, 500 Å, and (d) 2.5 kW, 2500 Å.

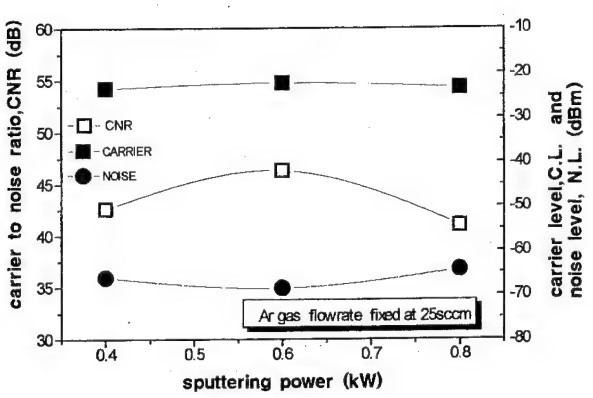

FIG. 4. Dependence of CL, NL, and CNR on the sputtering power for magneto-optical TbFeCo film in SiN 500 Å/TbFeCo 200 Å/SiN 200 Å/Al 600 Å disks at a constant sputtering Ar gas flow rate of 25 sccm. Sputtering powers for the first and third SiN layer were fixed at 1.5 kW with sputter Ar/N_2 gas flow rate of 30 sccm/11 sccm, and for Al layer at 0.6 kW with 25 sccm, respectively.

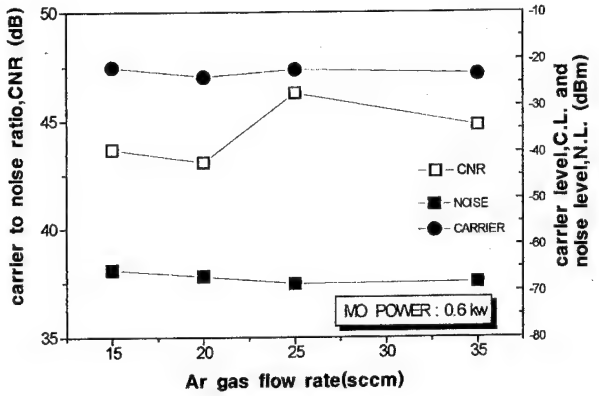

FIG. 5. Dependence of CL, NL, and CNR on the Ar gas flow rate for magneto-optical TbFeCo film in SiN 500 Å/TbFeCo 200 Å/SiN 200 Å/Al 600 Å disks at fixed 0.6 kW. Sputtering conditions for the first and third SiN and Al layer are as same as above in Fig. 4.

improved from −65.5 dB to the lowest value of −68.5 dB. This seems to be attributed to the previous experimental results: The film surface morphologies of the magneto-optical layers were smooth and featureless at an optimum sputtering pressure for the high CNR. However, they were rough at the high pressure because the film contained microvoid-surrounding amorphous structures.[5,6] So far the optimum sputtering conditions for the maximum CNR such as power levels and gas flow rates for the first dielectric, the third antioxidation SiN film layers, and the $Tb_{20.7}Fe_{71}Co_{8.3}$ film have been determined experimentally. Based on these results, the effect of the Al sputtering conditions on CNR of the magneto-optical disks was investigated. The data revealed that the highest CNR of 46.3 dB (=CL −22.2 dB, NL −68.5 dB) was observed at 0.6 kW with 25 sccm. The influence of the sputtering conditions for the Al layer on the CNR was little, compared to that of the sputtering conditions for the SiN layers and magneto-optical layers. The static magneto-optical properties of the four layered SiN/TbFeCo/SiN/Al deposited on the Corning glass under these sputtering conditions were measured at 532 nm by the Kerr spectrometer and are as follows: coercivity—7.63kOe; Kerr rotation angle—0.913°, ellipticity—0.407°, reflectivity—16°–38%.

TABLE II. Sputtering conditions for the first and third SiN and Al film layers with variation in sputtering power for the TbFeCo layer.

Layer	Sputtering power (kW)	Ar gas flow rate (sccm)
First SiN	1.5	···
TbFeCo	0.4–0.8	25
Third SiN	1.5	···
Al	0.6	25

IV. CONCLUSIONS

Based on the experimental results and discussion, it has been concluded that the dynamic characteristics measured at a green laser (λ=532 nm) of the 5.25-in.-diam TbFeCo magneto-optical disks are substantially influenced by the sputtering parameters. Especially, the lowest NL resulting in a CNR as high as 46.3 dB is attributed to the isotropic, fine, spherical grains in the first SiN film deposited at 1.5 kW as evidenced from the surface morphologies of the AFM. The CNR was affected by the sputtering power and Ar gas flow rate for the magneto-optical layer, but it was little dependent on the sputtering power for the reflection Al layer.

Recently, new mechanisms have been proposed to explain the giant enhancements of M-O Kerr effect.[1] In this work, we use magnetic image effect to explain the Kerr angle enhancement of M-O media on Co-base amorphous films. The M-O layer and reflection layer were produced by using conventional dc magnetron sputtering processes. The Kerr hysteresis loops of M-O films were measured with wavelength from 500 to 860 nm, and the peak applied field was 9 kOe. We have studied the enhancements of Kerr angle in TbFeCo amorphous film which sandwiched by AlN layers and backed with Co-base amorphous film. There is a remarkable increase of Kerr angle with value 1.85° at wavelength 640 nm. At wavelength 780 nm, the Kerr angle of magneto-optic medium on Co-base amorphous ribbon has been significantly enhanced by a factor of 3.1 as compared to that on Al foil. Because of its high permeability and low coercivity, the Co-base amorphous film serve as a magnetic shielding material which can induce the magnetic image effect for M-O film. Theoretical calculations show that the Kerr angle can be enhanced by the image magnetic field. The calculated values of Kerr angle are in good agreement with experiment results. An explicit equation to calculate the Kerr angle will be discussed. © *1996 American Institute of Physics.* [S0021-8979(96)80808-4]

A dynamic study of domain formation mechanism during thermomagnetic recording based on micro-Hall effect measurements

Yung-Chieh Hsieh, S. N. Gadetsky, and M. Mansuripur
Optical Sciences Center, University of Arizona, Tucson, Arizona 85721

M. Takahashi
Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo 185, Japan

A method for analyzing the dynamics of domain formation during the thermomagnetic recording process has been developed based on the extraordinary Hall effect.[1,2] A magnetic domain is written at the center of a cross-shaped magneto-optical sample having an area of 5×5 μm^2, and the Hall voltage is monitored during the recording process. As far as domain nucleation is concerned, we find that the temperature gradient around the transition region (i.e., the region whose temperature is between the critical temperature for magnetization reversal and the Curie point) is very important. Under the conditions of high power and short pulse-width laser, a domain can form only during the cooling period. However, it is possible for a domain to form during the heating cycle under a low power, long pulse laser beam. © *1996 American Institute of Physics.* [S0021-8979(96)06108-1]

I. INTRODUCTION

In thermomagnetic recording, a focused laser beam creates a hot spot in a thin magnetic film, thus allowing an external magnetic field to reverse the direction of local magnetization. This is a very complex dynamic phenomenon involving the nucleation of one or more domains, followed by domain expansion and/or contraction.[3] The details of this process depend on the recording conditions and the composition of the recording material. To enhance recording density, one must write domains as small as possible under the constraint of an acceptable signal-to-noise ratio in readout. To achieve this goal, one may reduce the laser wavelength and increase the numerical aperture of the objective lens in order to attain a small, diffraction-limited focused spot. Alternatively, one might strive to develop a technique that allows the writing of small domains even when the focused light spot is not as small. In the latter case, the mechanism of domain formation will have to be better understood, and the most suitable combination of material properties and recording conditions must be adopted. For example, we have observed that under certain conditions the newly formed domains shrink during the cooling cycle. In such cases, the small size of the final domain might be misleading, since it may have damaged an adjacent domain while it was being recorded. Because the existing "static" methods of domain observation and measurement monitor only the final state of a recorded domain, they are incapable of providing insight into problems that are of a "dynamic" nature. On the other hand, dynamic measurement techniques, such as the one described in this article, are quite attractive since they enable the sensing and monitoring of a domain while it is being written.

In this article, we describe a micro-Hall effect measurement scheme for the study of domain formation mechanism. The Hall voltage is proportional to the instantaneous average magnetic moment within the measured area of the sample. By monitoring the Hall signal during thermomagnetic recording, we observe the process of domain formation in real time.

II. EXPERIMENTAL SETUP

A schematic diagram of the experimental setup is shown in Fig. 1(a). The laser beam is focused at the center of the magneto-optical (MO) sample, and a perpendicular magnetic field is applied by a small coil having a diameter of 2 mm. The maximum available field is 750 Oe, which corresponds to a current of 2.5 A through the coil. In order to monitor the variations of Hall voltage caused by the formation of a single domain, a cross-shaped sample, shown in Fig. 1(b), was prepared. The central part of the cross, which has an area of 5×5 μm^2, is made of TbFeCo film. Two different magnetic

films were used in our studies. Sample 1 had a thickness of $\delta=25$ nm, coercivity $H_c \geq 25$ kOe at room temperature, and Curie and compensation point temperatures of $T_c=230$ °C and $T_{comp}=-50$ °C, respectively. Sample 2 had $\delta=100$ nm, $T_c=260$ °C, $T_{comp}=190$ °C, and $H_c=5$ kOe. The results presented in Secs. III A and III B were obtained using sample 1, while those in Sec. III C correspond to sample 2. In both samples, the magnetic film was sandwiched between a 75 nm thick SiN underlayer and a 200 nm thick SiN overlayer. The four aluminum electrodes, having a thickness of 300 nm each, were connected to the four sides of the MO film. The Hall signal was measured using the four-point probe method. The magnitudes of the applied magnetic field H, the laser power P, and the laser pulse duration T were all adjustable. Temporal relations among the magnetic field pulse, the Hall current pulse, and the laser current pulse are shown in Fig. 1(c). The Hall current pulse has been delayed by 800 μs in order to avoid perturbations caused by the induced voltage from the magnetic field pulse.

III. RESULTS AND DISCUSSION

A. Recording with a short laser pulse

Here the laser power $P=8$ MW and its pulse width $T=200$ ns. One set of our measurement results is shown in Fig. 2. In Fig. 2(a) the laser pulse is turned on, but no domain is being formed. For this measurement, we saturate the magnetic moment of the sample in the $+Z$ direction, and maintain a +750 Oe field on the sample in order to prevent domain formation during the experiment. The vertical dash lines in Fig. 2 show the duration of the laser pulse. The laser creates a time-dependent temperature profile in the film. We define the Curie disk as the region where at any given instant of time the temperature is higher than the Curie temperature. In the early stages of heating, the radius of the Curie disk is zero, but once formed, it rapidly increases with time. The Hall signal drops quickly during the heating cycle because the magnetization decreases with the rising of temperature. Once the laser is turned off, the signal gradually returns to its original level. In Fig. 2(b) a domain is being written in the presence of a −300 Oe field. The signal in this case also decreases when the laser is first turned on, but it does not return to the original level since a domain is now formed in the region of the hot spot. The voltage difference between the initial and final levels is proportional to the size of the written domain. Figure 2(c) represents the case of domain rewriting. Following the writing of a domain, we turn on the laser once again with the same power and pulse duration, and without changing the magnetic field. Observe that the initial signal level in Fig. 2(c) is the same as the final level in Fig. 2(b). During the heating period the signal decreases, but it recovers to its original level after cooldown. This indicates that the size of the domain remains the same after rewriting.

Variations of the Hall voltage with time shown in Fig. 2(b) are caused both by the variations of the magnitude of magnetization due to the temperature change, and by the formation of a reverse domain after a certain point in time. To obtain the signal caused by magnetization reversal alone, we subtract the signal in Fig. 2(a) from that in Fig. 2(b) and refer to the difference, shown in Fig. 2(d), as the differential writing signal. This differential Hall signal indicates that the signal arising from domain formation does not have any significant value until after the laser has been turned off. Under these recording conditions, therefore, domain formation must occur during the cooling period. The reason for this behavior may be speculated to be as follows. The temperature of the region in which the domain nucleates should be greater than some critical temperature, T_{crit}, which is a function of the strength of the applied magnetic field H, and is lower than the Curie temperature. We define the region in which the temperature is higher than T_{crit} as the critical disk. By definition, the critical disk is always greater than the Curie disk. A domain can form only in the annular region between the Curie disk and the critical disk. If the temperature gradient is so large that this annular region is narrower than the width of a magnetic domain wall, then no domains can form. In the cooling process, however, temperature gradients are on the decline, and nucleation should occur more readily.

Figure 2(e) shows the difference between the signals in Figs. 2(a) and 2(c). Observe that, in the rewriting process, the signal arising from the reversed domain reaches a minimum and then returns to its initial value. The nonzero value of the minimum signal in this case indicates that a certain part of the domain survives during the heating period.

B. Recording with a long laser pulse

The pulse width T used in this case was 1 μs, and the applied magnetic field H was −450 Oe. Figures 3(a)–3(c) show the differential writing signals during recording experi-

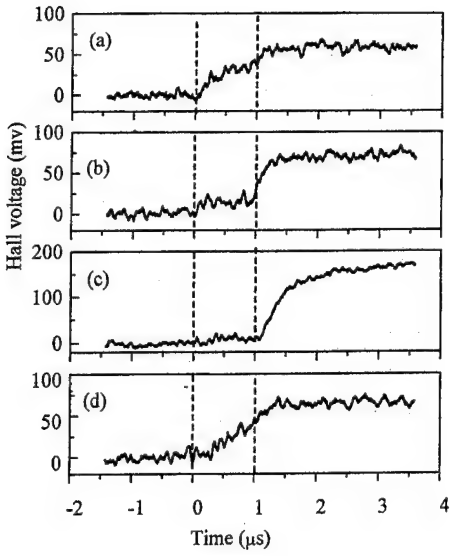

FIG. 3. Differential writing Hall signals for a Fe-rich sample obtained during recording with a $T=1$ μs laser pulse and in the presence of a magnetic field $H=-450$ Oe. (a) $P=1$ MW; the domain is formed early in the heating cycle. (b) $P=2$ MW; the domain signal during the heating period is smaller than that in (a) due to the higher temperature levels. (c) $P=5$ MW; the domain no longer forms during the heating cycle. (d) $P=5$ MW, but the laser is slightly out of focus. In the first 300 ns, no region of the MO film reaches T_{crit}. After that, the critical disk is formed and expands rapidly.

ments corresponding to laser power levels of $p=1$, 2, and 5 MW, respectively. In Fig. 3(a), we observe that a domain forms in the beginning of the heating period and that it continues to grow afterwards. This result can be explained as follows. Because of the low level of laser power being used, it takes the magnetic film a long time to reach the Curie temperature. But, during this period, heat diffusion broadens the temperature profile. The time duration in which the Hall signal increases rapidly corresponds to a rapidly expanding critical disk. In Fig. 3(b) essentially the same phenomena occur, but the signal during the heating cycle is smaller than that in Fig. 3(a). This is due to the fact that the magnetization decreases with a rising temperature. In Fig. 3(c), the domain differential writing signal does not have a significant value before the laser is turned off. This is similar to the behavior described in Sec. III A in conjunction with a short laser pulse. Note in Fig. 3 that the final domain size is increasing with the increase of the laser power. Figure 3(d) shows the Hall signal during writing under the same conditions as in Fig. 3(c) except for a slight defocusing of the laser beam. This figure indicates that the domain has formed during the heating cycle. The reason for this behavior is that, as a result of defocusing, the temperature profile has broadened.

C. Domain size variations during the cooling period

In this section, the Tb-rich samples are measured. As in the preceding experiments, the saturated state of the magnetization is along the $+Z$ direction. Figure 4 shows the differential writing and rewriting signals for two different magnetic fields when the laser pulse width $T=530$ ns and the laser power $P=9.3$ MW. The heavy curves show the differential writing signals, while the light curves are the differential rewriting signals. In both cases, the level of the rewriting signal immediately after heating is greater than its initial level. This indicates that the written domain expands somewhat during rewriting. In Fig. 4(a), where $H=+300$ Oe, the writing signal slowly decreases after reaching a maximum value. The fact that the initial level of the rewriting signal is below the maximum value of the writing signal indicates a shrinkage of the recorded domain during the cooling cycle. In case Fig. 4(b), where $H=+600$ Oe, the domain does not shrink significantly during the cooling phase of the writing process. This is due to the presence of a stronger magnetic field in this case compared to Fig. 4(a). The strong magnetic field in Fig. 4(b) also causes the domain to expand during rewriting.

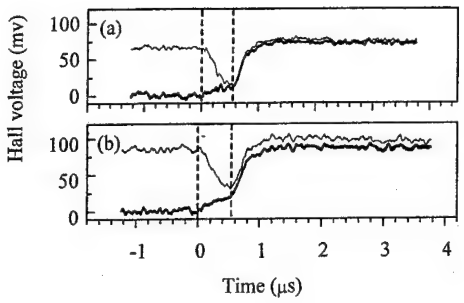

FIG. 4. Differential writing (dark) and rewriting (light) signals for a Tb-rich sample in the presence of two different magnetic fields. (a) With $H=+300$ Oe the domain shrinks somewhat during cooling. (b) With $H=+600$ Oe, the domain does not shrink during writing, but expands during rewriting.

IV. CONCLUDING REMARKS

From the type of measurement described in this article, in addition to the above information, one can reconstruct the temperature profile within the sample by employing the known dependence of magnetization on temperature. This is a helpful step in furthering our understanding of the recording mechanism. We will concentrate on studying the measurements of the thermal constants of MO media in the future.

The rate of domain growth in magneto-optic recording media (abstract)

J. Earl, A. Lyberatos, and R. W. Chantrell
Physics Department, Keele University, Keele, ST5 5BG, United Kingdom

The magnetization reversal in magneto-optic media occurs in general by a process of nucleation followed by domain growth. The rate of domain growth is of importance in thermomagnetic recording. Under steady external field conditions, a slow thermoactivated domain growth is observed[1] and the time dependence curves $M(t)$ are often described[1] using a theory by Fatuzzo.[2] The Fatuzzo theory assumes a constant rate of expansion v of cylindrical domains; however, it does not consider the dispersion in the energy barriers or the formation of dendritic domain structures that may arise, for example, from the spatial and temporal variations of the demagnetizing field. Monte Carlo simulations of domain growth were performed using a model that considers distinct intrinsic energy barriers for nucleation and wall motion and incorporates the contribution of the demagnetizing and domain wall energy in the computation of the energy barriers. The rate of domain expansion, $v = dR_g/dt$, where R_g is the radius of gyration, was found to be constant during the initial stage of the growth process but decreases for large R_g as a result of the reduction in demagnetizing strength. Small fluctuations in v are observed arising from the variation of the domain shape during the growth process. The simulations have also shown that the dependence on the applied field is exponential, $v = v_0 \exp(H/H_f)$, where H_f is the fluctuation field, in good agreement with experiment.[1,3,4] The exponential dependence was found to be valid even in the case of dendritic domain growth, suggesting that the Fatuzzo theory may be useful in the description of the growth of domains of irregular shape. Sensitivity enhancement of Co/Pt superlattices through underlayer composition modification

T. K. Hatwar and C. F. Brucker
Optical Recording Materials Laboratory, Imaging Research and Advanced Development, Eastman Kodak Company, Rochester, New York 14650-2017

Co/Pt superlattice films for magneto-optical recording have a relatively high Curie temperature compared to rare earth-transition metal films, which has led to criticism of their recording sensitivity at higher disk velocities. We have prepared high-performance Co/Pt disk recording media using $(In_2O_3)_{100-x}(SnO_2)_x$ (ITO) as the underlayer. We have observed a two-fold increase in recording sensitivity as x is increased from 0 to 75 mol % SnO_2. We have correlated measured sensitivity behavior with composition-induced changes in the microstructure and electrical resistivity in the ITO underlayer. ITO deposited with low SnO_2 content exhibits crystalline microstructure and low electrical resistivity, whereas ITO deposited with high SnO_2 content exhibits amorphous microstructure and high electrical resistivity. The reduction in crystallinity with increasing SnO_2 content is expected to decrease the ITO thermal conductivity, which can explain the increase in recording sensitivity. Small changes in Co/Pt coercivity as a function of x can easily be compensated by adjusting the ITO sputtering pressure. The optimum combination of Co/Pt sensitivity and coercivity can be readily achieved by controlling the ITO underlayer composition and sputtering pressure. © *1996 American Institute of Physics.* [S0021-8979(96)28308-5]

I. INTRODUCTION

Co/Pt multilayers have been investigated as a future generation magneto-optical (MO) recording media using blue lasers. These films exhibit large perpendicular anisotropy, which depends on the film composition, deposition conditions, quality of the substrate surface, and the underlayer.[1,2] Recently, we have shown that Co/Pt media with high perpendicular anisotropy and high coercivity can be achieved through microstructural modification of the underlayer.[3] A smooth $(In_2O_3)_{100-x}(SnO_2)_x$ (ITO) underlayer deposited at low sputtering pressure results in high squareness and anisotropy of the multilayers. These multilayers also possess a higher Curie temperature than the rare earth-transition metal alloys, resulting in low recording sensitivity (i.e., requires high write power). Higher writing sensitivity is desirable for future generation disk drives to permit higher rotation speed for reduced access time and faster data rate. Also, write/erase cyclability depends on the writing threshold power. Efforts have been made to improve the writing sensitivity of these Co/Pt media by lowering the Curie temperature via adjusting the Co/Pt ratio, and by addition of an element in the Co layer such as Ni or Re, etc.[4,5] However, these approaches reduced the Kerr rotation of the Co/Pt multilayer. We enhanced the sensitivity of the Co/Pt media by modifying the composition of the ITO underlayer, with no degradation in Kerr rotation. In this article, we present both the static and dynamic performance of the Co/Pt multilayer disks using ITO underlayers of varying composition.

II. EXPERIMENT

Co/Pt multilayers were prepared by dc magnetron sputtering Co and Pt targets using Kr gas. ITO films were prepared by dc sputtering homogeneous targets of In_2O_3 and SnO_2. Targets of varying amounts of In_2O_3 and SnO_2 prepared by a hot press method were used to obtain films of various ITO compositions. The deposition pressure for the Co/Pt superlattice was 10 mT Kr, and that for the ITO underlayer was 5 mT Ar+1% O_2. Structural properties of ITO and Co/Pt films were measured by x-ray diffraction. The magnetic and magneto-optic properties were measured with a vibrating sample magnetometer and a polar Kerr loop tracer using a 780 nm wavelength laser. An UV-cured lacquer protective overcoat of 5–10 μm was formed by a spin coating method on the Co/Pt multilayer to improve the mechanical durability of the disk. The dynamic measurements were made using a 780 nm wavelength laser, 0.75 μm mark length, 6.03 m/s disk velocity, 3.87 MHz carrier frequency, 90 ns pulse, 30 kHz bandwidth, 300 Oe bias field, 0–10 mW write power, and 1.5–2.0 mW read power. This mark length and carrier frequency correspond to standard international standard organization (ISO) test conditions for first generation 130 mm MO media, for which a narrow band signal-to-noise ratio of >45 dB is specified. Optimum recording power (ORP) was obtained using 3.5 μm marks, 7 m/s linear velocity, 1 MHz carrier frequency, and 50% duty cycle.

III. RESULTS AND DISCUSSION

The crystallanity of the ITO films was analyzed by x-ray diffraction and found to vary with the composition of the film. Figure 1 shows the x-ray diffraction pattern of the ITO films as a function of SnO_2 content. The In_2O_3 film is found to be crystalline, whereas the SnO_2 film is amorphous. ITO with 10% SnO_2 is crystalline, but less so than the In_2O_3 film. With increasing SnO_2 content, the film becomes less crystalline or becomes amorphouslike. Finally, ITO films with greater than 50% SnO_2 are completely amorphous, similar to SnO_2.

It is known that the coercivity of Co/Pt films depends on the type of underlayer. Previously, underlayers of poly-

 0021-8979/96/79(8)/5704/3/$10.00

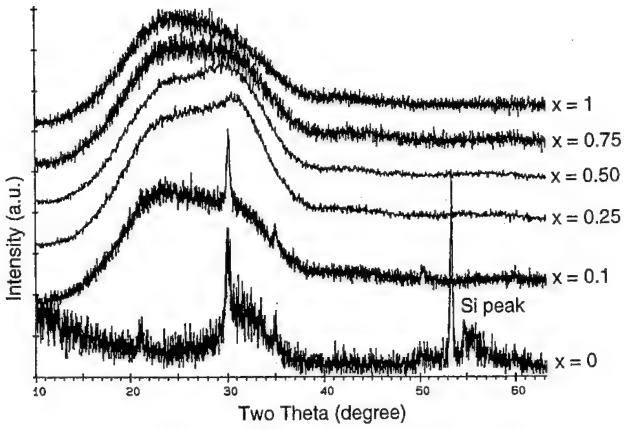

FIG. 1. X-ray diffraction pattern of $(In_2O_3)_{1-x}$ $(SnO_2)_x$ films deposited using Ar+1% O_2 gas. All films were deposited on glass substrates except In_2O_3, which was deposited on a silicon substrate.

crystalline materials, such as ZnO or In_2O_3, were found to be the most effective in enhancing the coercivity (1). The texture and epitaxial growth of the multilayer film was improved. We recently reported that amorphous ITO films also enhance the coercivity, anisotropy, as well as Kerr loop squareness of the Co/Pt superlattice structure. This enhancement depends on the deposition conditions of the ITO underlayer. The coercivity was found to increase monotonically with increasing pressure. For the purpose of comparison here we sputter deposited all the ITO compositions at a fixed pressure of 5 mT Ar+1% O_2. Twelve bilayers of Co 4 Å/Pt 8 Å were deposited on the ITO underlayers deposited on the glass substrate. Figure 2 shows the variation of coercivity as a function of ITO composition. Coercivities on the orders of 2400 Oe were obtained for the ITO films with 10–50 % SnO_2.

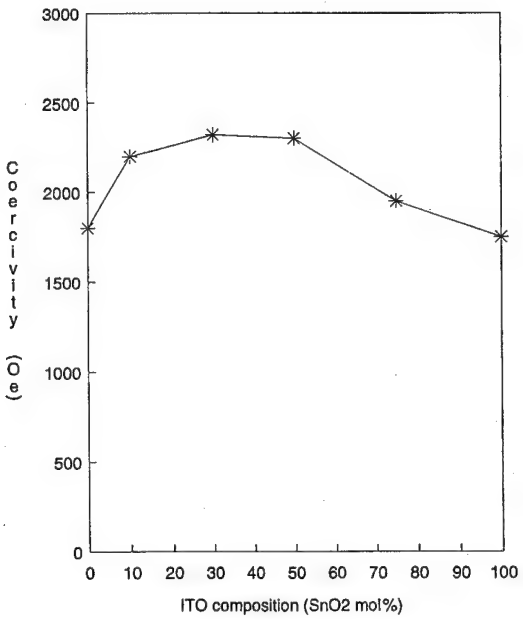

FIG. 2. Variation of coercivity of the Co/Pt multilayer as a function of composition of the ITO underlayer.

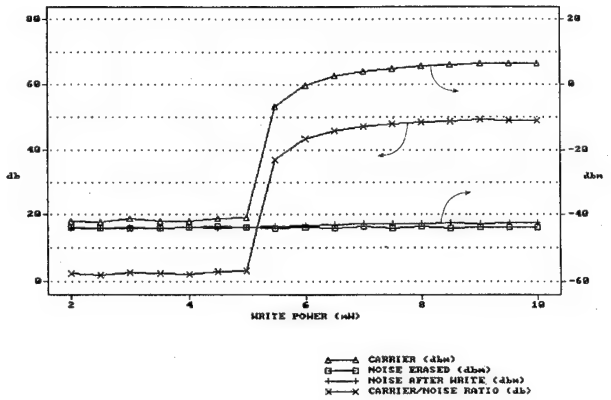

FIG. 3. Recording power dependence of carrier-to-noise ratio using a simple bilayer structure disk with ITO underlayer containing 30% SnO_2. The recording was done at a linear velocity of 5.66 m/s and mark length of 0.75 μm.

Full structure disks were prepared by depositing 12 bilayers of Co 4 Å/Pt 8 Å on 1000 Å ITO underlayers using polycarbonate (PC) and glass substrates. PC substrates with pregrooves of 1.6 μm pitch were used for testing recording properties. All the disks using various ITO compositions exhibited similar carrier levels as well as Kerr rotation, but they were obviously different in the noise level and the writing sensitivity. The disks with crystalline In_2O_3 underlayer were very noisy, whereas the disks with amorphous underlayers showed lower noise. The lower disk noise in the case of amorphous underlayers is attributed to their finer microstructure and smoother surface. Figure 3 shows the dependence of the recording performance on the writing laser power of the disk using ITO underlayer with 30% SnO_2. It shows that a CNR of greater than 48 dB is obtained for a 0.75 μm mark length, exceeding ISO specifications. Also, it is noteworthy that the unwritten and written noise levels are as low as those obtained from conventional rare earth-transition metal alloy disks, such as TbFeCo. Previously, the noise in the Co/Pt disk has been lowered by an additional step of sputter etching the substrate surface.[6,7]

Significant differences are also observed in the writing sensitivity. Figure 4 shows the optimum recording power for these disks as a function of ITO composition. The sensitivity of the disk is much higher for the high SnO_2 content disk. In fact a two-fold increase in recording sensitivity is observed as SnO_2 content is increased from 0 to 75%. This behavior is correlated to the composition-induced changes in the microstructure and thermal conductivity of the ITO underlayer. As noted above, ITO deposited with low SnO_2 content exhibits crystalline microstructure and low electrical resistivity, whereas ITO deposited with high SnO_2 content exhibits amorphous microstructure and high electrical resistivity. The change in resistivity is considerable, e.g., 0.017 Ω cm to 400 Ω cm for ITO with 10% SnO_2 and 50% SnO_2, respectively. The density of conduction electrons is much too low, however, to make any significant contribution to the ITO thermal conductivity. Rather, the ITO should be regarded as an electrical insulator whose lattice thermal conductivity depends primarily on the phonon mean free path. Increased phonon scattering due to irregular crystal structure can dramatically reduce the thermal conductivity coefficient. For ex-

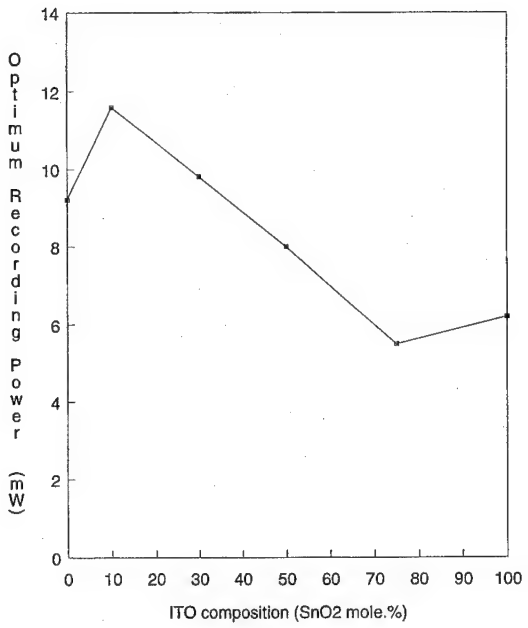

FIG. 4. Variation of the optimum recording power as a function of ITO composition of the underlayer.

ample, the random network of silicon-oxygen bonds in clear, fused quartz glass leads to an eight-fold reduction in thermal conductivity compared to crystalline quartz along the c axis.[8] In general, the thermal conductivity values of amorphous glasses at room temperature run about an order of magnitude below those of crystalline insulators. Although detailed thermal modeling has not been carried out, we note that the thickness of the ITO layer is substantially greater than the thermal diffusion length given the marking time employed in our experiment. The ITO layer thus acts as a "thermal barrier" between the MO layer and the substrate. Thus, we conclude that the reduction in crystallinity with increasing SnO_2 content decreases the ITO thermal conductivity, increasing its effectiveness as a thermal barrier, which results in the increase in recording sensitivity. Acting as it does as a "nucleation layer," the ITO film probably influences the microstructure of the MO layer as we observed in our previous studies.[3] As ITO amorphizes it is likely that the microstructure changes it induces in the MO layer alter the thermal and electrical conductivity of that layer as well.

IV. CONCLUSIONS

In conclusion, we have prepared a high performance Co/Pt multilayer media with high coercivity and high sensitivity. This was achieved by an optimum combination of composition and microstructure of the ITO underlayer. ITO films with higher SnO_2 content are amorphous in structure and appear to have lower thermal conductivity, which results in lower disk noise and higher recording sensitivity.

Magnetic circular dichroism (MCD) in core-level absorption provides insights into the element-specific and site-selective magnetic states of various magnetic materials. Fe_7S_8 and Fe_7Se_8 have the pseudo-NiAs-type crystal structure and are ferrimagnetic below 578 and ~450 K, respectively. We have measured MCD spectra in the Fe $2p$ ($L_{2,3}$) and Fe $3p$ ($M_{2,3}$) core-level absorption of these compounds. The $L_{2,3}$ MCD spectra were taken at ~80 K with the total electron yield method. The $M_{2,3}$ MCD spectra were measured at room temperature with the reflection method using the magnetic-field modulation technique. Both experiments were made using circularly polarized undulator radiation. The $L_{2,3}$ MCD spectra were found to exhibit a negative peak at the L_3 edge with a maximum intensity of $\sim 10^{-2}$ and a weaker positive peak at the L_2 edge. The MCD spectrum of Fe_7S_8 showed sideband features near the L_3 edge. Utilization of the magnetic-field modulation method allowed a detection of small MCD signals around the $M_{2,3}$ edges; the maximum signal intensity was of the order of $\sim 3\times 10^{-3}$. The $M_{2,3}$ MCD spectrum of Fe_7S_8 showed a MCD signal for a prethreshold multiplet, while that of Fe_7Se_8 exhibited no appreciable MCD signal for a prethreshold multiplet. The features observed in the $L_{2,3}$ MCD and $M_{2,3}$ MCD are consistent with an electronic band-structure calculation reported recently.[1]

A Co/Pt multilayer is one of the most attractive candidates for next-generation high-density magneto-optical recording media. With a decreasing Co layer thickness, the direction of the easy axis of magnetization changes from in-plane to out-of-plane. We have measured core-level MCD of Co/Pt multilayers. Six Co/Pt multilayer samples were prepared which had Co layer thicknesses from 3 to 14 Å. The MCD experiments were made using circularly polarized undulator radiation. The spectra were taken separately for the energy regions around the Co $M_{2,3}$ (and Pt O_3) and Pt $N_{6,7}$ (and Pt O_2) edges. The dichroic signals in reflectivity were recorded for two opposite directions of an external magnetic field of 2 T. We have also measured the reflectivity spectra down to 4 eV and have made Kramers–Kronig analyses to obtain the dielectric tensor. The dielectric tensor element which represents absorption MCD shows a dramatic change at the Co $M_{2,3}$ edges. The MCD spectra of thinner Co-layer samples are more asymmetric than those of thicker ones. This shows that the orbital magnetic moment of Co is enhanced as the Co layer thickness decreases. The MCD spectra become sharper and narrower with a decreasing Co layer thickness. This feature strongly reflects a band narrowing of the Co $3d$ state at or around the Co/Pt interfaces. The MCD spectra at the Pt $N_{6,7}$ edges show little dependence on the Co layer thickness. This can be explained by assuming that Pt atoms only at the interfaces are responsible for the MCD signals, since the surface density of Pt atoms is equal for all the samples. Combining the result at the Co $M_{2,3}$ edges with that at the Pt $N_{6,7}$ edges leads to the conclusion that perpendicular magnetic anisotropy mainly depends on the electronic structure of Co at Co/Pt interfaces and that Pt atoms at the interfaces play a partial role in magnetic anisotropy. Mössbauer and x-ray diffraction studies of the phase composition of crystallized $Nd_xFe_{81.5-x}B_{18.5}$ alloys with $7 \leqslant x \leqslant 16$ (abstract)

Zhao-Hua Cheng, Bao-gen Shen, and Jun-Xian Zhang
State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, People's Republic of China

Ming-xi Mao, Ji-jun Sun, Fa-shen Li, and Yi-de Zhang
Department of Physics, Lanzhou University, People's Republic of China

In previous work, the phase composition of melt-spun Nd-Fe-B with a low Nd concentration ($X \leqslant 6$ at. %) have been extensively investigated by means of x-ray diffraction, spin echo nuclear magnetic resonance, and Mössbauer spectra.[1] However, the phase composition of melt-spun Nd-Fe-B with intermediate and high Nd concentration has not been studied by Mössbauer effect. Based on the knowledge of the ^{57}Fe hyperfine parameters for $Nd_2Fe_{14}B$, $Nd_{1.1}Fe_4B_4$ and $Nd_2Fe_{23}B_3$, the phases produced during annealing Nd-Fe-B amorphous alloys can be identified with greater sensitivity by Mössbauer spectroscopy than by x-ray diffraction. In the present work, a combination of x-ray diffraction experiments and Mössbauer spectroscopy has been performed on annealed $Nd_xFe_{81.5}B_{18.5}$ ($7 \leqslant x \leqslant 16$). It is found that the samples with $7 \leqslant x \leqslant 9$ contain $Nd_2Fe_{23}B_3$ metastable phase and $Nd_{1.1}Fe_4B_4$ paramagnetic phase. The body-centered-cubic structure of $Nd_2Fe_{23}B_3$ cannot generate the hard magnetic properties. The samples with $12 \leqslant x \leqslant 16$ consist of $Nd_2Fe_{14}B$ magnetically hard phase and $Nd_{1.1}Fe_4B_4$ paramagnetic phase. The large coercivity for the high Nd content Nd-Fe-B originates from the very fine size of $Nd_2Fe_{14}B$ crystallites below the critical size of single domain particle, which has a pinning domain wall effect. © *1996 American Institute of Physics.* [S0021-8979(96)69708-7]

Slowly cooled $Ni_{0.5}Co_{0.5}Fe_2O_4$ has been investigated over a temperature range from 13 to 880 K using the Mössbauer technique. X-ray diffraction shows that it has an inverse spinel structure and a lattice constant of $a=8.346\pm0.005$ Å. The Mössbauer spectra that are laid less overlapping at low temperature have been fitted with two sextets in the ferrimagnetic state. The iron ions at both A (tetrahedral) and B (octahedral) sites are found to be in ferric high-spin states. Its Néel temperature T_N is found to be 865 ± 3 K. As the temperature increases toward T_N a more overlapping effect of the six-line patterns in A and B sites is observed and interpreted to have originated from different temperature dependencies of the magnetic hyperfine fields at A and B iron sites. Assuming that A–B magnetic interactions are stronger than A–A and B–B interactions, we have calculated the hyperfine fields at the A and B iron sites in ionic distribution $(Fe)_A[Ni_{0.5}Co_{0.5}Fe]_BO_4$ as a function of temperature. The theoretical Mössbauer spectra from the above calculated hyperfine fields are obtained and compared with experimental spectra. © *1996 American Institute of Physics.* [S0021-8979(96)74508-9]

$NiFe_2O_4$ is completely inverse spinel[1,2] and has the ionic distribution $(Fe^{3+})_A[Ni^{2+}Fe^{3+}]_BO_4$, where A and B indicates tetrahedral site and octahedral site in spinel structure, respectively. This was verified by measuring the area ratio $I_A/I_B=1.0$ of the Mössbauer patterns (two well-resolved sextets) corresponding to ^{57}Fe in A and B sites. $CoFe_2O_4$ is not completely inverse, and x-ray and magnetic studies report that the degree of inversion depends on the heat treatment.[3,4] Kim *et al.*[5,6] suggested that the atomic migration (cationic exchange of A and B site in $CoFe_2O_4$ and $Ni_{0.5}Co_{0.5}Fe_2O_4$) results from the area ratio analysis of two overlapped sextets of A and B Mössbauer pattern. This is different from the atomic migration that accompanied by the change of crystal structure.[7]

In this study Mössbauer spectra of $Ni_{0.5}Co_{0.5}Fe_2O_4$ have been collected over a wide temperature range 13–880 K. The subspectrum of A and B site at 13 K is well resolved and the overlapping effect of subspectra increases with increasing temperature. This overlapping effect is interpreted to originate from different temperature dependencies of the magnetic hyperfine fields at A and B site.

The sample $Ni_{0.5}Co_{0.5}Fe_2O_4$ was prepared by grinding together appropriate proportions of ferric oxide, nickel oxide, and cobalt oxide powders of 99.995%, 99.999%, and 99.999% purity, respectively, pressing the resulting mixture into pellets at 6000 kg/cm^2, firing in an evacuated and sealed quartz ampoule at 1000 °C for 3 days, and then slowly cooled to room temperature at a rate of 10 °C/h. The sample was ^{57}Fe enriched to 5 at. % of the metal atoms for Mössbauer measurements.

X-ray diffraction patterns of $Ni_{0.5}Co_{0.5}Fe_2O_4$ showed that the sample had the cubic spinel of a single phase. We could not find out a single diffraction peak of Fe_2O_3, NiO, CoO, Fe, $NiFe_2O_4$, $CoFe_2O_4$, $NiFe_2O_4$, etc. The lattice constant, $a=8.346\pm0.005$ Å, at room temperature was found by using Nelson–Riley function[8] and extrapolating to the backward diffraction ($\theta=90°$).

Mössbauer spectra were recorded using a conventional Mössbauer spectrometer of the electromechanical type with a 10-mCi ^{57}Co source in a Rh matrix.

Figure 1 shows some of the Mössbauer spectra of $Ni_{0.5}Co_{0.5}Fe_2O_4$ below the Néel temperature. The Néel temperature, $T_N=865\pm3$ K, was measured using the thermal scan method. Mössbauer absorption lines are two hyperfine-split sextets and they overlap increasingly with increasing temperature. Two sets of six Lorentzian lines were fitted to the Mössbauer spectra under the valid constraints, which are $\Gamma_j=\Gamma_{7-j}(j=1,2,3)\Gamma_j=\Gamma_{7-j}(j=1,2,3)$ of line-width and $I_j=I_{7-j}$ of intensity with $I_1:I_2:I_3=3:2:1$ when the electric quadrupole interaction is much weaker than the magnetic hyperfine interaction. The solid line on data points is sum of dot lines originated from Fe^{3+} of A and B sites. The results of computer analysis for two well-resolved sextets at low temperatures are presented in Table I.

We neglected the recoil-free fraction for intensity ratios in Table I. These intensity ratios confirm that $Ni_{0.5}Co_{0.5}Fe_2O_4$ is an inverse spinel of the cation distribution

$$(Fe^{3+})_A[Ni^{2+}_{0.5}Co^{2+}_{0.5}Fe^{3+}]_BO_4. \quad (1)$$

The isomer shift values at room temperature for the A and B subspectrum are found to be 0.15 ± 0.01 and 0.26 ± 0.01 mm/s relative to the Fe metal, respectively, which are consistent[1] with the high spin Fe^{3+} state. The smaller value of A site isomer shift is due to a larger covalency at the A site. The ferric character of the Fe ions is also manifested by the magnitudes of the magnetic hyperfine field; the field values at 13 K of the A and B patterns are found to be 511 ± 2 and 553 ± 2 kG, respectively, which are typical values for Fe^{3+} ions.

As can be seen in Fig. 1, the Mössbauer absorption lines overlap increasingly as the temperature approaches the Néel temperature T_N from below. The overlapping of the Mössbauer spectral lines may result from different temperature dependencies of the magnetic hyperfine fields at A and B iron site using the molecular field theory.[9,10]

In the spinel ferrites, the A–B magnetic interactions between the magnetic atoms on the A and B sites are stronger than A–A and B–B interactions.[11] According to the cation distribution Eq. (1), the molecular field acting on A-site

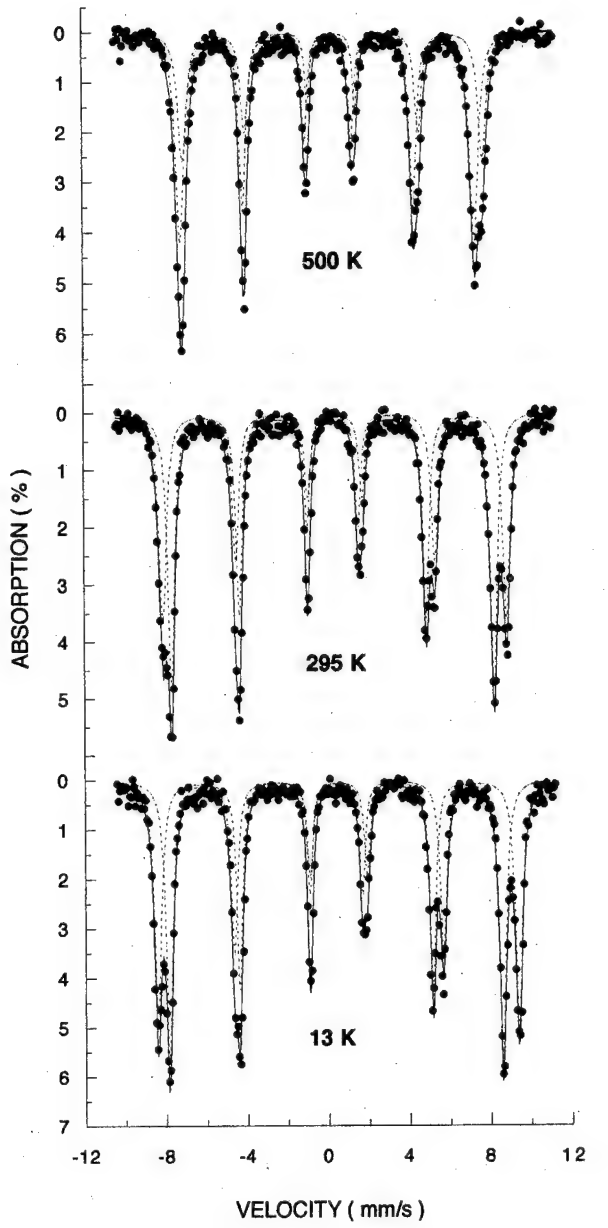

FIG. 1. Mössbauer spectra of $Ni_{0.5}Co_{0.5}Fe_2O_4$ below the Néel temperature.

Fe^{3+} ions with 12 next nearest neighbor B site ions (Ni^{2+}, Co^{2+}, and Fe^{3+}), is approximated by

$$H=-\frac{2}{g\mu_B}J\times 12\times\langle\bar{S}'\rangle. \tag{2}$$

Here, J is an exchange integral between Fe^{3+} and Ni^{2+}, Co^{2+}, or Fe^{3+} ions, μ_B is Bohr magneton, $\langle\bar{S}'\rangle$ is the average value of the B-site ion spin taken over all environments, and $\bar{S}'$ is the average value of S_z' for a particular environment. g is the g factor of an A-site Fe^{3+} ion.

On the other hand, the molecular field acting on B-site Fe^{3+} ions with 6 next nearest neighbor A-site Fe^{3+} ions is approximated by

$$H'=-\frac{2}{g'\mu_B}J\times 6\times\langle\bar{S}\rangle, \tag{3}$$

TABLE I. Magnetic hyperfine field H, electric quadrupole shift ΔE_Q, isomer shift δ, and intensity ratio $R(=I_A/I_B)$ at low temperatures T for $Ni_{0.5}Co_{0.5}Fe_2O_4$. δ is relative to the iron metal.

	H (kG)		ΔE_Q (mm/s)		δ (mm/s)		
T (K)	B	A	B	A	B	A	$R(=I_A/I_B)$
13	553	511	−0.01	0.00	0.37	0.25	1.08
77	552	511	−0.01	0.00	0.37	0.25	1.05
130	549	508	−0.01	0.00	0.35	0.23	1.01
180	545	506	−0.01	0.00	0.33	0.21	1.14
(Error)	±2	±2	±0.01	±0.01	±0.01	±0.01	±0.05

where S stands for the Fe^{3+} spin, and g' is the g factor of B-site ions.

It is true that the approximations given by Eqs. (2) and (3) are somewhat crude, because the exchange integrals are $J_{Fe-Fe}\cong J_{Fe-Ni}\cong J_{Fe-Co}$; the Néel temperature of 858 K[12] for Fe_3O_4 is nearly equal to 862 K[13] for $NiFe_2O_4$ and 870 K[5] for $CoFe_2O_4$. Now the average value of a A-site Fe^{3+} spin S can be written as

$$\langle\bar{S}\rangle=\bar{S}=-SB_S\left(\frac{g\mu_B SH}{k_BT}\right), \tag{4}$$

where $B_S(x)$ is the Brillouin function for a spin S. k_B and T represent the Boltzmann constant and temperature, respectively. Similarly, the average value of a B-site ion spin S' can be written as

$$\langle\bar{S}'\rangle=\bar{S}'=-S'B_{S'}\left(\frac{g'\mu_B S'H'}{k_BT}\right). \tag{5}$$

The magnetic ordering temperature can be easily derived from Eqs. (4) and (5) to be

$$T_N=\frac{2|J|}{3k_B}[S(S+1)S'(S'+1)\times 12\times 6]^{1/2}. \tag{6}$$

Introducing the reduced variables $\sigma=\langle\bar{S}\rangle/S$, $\sigma'=\langle\bar{S}'\rangle/S'$ and $\tau=T/T_N$, Eqs. (4) and (5) are combined to give the equations:

$$\sigma=-B_S\left(12\times a\times\frac{\sigma'}{\tau}\right), \tag{7}$$

$$\sigma'=-B_{S'}\left(6\times a\times\frac{\sigma}{\tau}\right), \tag{8}$$

where a is a constant given by

$$a=\frac{3SS'}{[S(S+1)S'(S'+1)\times 12\times 6]^{1/2}}. \tag{9}$$

For each reduced temperature τ, the reduced spin σ and σ' proportional to the reduced magnetic hyperfine field at the A and B site are calculated numerically by solving Eqs. (7) and (8) simultaneously.

Figure 2 shows that the temperature dependencies of the reduced hyperfine fields at the A and B site in $Ni_{0.5}Co_{0.5}Fe_2O_4$ are different. To compare the temperature dependencies of the hyperfine fields at the A and B site in detail, we put on $H_A(0)=511$ kG for A site and $H_B(0)=553$ kG for B site. Figure 3 presents the magnetic

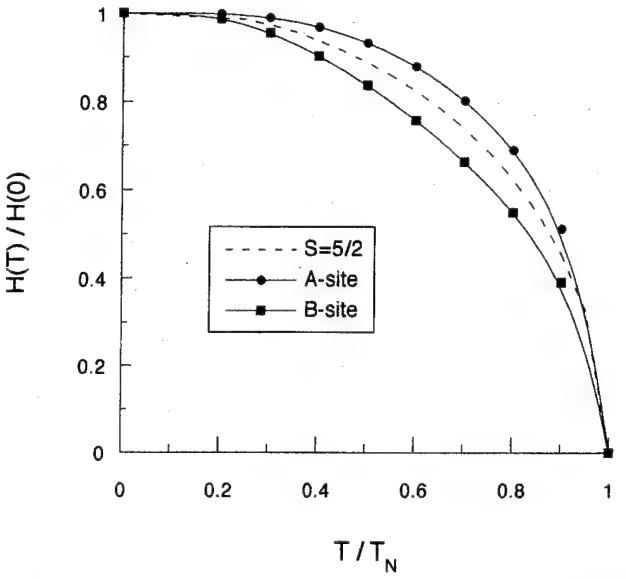

FIG. 2. Reduced hyperfine fields at the A and B site as a function of reduced temperature. The dash line is Brillouin function for spin $S=5/2$.

hyperfine fields at the A and B site as a function of reduced temperature and the hyperfine fields at the A and B site crossing each other.

As can be seen in Fig. 4, we calculated the theoretical Mössbauer spectra at various reduced temperatures using the hyperfine fields of Fig. 3 and line-width=0.38 mm/s, isomer shift=0.25 mm/s for A site and line-width=0.41 mm/s, isomer shift=0.37 mm/s for B site of the 13 K experimental parameters in Fig. 1. The calculated Mössbauer spectra are nearly consistent with those in Fig. 1, but 0.25 T_N (216 K) and 0.35 T_N (303 K) are not in accord with 295 K and 500 K, respectively. We may interpret this discord in the magnetic ions of lowest level by Hund's rule.

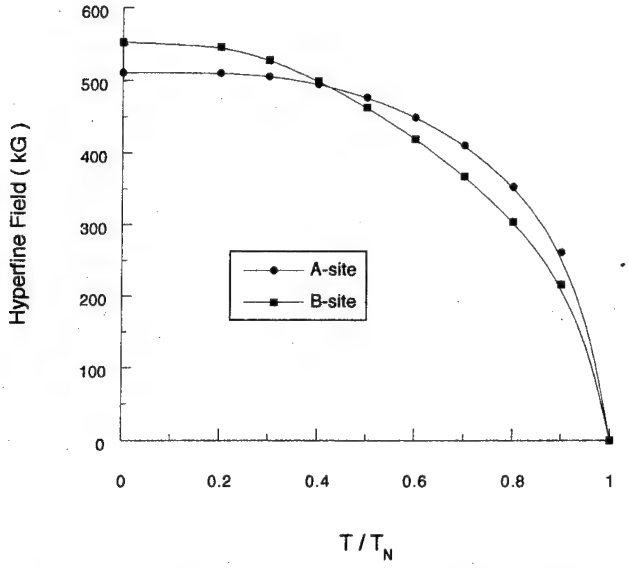

FIG. 3. Magnetic hyperfine fields at the A and B site as a function of reduced temperature.

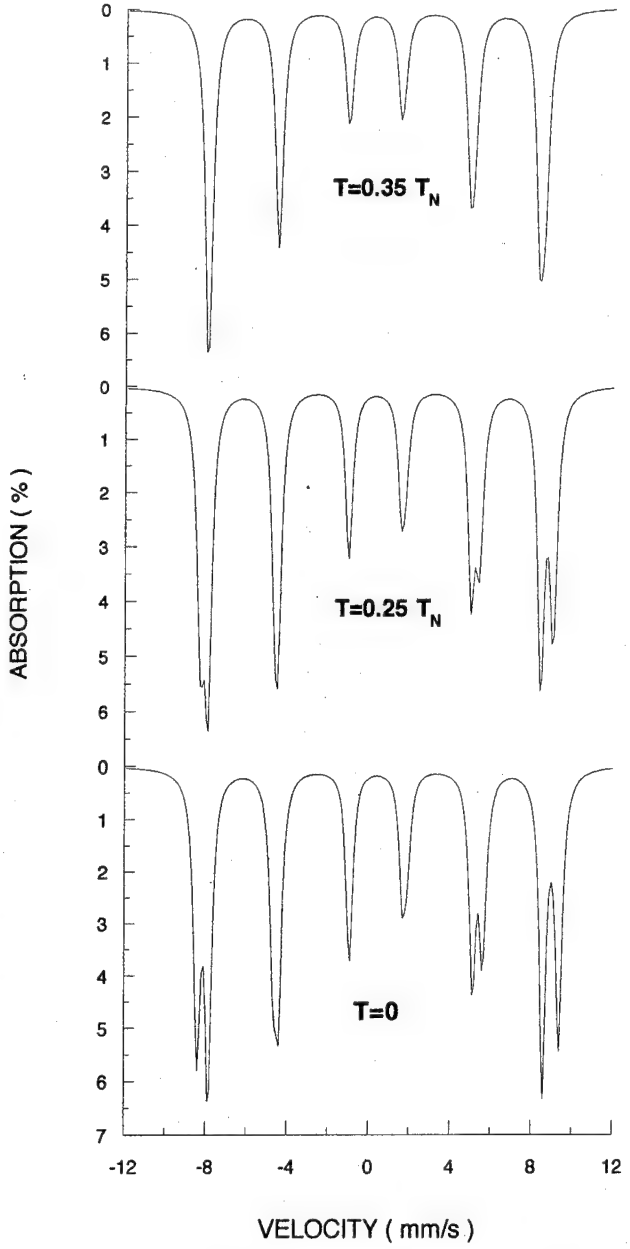

FIG. 4. Mössbauer spectra calculated by the molecular field theory at various reduced temperatures.

A ^{57}Fe Mössbauer study of $Gd_2Fe_{17-x}Ga_xC_2$ (x=0–6) has been carried out in order to reveal the effects of Ga substitution on the Fe-sublattice magnetic properties. We have used a simplified fitting model which uses six broadened sextets in the theoretical fit to the spectra of $Gd_2Fe_{17-x}Ga_xC_2$. Our results suggest that the electronic factor plays an important role in determining the Fe magnetism in the substituted $R_2Fe_{17-x}T_x$ (T=Al,Ga,Si,Ti,...) compounds and their carbides. The average Fe magnetic moment in $Gd_2Fe_{17-x}Ga_xC_2$ varies from $1.99\mu_B$ for x=0 to $0.94\mu_B$ for x=5 at room temperature. Therefore, the optimum substituent concentration would be $1 \leqslant x \leqslant 3$ for the substituted $R_2Fe_{17-x}T_x$ compounds as potential permanent magnet materials. [S0021-8979(96)74608-5]

I. INTRODUCTION

The substitution of Ga for Fe in R_2Fe_{17} (2:17) phase has been shown[1,2] to enhance both the Curie temperature and uniaxial anisotropy of 2:17 phase. In particular, the $Sm_2Fe_{17-y}Ga_y$ compounds exhibit uniaxial anisotropy for y in the range of $1 \leqslant y \leqslant 5$[1] but have a planar anisotropy without the Ga substitution. The Curie temperature shows a maximum at $y \sim 3$, and reaches 635 K. In addition, this substitution facilitates the formation of interstitial carbides $R_2Fe_{17}C_x$ directly by conventional arc-melting[3] with higher carbon content, x, reaching about 2.5 (otherwise it is only about $x \sim 1.0$ without Ga substitution). A uniaxial anisotropy field B_a greater than 9 T at 293 K for $Sm_2Fe_{14}Ga_3C_2$ is observed.[1] Moreover, a room temperature coercivity of $\mu_{0i}H_c$=1.5 T has been obtained in $Sm_2Fe_{14}Ga_3C_{1.5}$ prepared by melt spinning.[4,5] These results suggest that $Sm_2Fe_{14}Ga_3C_x$ might be a possible new material for sintered permanent magnets.

Here we present a ^{57}Fe Mössbauer study of $Gd_2Fe_{17-x}Ga_xC_2$ (x=0–6). The effect of Ga on the magnetism of Fe sublattice will be discussed through the hyperfine parameters obtained.

II. RESULTS AND DISCUSSION

This work is a part of our systematic study of the $R_2Fe_{17-y}Ga_yC_x$ series of compounds. The bulk magnetic properties of $Gd_2Fe_{17-x}Ga_xC_2$ (x=0–6) compounds have been studied in detail previously.[6] The sample preparation techniques are described in Ref. 6. ^{57}Fe Mössbauer spectroscopy was carried out at 293 K in a standard transmission geometry using a ^{57}CoRh source, calibrated with an α-Fe foil.

In order to determine the number of magnetic sextets needed in the theoretical fitting, we need to consider the local environment of each Fe site in the rhombohedral Th_2Zn_{17} structure. There are four Fe sites, namely 6*c*, 9*d*, 18*f*, and 18*h*; the carbon atoms occupy the 9*e* site. Therefore for the case of R_2Fe_{17}, the required number of sextets is four for easy-axis magnetization and seven for easy-plane ordering.[7,8] In the rhombohedral Th_2Zn_{17} structure with the interstitial carbon atoms occupying 9*e* site, both the 18*f* and 18*h* Fe sites have one neighboring carbon atom. Thus, the introduction of the carbon atoms splits further each of the 18*f* and 18*h* sites' spectra into two subspectra. Since all $Gd_2Fe_{17-x}Ga_xC_2$ compounds have a planar easy magnetization direction, the total of number of sextets needed is eleven for fitting the spectra of $Gd_2Fe_{17}C_2$. Introduction of Ga atom further complicates the situation due to preferential site occupation of the Ga atoms. Previous neutron diffraction[9–11] and ^{57}Fe Mössbauer studies[12–14] on $R_2Fe_{17-y}Ga_y$ suggest that the Ga atoms preferentially occupy mainly the 18*h* site of the Th_2Zn_{17} structure when $x \leqslant 4$ and occupy the 18*h*, 18*f*,

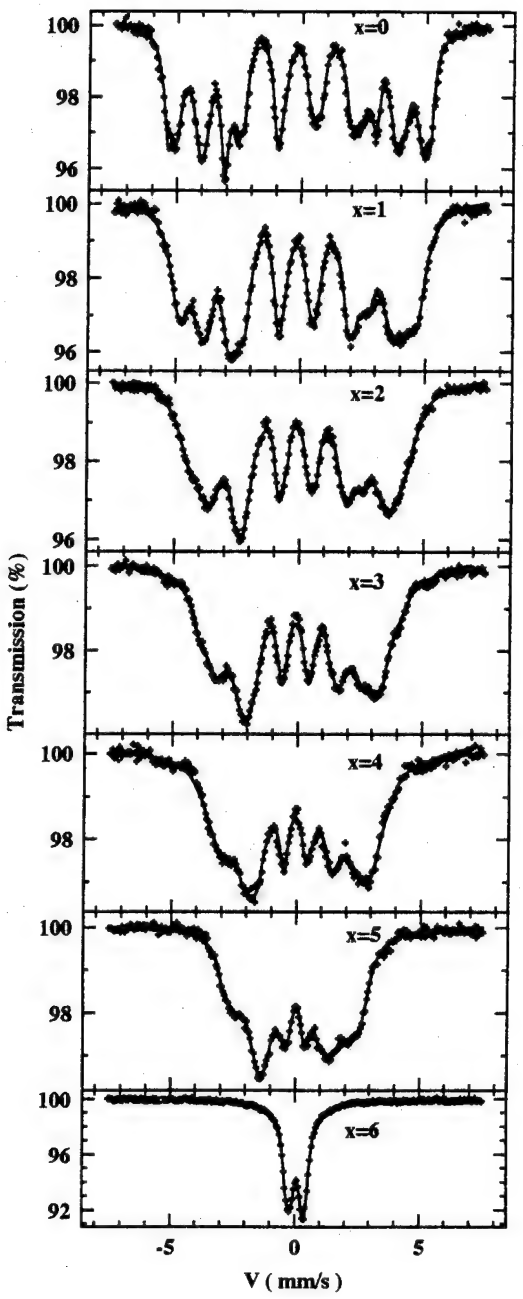

FIG. 1. The Mössbauer spectra of $Gd_2Fe_{17-x}Ga_xC_2$ (x=0−6) at room temperature with the fits shown as full curves.

TABLE I. Hyperfine parameters: isomer shift (IS), quadrupole splitting (QS), hyperfine field ($\mu_0 H_{hf}$) and relative area (I), deduced from the theoretical fits to the Mössbauer spectrum of $Gd_2Fe_{15}Ga_2C_2$ at room temperature.

Site	IS (mm/s)	QS (mm/s)	$\mu_0 H_{hf}$ (T)	I (%)
6*c*	−0.01(3)	−0.01(5)	27.8(2)	18(5)
9*d*	−0.18	0.28	25.5	14
18*f*	−0.17	0.05	22.6	23
	−0.13	0.41	19.4	14
18*h*	0.16	0.02	22.7	19
	0.17	0.20	16.8	12

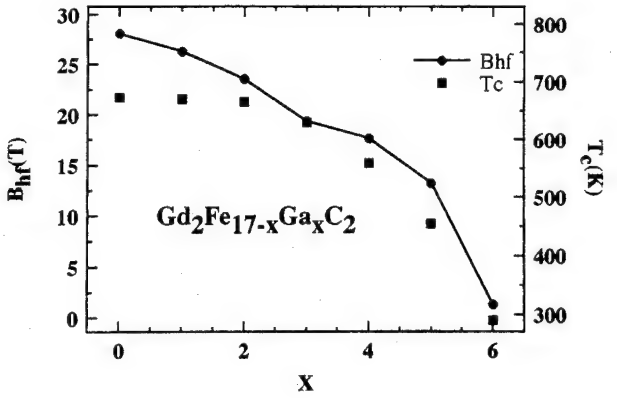

FIG. 2. Ga concentration dependence of average hyperfine field of $Gd_2Fe_{17-x}Ga_xC_2$ (x=0−6) at room temperature.

and 6*c* sites for $x>4$. The number of sextets thus needed is more than twenty if we intend to analyze the experimental spectra of $Gd_2Fe_{17-y}Ga_y$ in terms of an exact binomial distribution of the nearest-neighbor Ga environments. From the point of view of fitting the spectra, this is an unmanageable situation; some simplification must be introduced. Therefore, we have used a simplified fitting model[13] using six broadened sextets in the theoretical fit to the spectra of $Gd_2Fe_{17-y}Ga_yC_2$ compounds which ignores the local Ga and C environment of each Fe site. For $Gd_2Fe_{11}Ga_6C_2$ only one doublet is needed since it is paramagnetic at room temperature. This model reproduces the experimental absorption well, but some problems are found with the relative intensities.[15]

Figure 1 shows the Mössbauer spectra of $Gd_2Fe_{17-x}Ga_xC_2$ (x=0−6) collected at room temperature, together with the theoretical fits shown as solid lines. It is clear from this figure that the theoretical fits are satisfactory. Table I gives the hyperfine parameters resulting from the fits to the Mössbauer spectrum of $Gd_2Fe_{15}Ga_2C_2$ as a typical example of the $Gd_2Fe_{17-y}Ga_yC_2$ series. These results indicate that the Ga atoms preferentially occupy the 18*h* site as revealed by above mentioned Neutron diffraction studies[9–11] and ^{57}Fe Mössbauer studies.[12–14]

The average hyperfine field $\langle B_{hf} \rangle$ as a function of Ga concentration is shown in Fig. 2. It can be seen that the $\langle B_{hf} \rangle$ decreases with Ga concentration which corresponds mainly to the decrease of the Curie temperature due to the Ga substitution (also shown in Fig. 2 for comparison). Of particular interest is the hyperfine field behavior at low Ga concentrations (there is a kink for $x\sim3$) where the field increases with decreasing x while the Curie temperature remains essentially constant. This observation suggests that electron transfer effects between the Fe and Ga are important in determining the Fe magnetism in these compounds. In fact, recent theoretical studies[16,17] suggest that the enhancement of Curie temperature observed in the $R_2Fe_{17-x}T_x$ systems by any substituent, T=Al,Ga,Si,Ti... is attributed to be electronically in origin other than due to the simple volume expansion effect. The effect of the substitution is to fill out

the Fe 3*d* spin-up subband and the substituted compound thus becomes a strong magnet.[18]

Finally, using a conversion factor of 14.1 T/μ_B for 2:17 carbides,[19] the average Fe atomic magnetic moment in $Gd_2Fe_{17-x}Ga_xC_2$ varies from 1.99μ_B (x=0) to 0.94μ_B (x=5) at room temperature. Therefore, only those compounds with the low substituent concentration (x<3) have useful magnetization as potential permanent magnet materials.

III. CONCLUSION

Our present ^{57}Fe Mössbauer study on $Gd_2Fe_{17-x}Ga_xC_2$ (x=0−6) compounds suggests that the electronic factor plays an important role in determining the Fe sublattice magnetism in the substituted $R_2Fe_{17-x}T_x$ (T=Al,Ga,Si,Ti...) compounds and their carbides. The observed kink at $x\sim3$ in the Ga concentration dependence average hyperfine field indicates that there exist electron transfer effects between the Fe and Ga. The optimum substituent concentration would be $1\leqslant x\leqslant 3$ for the substituted $R_2Fe_{17-x}T_x$ compounds as potential permanent magnet materials.

The low-temperature rate of electron capture beta decay in magnetic materials

L. M. Folan, V. I. Tsifrinovich, and V. A. Sheverev
Department of Applied Mathematics and Physics, Polytechnic University, 6 Metrotech Center, Brooklyn, New York 11201

Electron capture β-decay in $^{54}Mn^{2+}$ ions in solids is analyzed. It is shown that the decay rate of $^{54}Mn^{2+}$ should decrease significantly at low temperatures, approaching a limit of 35% of its room temperature value. It is also shown that the decay rate at low temperatures can be manipulated using resonant electromagnetic fields and the rate can be modulated by a factor of four. Extension to other species is suggested and potential applications are described. © *1996 American Institute of Physics.* [S0021-8979(96)74708-2]

It was pointed out recently that the rate of electron capture beta decay of paramagnetic atoms and ions, confined in atom and ion traps, can be effectively controlled when their temperature is comparable to the hyperfine splitting of the ground state.[1,2] This provides opportunities to create modulated gamma ray and neutrino sources and for the development of new probes of both nuclear decay and hyperfine transitions. In this paper we show that the possibility exists to observe similar phenomenon for dilute magnetic impurities in solids, in the presence of an external magnetic field. The control of a nuclear decay in solids has many more potential applications than trapped atoms or ions because of the large density of radioactive nuclei achievable in solids and the ability to exploit long-lived isotopes.

As a simple example, for both theoretical analysis and experimental verification, we will consider divalent ^{54}Mn ions in a diamagnetic host. We will show that the decay rate of $^{54}Mn^{2+}$ depends significantly on the populations of the hyperfine levels of the system and consequently the decay rate can be manipulated using temperature or resonant electromagnetic fields. ^{54}Mn has spin $I=3$ and magnetic moment $\mu=+3.28$[3,4] The disintegration scheme is extremely simple, ^{54}Mn decays by electron capture to the first excited state of the stable isotope ^{54}Cr:

$$^{54}_{25}\mathrm{Mn}+e^{-}\rightarrow{}^{54}_{24}\mathrm{Cr}^{*}+\nu, \tag{1}$$

where ν denotes a neutrino, and no other decay branches have been detected.[5] The daughter nuclear state has spin $I=2$ and the same (positive) parity as the parent. Such a transition is caused by the Gamow–Teller interaction, which changes the nuclear spin by one unit but preserves the parity of the nucleus.[6,7]

In divalent manganese ions the $3d$-electron shell is half filled with electrons. The ground state has electronic spin $S=5/2$ and no net orbital angular momentum. The hyperfine fields at the nuclei of these ions have been extensively studied.[8] The fields are caused mainly by exchange polarization of the internal s-shells. In particular, according to spin-polarized Hartree–Fock calculations,[9] the $1s$-shell gives a contribution of -3 T, the $2s$-shell gives -141 T and the $3s$-shell yields $+74$ T. The resultant field of -70 T is close to the value -65 T derived from the analysis of experimental data.[10] The negative sign means that the hyperfine field is oriented opposite to the electronic magnetic moment.

Consider a sample of divalent manganese ions in a diamagnetic solid and assume the $^{54}Mn^{2+}$ ions are very dilute, so that dipolar and exchange interactions between them can be ignored. In the presence of an external magnetic field $\mathbf{H}$, the electronic magnetic moment in the ground Zeeman state is oriented along $\mathbf{H}$. Because the electron gyromagnetic ratio is negative, the electronic spin direction is opposite $\mathbf{H}$. The first (lowest) hyperfine level of the ground state has the nuclear magnetic moment $\boldsymbol{\mu}$ oriented in the direction of the hyperfine field $\mathbf{H_n}$, i.e., opposite $\mathbf{H}$ (we assume $H<H_n$). Because the ^{54}Mn gyromagnetic ratio is positive, the nuclear spin has the same direction as $\boldsymbol{\mu}$.

Let the $+z$-axis be oriented in the direction of the external field $\mathbf{H}$. Then the z-projection of the total angular momentum of the system F_z is a conserved quantity. There are seven hyperfine levels in the ground Zeeman state of the $^{54}Mn^{2+}$ ion, having F_z values from $-11/2$ to $+1/2$. The first hyperfine level $F_z=-11/2$ corresponds to the state

$$|S_z,I_z\rangle=|-5/2,-3\rangle. \tag{2}$$

The second level $F_z=-9/2$ is approximately $|-5/2,-2\rangle$ (we assume, as usual, that the Zeeman splitting for the electronic system is large compared to the hyperfine splitting, and therefore the admixture of the state $|-3/2,-3\rangle$ with the same value F_z is small). The remaining levels follow appropriately.

Following a nuclear decay, one has a ^{54}Cr nucleus with spin $I'=2$ (primed quantities refer to final states), a neutrino with spin 1/2 and an electronic system with total spin $S'=2$ or $S=3'$, corresponding to the capture of an s-electron with spin parallel or antiparallel to the electronic spin of the parent ion. The lowest hyperfine level of the daughter system has a z-projection of the total angular momentum $F'_z = -11/2$. This corresponds to the state

$$|S'_zI'_z\nu'_z\rangle=|-3,-2,-1/2\rangle, \tag{3}$$

where ν'_z denotes the z-projection of neutrino spin. The next value, $F'_z=-9/2$, corresponds to three states, which can be written approximately as

$$|-3,-2,+1/2\rangle,|-3,-1,-1/2\rangle \text{ and } |-2,-2,-1/2\rangle. \tag{4}$$

We neglect "shake-up" processes in the electronic system and in particular, we ignore transitions which involve a change of spin state for the $3d$-electrons.

 0021-8979/96/79(8)/5716/2/$10.00

It is easy to show that any of the values $F_z'=-7/2$, $-5/2,-3/2$ corresponds to four possible final states, $F_z'=-1/2$ to three and $F_z'=+1/2$ to only one final state. The number of decay channels N_i for the ith hyperfine level of the initial system is equal to the number of final states with $F_z'=F_z$. This is because the z-projection of the total angular momentum is conserved during an electron capture decay. Therefore, the first hyperfine level of the initial system has one channel for decay, the second level has three channels, the third has four channels and so on.

One can intuitively understand this result by taking into consideration the four possibilities encountered in an electron capture decay:

(1) Annihilation of an electron with spin "up" and emission of a neutrino with spin "down"—the spin projection of the nucleus I_z must increase by one unit to conserve F_z;

(2) Annihilation of an electron with spin "down" and emission of a neutrino with spin "up"— the value of I_z must decrease by one unit to conserve F_z;

(3) and (4) Absorption and emission of leptons with the same spin ("up" or "down") with no change in I_z.

If the initial state of a $^{54}Mn^{2+}$ system corresponds to the first hyperfine level with $I_z=-3$, and the daughter nucleus has spin $I'=2$, the value I_z must increase by one unit. Thus in the decay only the first possibility described above is allowed. If the initial state corresponds to the second hyperfine level $I_z=-2$, the second possibility (decrease of I_z by one unit) is forbidden but the other three possibilities are allowed. For the initial state $I_z=-1$ all the possibilities are allowed and similar considerations apply to the other levels.

Assuming, for simplicity, equal decay probabilities for all the channels, we obtain the ratio of decay probabilities for the seven hyperfine levels as 1:3:4:4:4:3:1. The temperature dependence of the decay rate is then given for the case of $^{54}Mn^{2+}$ by

$$W/W_\infty=(7/20)\left[\sum_{i=1}^{7} N_i \exp\left(\frac{-E_i}{kT}\right)\right] \Big/ \left[\sum \exp\left(\frac{-E_i}{kT}\right)\right], \tag{5}$$

where W_∞ is the decay rate for $T\to\infty$ (i.e., $T\gg E_i/k$) and E_i is the energy of the ith level

$$E_i=\Delta(i-1),\Delta=(\mu/I)(H_n-H). \tag{6}$$

Putting $H=5$ T, $H_n=65$ T for our example, one obtains $\Delta/k\approx 24$ mK. The temperature dependence of W/W_∞ is plotted for this value of Δ/k in Fig. 1. One can see that the decay rate decreases with temperature, approaching its minimum value $W_{\min}=0.35W_\infty$ when the temperature approaches zero. For $T\ll\Delta/k$ one can transfer the initial system to the second and third hyperfine levels using nuclear magnetic resonance techniques. As a result, the decay rate can be increased by a factor of four, to its maximum value $W_{\max}=1.4W_\infty$.

In summary, we estimated the decay rate of ^{54}Mn nuclei in divalent Mn ions for magnetically dilute solids in an external magnetic field. It was shown that at temperatures comparable to the hyperfine splitting of the ground state, the electron capture decay rate may be controlled effectively with temperature and resonant electromagnetic fields. According to our estimates, the electron capture rate of ^{54}Mn can be decreased to 0.35 times and increased to 1.4 times its high temperature value of 0.81/yr. Techniques of microwave and optical pumping could be used to align the spins and produce significant dynamic nuclear polarization.

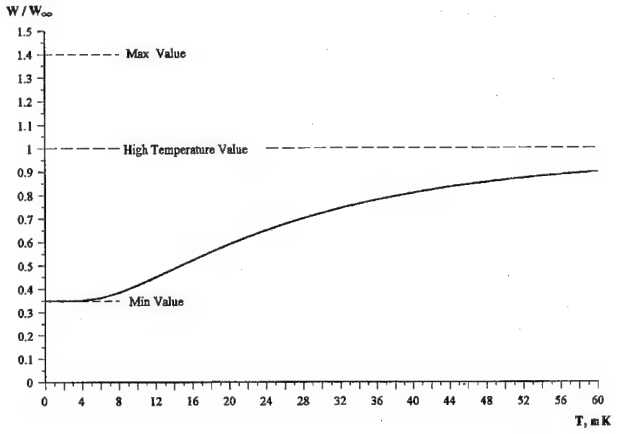

FIG. 1. The temperature dependence of the electron capture decay rate of $^{54}Mn^{2+}$ assuming $\Delta/k=24$ mK.

Similar considerations are valid for many other isotopes which decay by electron capture, i.e., their decay rates in paramagnetic ions depend significantly on the populations of the hyperfine levels and can consequently be controlled. We also suspect that the same effect could be observed in magnetically ordered media in spite of large exchange interaction between the ions. Potential applications of phenomenon considered here for solids are very promising. These include artificially induced changes of decay rate for transportation and utilization of radioactive isotopes, modulated long-lived sources of gamma rays and neutrinos, and new methods for detection of nuclear magnetic resonance, among others. The authors are delighted to acknowledge the assistance of Robert Lee, a YES program summer researcher.

Bragg diffraction of laser light by magnetostatic forward volume waves in a layered yttrium–iron–garnet film geometry

Liang-Ping Peng, J. P. Parekh, and H. S. Tuan
Electrical Engineering Department, State University of New York at Stony Brook, Stony Brook, New York 11794

The present article reports a theoretical study of Bragg diffraction of laser light by magnetostatic forward volume waves (MSFVWs) in a double-yttrium–iron–garnet(YIG)-film-layered structure. The layering provides a means of achieving a significant enhancement in bandwidth for nondispersive MSFVW propagation, leading in turn to a significant enhancement in bandwidth for magneto-optic (MO) coupling. Numerical computations comparing bandwidth for MO coupling between a single-YIG-film geometry and a double-YIG-film geometry are presented. © *1996 American Institute of Physics.* [S0021-8979(96)74808-1]

INTRODUCTION

Interest in Bragg diffraction of laser light by magnetostatic waves in epitaxial yttrium–iron–garnet (YIG) films arises from the potential for large time-bandwidth and tunable optical signal processing at microwave frequencies in the range from about 2 GHz to about 20 GHz.[1–6] The bandwidth for magneto-optic (MO) coupling is limited primarily by the bandwidth of magnetostatic wave (MSW) propagation. The use of an *inhomogeneous* bias field as a means of enhancing the bandwidth for MSW propagation, and thereby the bandwidth for magneto-optic (MO) coupling, has previously been reported[6] for the case of magnetostatic forward volume waves (MSFVWs) in a single YIG-film geometry. The present article reports an alternative approach also employing MSFVWs for enhancing the bandwidth for MO coupling through enhancement of bandwidth for nondispersive MSFVW propagation, i.e., the use of a layered YIG-film in conjunction with a separated ground plane. The computations presented here show a significant improvement in bandwidth for MO coupling arising from the use of a layered YIG-film geometry.

THEORY AND NUMERICAL RESULTS

A double-YIG-film-layered structure supporting MSFVWs is treated in which the top YIG-film layer (labeled YIG1) is Bi-doped and the lower layer (labeled YIG2) is pure YIG as shown in Fig. 1. The MO coupling effect is accentuated in the YIG1 region by choosing it to be Bi-doped. The dc bias magnetic field $\mathbf{H}_0$ is applied normal to the YIG films so that the MSW wave-type supported by the structure is MSFVW. In Fig. 1, the ground plane placed above the YIG1 Bi-doped film is omitted for the sake of simplicity. An *orthogonal* MO coupling geometry is treated, with the incident light wave essentially trapped within the YIG1 film propagating orthogonal to the MSFVW. The TM→TE mode coupling treated here assumes the lowest optical waveguide modes of the structure.

The MO coupling efficiency η is found to assume the standard expression

$$\eta = \sin^2(K_{\pm} L), \tag{1}$$

where $K_{\pm} = k_1 \pm k_2$ is the MO coupling coefficient representing the Stokes and anti-Stokes conditions, respectively. The quantities k_1 and k_2 depend upon the magnitudes of the components of the rf magnetization $\mathbf{m}$ and their distribution across the YIG1 film. The expressions for k_1 and k_2 differentiate the present geometry from previous studies since the field distributions in the YIG1 film vary with geometry.

Sample computations of the frequency-variation of the MO coupling efficiency η are presented in Figs. 2–5. In each of these figures, two curves are plotted, one for the present double-YIG-film-layered geometry and the other for a single-YIG-film geometry. The computations in the layered-YIG-film case are for YIG1 film thickness $d_1 = 9$ μm, YIG2 film thickness $d_2 = 60$ μm, saturation magnetizations of the two films $\mu_0 M_{01} = 1{,}750$ G and $\mu_0 M_{02} = 1{,}878$ G, ground plane separation from YIG1 film $h = 625$ μm, aperture of MSFVW microstrip transducer $L = 0.88$ cm, and applied bias field $\mu_0 H_0 = 3{,}678$ G. These parameter values are also the ones used in the single-YIG-film geometry computations except that in the latter geometry d_2 is set to zero. The computations also employ the same value $\mu_0 m_x = 68$ G for the x-component of rf magnetization in the YIG1 film for both the layered-film and single-film geometries, thereby maintaining the same rf power in the YIG1 film for the two geometries.

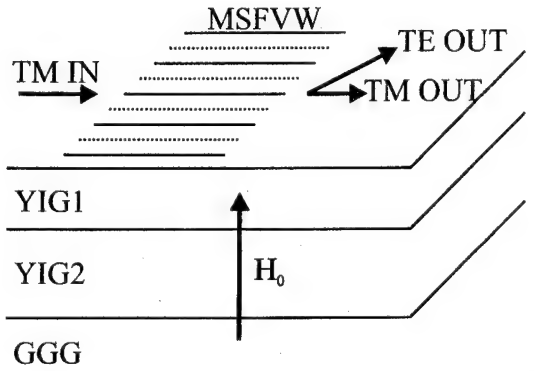

FIG. 1. Double-YIG-film geometry showing the directions of MSFWV propagation and of incident and scattered laser waveguide modes.

 0021-8979/96/79(8)/5718/3/$10.00

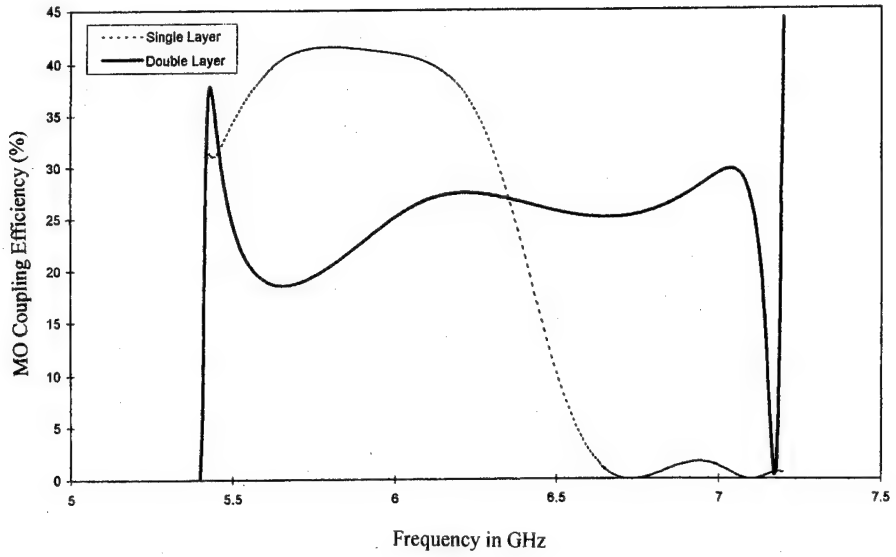

FIG. 2. Computed frequency variation of MO coupling efficiency for the case of MSFVW transducer width of 25 μm.

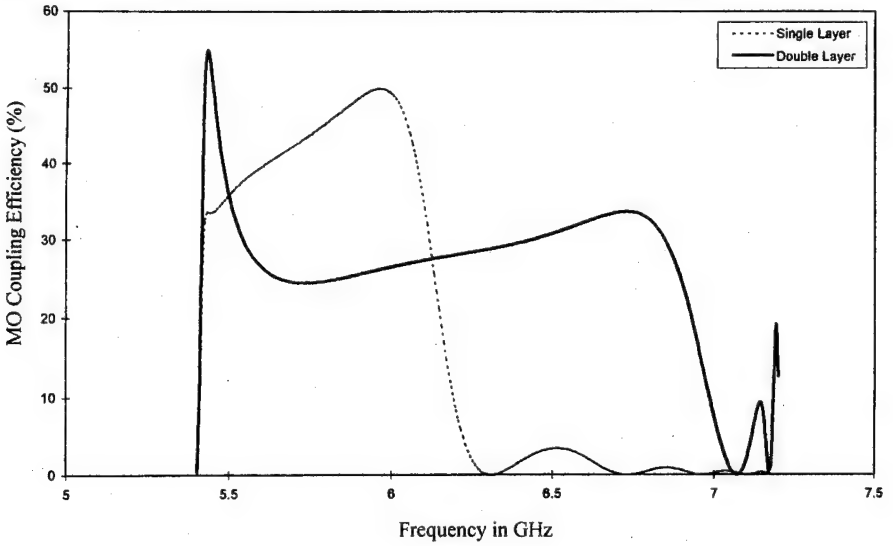

FIG. 3. Computed frequency variation of MO coupling efficiency for the case of MSFVW transducer width of 50 μm.

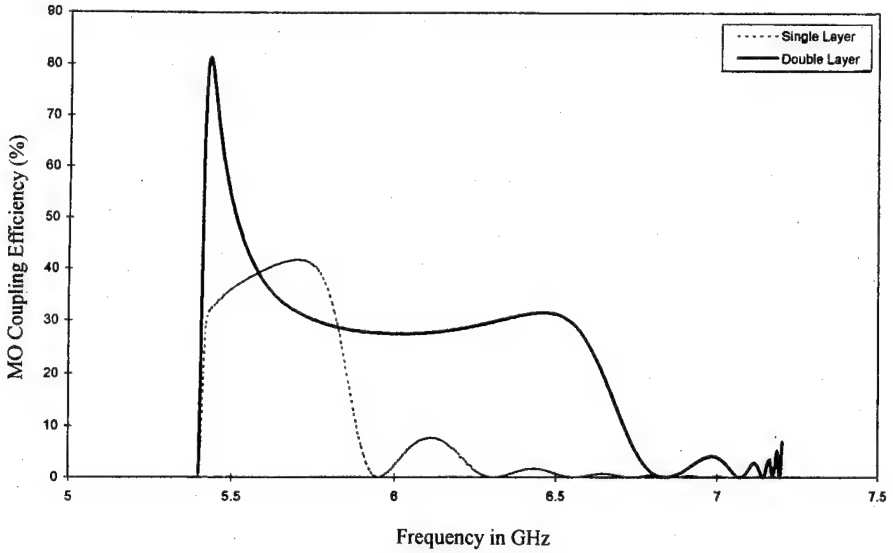

FIG. 4. Computed frequency variation of MO coupling efficiency for the case of MSFVW transducer width of 100 μm.

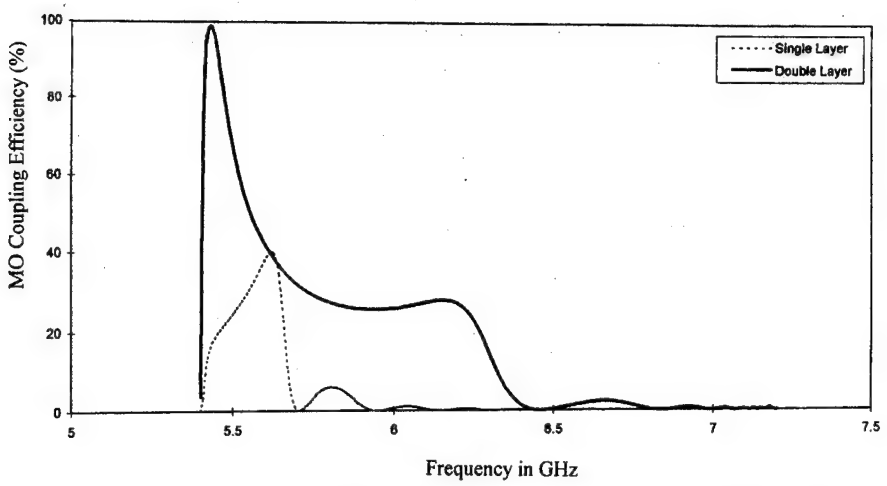

FIG. 5. Computed frequency variation of MO coupling efficiency for the case of MSFVW transducer width of 200 μm.

In going from Fig. 2 to Fig. 5 sequentially, the width of the microstrip transducer is incremented in the following order: $w=25$ μm (Fig. 2), $w=50$ μm (Fig. 3), $w=100$ μm (Fig. 4) and $w=200$ μm (Fig. 5). The computations presented in Figs. 2–5 contain two salient features:

(i) For a given value of microstrip transducer width w, a significant improvement in bandwidth for MO coupling takes place with the use of a layered YIG-film structure over a single YIG-film structure.

(ii) The bandwidth for MO coupling goes down monotonically with increase in the microstrip transducer width w for both the single-film and layered-film geometries. This effect is, of course, consistent with the *antenna array* effect associated with the *extended* nature of a microstrip transducer[7] relative to a line-current source.

CONCLUSION

The present article reports theoretical computations demonstrating that a layered-YIG-film MSFVW geometry provides a method of achieving a *significant* enhancement in the bandwidth for MO coupling over a single-YIG-film geometry. One advantage of the present method over the use of an inhomogeneous bias field is the practical difficulty implicit in the latter method of implementing an accurate inhomogeneous bias-field profile.

Modulation of magnetostatic surface wave in garnet film by optical pulses

Y. K. Fetisov and A. V. Makovkin
Moscow Institute of Radioengineering, Electronics and Automation, Vernadskogo 78
Moscow 117454, Russia

Microwave power modulation in a magnetostatic surface wave (MSSW) transmission line containing an yttrium-iron-garnet film of thickness 20 μm in the 3–4 GHz frequency band with optical pulses of duration 2 ms and energy of 20 μJ has been investigated. At microwave powers less than 1 mW a slow thermal modulation with magnitude up to 4% and characteristic time of 0.5 ms took place. At power levels 1–100 mW a fast modulation of the transmitted signal with magnitude up to 10% and characteristic time of about 1 μs caused by nonlinear properties of MSSW was observed. © *1996 American Institute of Physics.* [S0021-8979(96)74908-0]

INTRODUCTION

Magnetostatic spin waves (MSWs) propagating in microwave region in magnetically biased planar magnetic structures containing epitaxial yttrium-iron-garnet (YIG) films are widely used in microwave signal processing devices.[1] Characteristics of the waves such as wave length, velocity of propagation, efficiency of excitation, and propagation losses depend strongly on magnetic and electrical parameters of the structure. It is of great interest to use these dependences to design optically controlled microwave devices.

The basic mechanism by which light influence on MSW characteristics is a heating of the YIG film due to absorption of light energy. The heating results in a decrease in the YIG magnetization and gives rise to a change in MSW dispersion characteristics. The irradiation of garnet structure with short high-energy laser pulses gives rise to considerable heating of the film, that may be used to control the wave length, velocity of propagation, and MSW frequency as well.[2]

This paper presents results of experimental investigation of modulation of magnetostatic surface waves (MSSW) propagating in a free YIG film by low energy optical pulses. The measurements have been carried out for linear as well as for nonlinear regimes of MSSW propagation.

MSSW TRANSMISSION LINE

A schematic of MSSW transmission line used in the experiments is shown in Fig. 1. The YIG film of thickness $d=20$ μm, saturation magnetization $4\pi M=1750$ G, and uniform FMR line width $\Delta H\simeq 0.6$ Oe was grown by the LPE method on a gadolinium-gallium-garnet (GGG) substrate of thickness 0.5 mm and dimensions of 2 mm×20 mm. Two microstrip transducers of width 50 μm and length 2.5 mm evaporated on two alumina substrates were used to excite and to receive MSSW. The alumina substrates were placed in close contact with the film surface so that the distance between the transducers was equal to 5 mm. The structure was placed in a uniform dc magnetic field of $H=630$ Oe applied tangentially to the film plane and parallely to the transducers.

The upper surface of the YIG film was irradiated with optical pulses of wave length $\lambda=0.44$ μm, duration 2 ms, and rise time of 0.1 ms from a He-Cd laser with output power up to $I=10$ mW. A lens allowed focusing of the optical beam to a circle of 0.1 mm diameter at any point of the film.

A microwave signal $P_{in}(f)$ of frequency $f=3$–4 GHz and power up to 1 W was applied to the input transducer. The signal excited a MSSW of the same frequency f with a wave number k, which propagated in the YIG film toward the output transducer. An output microwave signal $P_{out}(f)$ was registered for different optical powers I and different positions of the beam on the film surface.

Figure 2 shows the measured dependence of the output microwave signal power $P_{out}(f)$ versus the wave frequency f (frequency response of transmission line) at low power of the input microwave signal $P_{in}\lesssim 1$ mW. One can see, that MSSWs propagate within a frequency band between the lower $f_L=3555$ MHz and the upper $f_U\sim 4000$ MHz boundary frequencies. At low power the minimal insertion loss was equal to $L(f)=10\ \lg\{P_{out}(f)/P_{in}(f)\}=-6.8$ dB.

For MSSW propagating in a linear regime in an infinite ferrite film the boundary frequencies can be found using the well-known dispersion equation:[3]

$$f_L(k=0)=\gamma\sqrt{H(H+4\pi M)}$$

and

$$f_U(k=\infty)=\gamma(H+2\pi M),$$

where $\gamma=2.8$ MHz/Oe is the gyromagnetic ratio. Calculated and measured values for f_L will coincide if an effective magnetic field in the film is taken to be equal to $H=667$ Oe. The insignificant difference between calculated and measured fields may be due to anisotropy of YIG and demagnetizing effects. The ripple in the frequency response with a period of ~40–10 MHz is conditioned by an interference between MSSW and a direct electromagnetic induction. The ripple with a period of ~4–5 MHz in a narrow lower frequency region (see inset in Fig. 2) may be due to a change in the wave dispersion in this region or due to interference between a main mode and higher-order transverse MSSW modes propagating in the structure of finite width.

At input signal powers $P_{in}\simeq 1$–100 mW an increase in the transmission loss near the upper edge of the MSSW band (curve 2 in Fig. 2) as well as a shift of the lower boundary frequency of up to $\Delta f_L\simeq 1$ MHz toward smaller frequencies were observed. Increase in the loss was due to nonlinear three-wave decay processes allowed for MSSW only in the frequency range $f\geqslant 2\gamma H$ ($f\geqslant 3.73$ GHz for $H=667$ Oe).[4] The

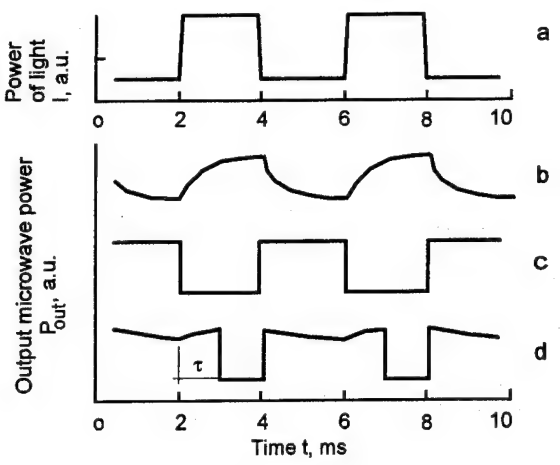

FIG. 3. Time-dependences for optical MSSW modulation in YIG film: (a) envelope of optical pulses; (b) envelope of output signal for "slow" modulation, f=3624 MHz; (c) and (d) envelope of output signals for "fast" modulation, f=3563 MHz.

shift of the lower boundary frequency was evidenced of a decrease in the YIG film magnetization of about $\Delta(4\pi M) \simeq 0.7$ G at high powers of input microwave signal.

EXPERIMENTAL RESULTS AND DISCUSSION

Two kinds of MSSW modulation have been observed by irradiating the YIG structure with optical pulses.

At low levels of input microwave power $P_{in} \leqslant 1$ mW, when MSSW frequency was positioned within the regions A or B on the frequency response (see Fig. 2), a "slow" amplitude modulation of MSSW signal with the magnitude $\eta=(\Delta P_{out}/P_{out})100\%$ of up to 4% and characteristic relaxation time about of $\tau_1 \simeq 0.5$ ms was observed [see Fig. 3(b)]. The magnitude of modulation was increased linearly with the increase in the optical power (see Fig. 4) and depended critically on the light beam position on the film surface.

This type of MSSW modulation was conditioned by a local heating of the garnet film due to absorption of optical energy. The heating resulted in a local decrease in the YIG magnetization $\Delta(4\pi M)$ and provided a downward shift of the whole frequency response, which gave rise to an increase or decrease in the output microwave signal power. Numerical calculations showed, that under the influence of optical pulses with energy of $W=20$ μJ and duration of $\tau=2$ ms a YIG film area of ~0.1 mm diameter was heated by $\Delta T \approx 10$ K and then cooled with a characteristic time of about $\tau_1 \approx 0.5$ ms. Such variation in the temperature corresponded to a local changing in the YIG film magnetization by $\Delta(4\pi M) \approx 30$ G.

The real spatial distribution of MSSW high-frequency magnetization $m(r,f)$ over the plane of a garnet structure of finite dimensions is essentially nonuniform. So, to provide maximum efficiency of thermal MSSW modulation, a laser beam should be focused on the film regions where the magnetization $m(r,f)$ is a maximum. It seems, this approach may be used as an indirect method to measure a spacial distribution of MSW fields in planar ferrite structures.[5]

For the first time, at high levels of microwave power $P_{in}>1$ mW a new "fast" modulation of MSSW amplitude has been observed in a narrow frequency region (~10 MHz) just above the lower boundary frequency f_L of the transmis-

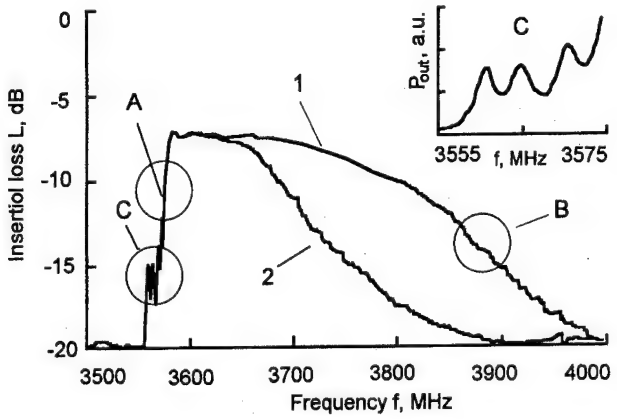

FIG. 2. Measured frequency responses of MSSW transmission line at different levels of input microwave power P_{in}, mW: 1–0.5, 2–500.

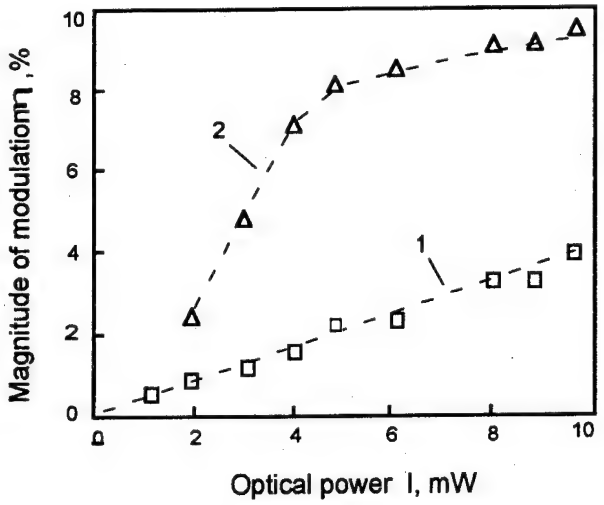

FIG. 4. Magnitude of MSSW modulation η as a function of power I of optical pulses: 1: thermal modulation; 2: "fast" modulation.

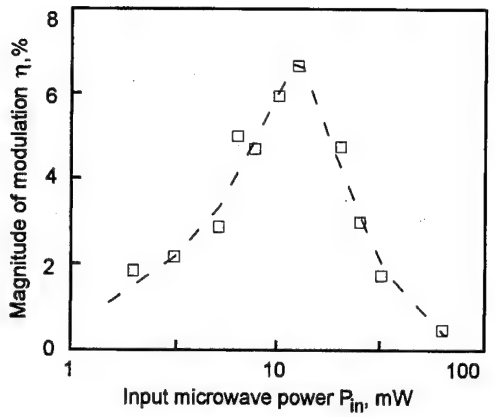

FIG. 5. Magnitude of "fast" MSSW modulation η as a function of input microwave power P_{in}.

sion band (region C in Fig. 2). Characteristic rise time and fall time for such a modulation were equal to $\tau_2 \simeq 1$ μs. This was approximately 10^2 times less than the rise time for optical pulses [Fig. 3(c)]. For certain positions of optical beam on the film surface the microwave pulse was delayed with respect to the optical pulse by time of about 0.1–2 ms [see Fig. 3(d)].

Figure 4 shows a typical threshold-like dependence of magnitude of modulation η versus the optical power I. The "fast" modulation was observed only for optical powers $I \geqslant 2$–3 mW. The magnitude of modulation was increased almost linearly with the increase in I and was saturated at the maximum level of $\eta \approx 10\%$. Figure 5 shows a typical dependence of modulation magnitude η versus input microwave power P_{in}, measured at maximum power and fixed position of optical beam on the film surface. The modulation appeared at microwave powers of about $P_{in} \simeq 1$ mW, its magnitude reached a maximum at $P_{in} \simeq 10$ mW, the modulation was completely vanished for microwave power $P_{in} > 100$ mW.

The results described led to the conclusion that "fast" modulation of output microwave power with optical pulses is conditioned by nonlinear properties of MSSW. The modulation was observed in the frequency region, where such nonlinear phenomena as auto-oscillations, formation of solitons, and self-channelizing of MSW can take place. As shown,[6] the Lighthill criterion

$$[\partial^2 f(k)/\partial k^2][\partial f(k)/\partial(|u|^2)] < 0,$$

(where $|u|^2$ is the dimensionless power of the wave) is not satisfied for MSSW in a free infinite film and the wave is stable with respect to longitudinal perturbations of amplitude. However, when the structure has a finite width and a metal screen is present, then near the lower boundary frequency f_L (where $k \to 0$) the MSSW dispersion law is considerably modified and multimode propagation of MSSW takes place.[7] This can create conditions such that the Lighthill criterion is satisfied and a self-modulation of MSSW appears.[8]

Besides that, as it is seen from the inset of Fig. 2, that frequency response of MSSW line is well modulated in this region. Such a shape of transmission characteristic together with a high nonlinearity in the system can result in a bistability and arising of the self-pulsations in the transmitted microwave power is analogous with bistability in optical systems.[9] It seems, in both cases a heating of garnet film with optical pulses stimulated transitions in the system from one stable state to another resulting in a modulation of output microwave power. A small value of transition time τ_2 was determined by the microwave characteristics of the garnet film, not by the velocity of the film heating. A theory describing stimulated transitions in bistable MSW lines and resonators is under development now.

We employ a transfer matrix formalism to study dipole-exchange spin waves in a perpendicularly magnetized multilayered structure consisting of identical magnetic layers alternated by nonmagnetic spacers, assuming both intralayer and interlayer exchange interactions. The interlayer exchange and the anisotropies at the magnetic layer boundaries are taken into account via linearized Hoffman boundary conditions. The bulk-mode bands for the case of infinite multilayers and the bulk and surface modes for semi-infinite multilayers are derived. Applications are made to recent ferromagnetic resonance data for Co/Pt multilayers. The extension of our theory to finite multilayers is discussed. © *1996 American Institute of Physics.* [S0021-8979(96)75008-9]

I. INTRODUCTION

The spectra of microwave excitations in magnetic multilayers and superlattices provide valuable information about the structural and magnetic parameters of the sample. In particular, characteristic parameters of exchange coupling between magnetic layers can be deduced.[1–3] Typically, the spectra of magnetic excitations in multilayers have been studied experimentally by either ferromagnetic resonance (FMR) [wave number $k\sim 0$] or Brillouin light scattering (BLS) [$k\sim 10^5$ cm^{-1}]. It is important to have a theory that covers all the experimentally accessible wave numbers.

In previous related work[4,5] we developed an analytic theory of BLS in magnetic multilayers. The purpose of the present paper is to give a variant of this approach that applies to FMR. We take into account both dipole-dipole and exchange interactions within each magnetic layer. The interlayer exchange coupling through a nonmagnetic spacer is incorporated phenomenologically through linearized Hoffman boundary conditions.[1] Here we are not concerned with the mechanism of this coupling or its oscillations (see, e.g., Ref. 6). We assume that the phenomenological quantity A_{12} characterizing the strength of interlayer exchange coupling depends exponentially on the spacer thickness ℓ as

$$A_{12}=A_{12}^0 \exp(-\ell/b), \tag{1}$$

where the interaction amplitude A_{12}^0 and characteristic length b are the fitting parameters in our theory.

In contrast with existing theories of FMR spectra in magnetic multilayers[3] we do *not* assume uniformity of the variable magnetization across the thickness of a magnetic layer, but rather calculate this distribution for each value of a spacer thickness ℓ assuming that the interlayer exchange leads to a renormalization of interface pinning.[4] Also we do not introduce effective volume uniaxial anisotropies in the magnetic layer depending on interlayer exchange interaction, as was done in Ref. 3.

Comparing our theory with recent FMR experiments in Co/Pt multilayers,[2,3] we find that we can explain the behavior of the collective quasi-surface mode of the FMR as a function of the spacer thickness ℓ and we determine the characteristic parameters A_{12}^0 and b.

II. TRANSFER MATRIX FORMALISM FOR A MULTILAYER

We use a traditional transfer matrix formalism (e.g., see Ref. 7 for a general review and Refs. 8 and 9 for specific applications to magnetic multilayers) to derive the spectrum of dipole-exchange spin waves in infinite and semi-infinite magnetic multilayers consisting of identical magnetic layers of the thickness L separated by nonmagnetic spacers of thickness ℓ. For waves propagating within any magnetic layer j we write the wave variables (i.e., variable magnetizations in the case of spin waves) in the form:

$$n(\mathbf{r},z)=\exp(i\mathbf{k}\cdot\mathbf{r})[A_+^j f_+(z,q_z)+A_-^j f_-(z,q_z)], \tag{2}$$

where $\mathbf{r}$ and $\mathbf{k}$ denote the in-plane position vector and wave vector, respectively, while z and q_z are the coordinate and wave number in the perpendicular direction. Also $f_\pm$ are appropriate single-layer eigenfunctions representing waves propagating in the $\pm z$ directions. We define a vector representation for the transverse wave amplitudes in the form:

$$|A^j\rangle=\begin{bmatrix}A_+^j\\A_-^j\end{bmatrix}, \tag{3}$$

Using the boundary conditions to account for the interaction of adjacent magnetic layers via the spacer, we obtain $|A^{j+1}\rangle=T|A^j\rangle$, where T is a 2×2 transfer matrix[7] of the system. On the other hand, the translational symmetry of an infinite superlattice yields Bloch's theorem, i.e., $|A^{j+1}\rangle=\exp(iQL_0)|A^j\rangle$, where Q is the Bloch vector (or the wave vector of a collective excitation envelope in a multilayer) and $L_0=L+\ell$ is the periodicity length in our problem. Combining the above relationships we obtain an equation for Q and q_z in the form:

$$\cos(QL_0)=\frac{1}{2}\mathrm{Tr}\ (\mathbf{T}(q_z)), \tag{4}$$

 0021-8979/96/79(8)/5724/3/$10.00

The modes form continuous bands with Q real. The boundaries correspond to putting $\cos(QL_0)=\pm 1$ in Eq. (4), yielding conditions satisfied by wave number q_z.

In the case of a semi-infinite multilayer there may also be surface-like solutions with imaginary Q in addition to the bulk-like (real Q) modes. The presence of a surface yields the boundary condition at the top surface, having the general form of $C_+A_+ + C_-A_- = 0$, giving

$$C_-(T_{11} - \exp(-iQL_0)) - C_+T_{12} = 0. \tag{5}$$

The solution of Eqs. (4) and (5) yield the values of q_z and Q for the surface and bulk modes of a semi-infinite multilayer. If the structure is finite, the formalism can be extended to account for another boundary condition at the lower surface of the multilayer. This makes the bulk modes quantized and also modifies the surface mode frequencies.

We now assume that the normal spin wave (SW) modes in each layer are eigenfunctions of the intralayer exchange operator, i.e., $f_\pm(z,q_z)=\exp(\pm iq_z z)$ as in Ref. 10. This yields the dispersion relationship in the form:

$$\omega_{\mathbf{k}n} = \omega_H + \alpha\omega_M(\mathbf{k}^2 + q_z^2), \tag{6}$$

where $\omega_H = \gamma(H - 4\pi M_0)$, $\omega_M = \gamma(4\pi M_0)$, γ is the gyromagnetic ratio, $\alpha = A/(2\pi M_0^2)$ is the exchange constant, $4\pi M_0$ is the saturation magnetization, and H is the external bias magnetic field (directed perpendicular to the layers).

With surface anisotropy and interlayer exchange included and following the notations of Ref. 6, we may write the linearized Hoffman boundary conditions[1,4] in the form:

$$\left[-\frac{dm_{j+1}}{dz} + (d^U + \beta)m_{j+1}\right]_{\text{upper}} - [\beta m_j]_{\text{lower}} = 0;$$
$$\left[\frac{dm_j}{dz} + (d^L + \beta)m_j\right]_{\text{lower}} - [\beta m_{j+1}]_{\text{upper}} = 0 \tag{7}$$

for the bulk layers, and

$$\left[-\frac{dm_1}{dz} + d^{SU}m_1\right]_{\text{upper}} = 0; \quad \left[\frac{dm_N}{dz} + d^{SL}m_N\right]_{\text{lower}} = 0 \tag{8}$$

for the external surfaces of the multilayer. Here m_j is the variable magnetization in layer j, d^U, and d^L are the pinning parameters at the upper and lower surfaces of each magnetic layer, while d^{SU} and d^{SL} are the pinning parameters at the upper and at the lower external surfaces of the multilayer, respectively. Pinning parameters $d = K_S/A$, measured in cm^{-1} units,[10] are determined by the ratio between the constant of surface anisotropy K_s and the exchange constant A. Parameter $\beta = A_{12}/A$ is also measured in cm^{-1} and characterizes exchange coupling between the magnetic layers.[4]

Equations (7) and (8) correspond to the SW modes in an exchange approximation, with the dipole-dipole interaction taken into account only in the lowest order. This approximation is adequate in two physical situations:

(1) *FMR and Long-wavelength SW.* In this case $\mathbf{k} \cong 0$; the dipole interaction is close to saturation and results only in an effective renormalization of the uniform Zeeman field by a demagnetization field (in ω_H).

(2) *Short-wavelength exchange waves,* $\mathbf{k} \gg 1$ (normally, of order of magnitude 10^6 cm^{-1} and larger). In this case the dipolar contribution to the energy of the wave is small because of the long-range character of the weak dipole-dipole interaction.

Using the perturbation theory developed in Ref. 10 it is possible to obtain SW dispersion relations in magnetic multilayers for any values of $\mathbf{k}$. In particular, this was done in Ref. 5 for the interpretation of BLS experiments.

With the assumed form for $f_\pm(z,q_z)$ and denoting $d_{L,U} = d^{L,U} + \beta$, we get the following equations for q_z and Q in the case of a semi-infinite multilayer:

(1) *Bulk band boundaries* (q_z and Q real, $\cos(QL_0)=\pm 1$):

$$(d_L + d_U)\frac{\cos(q_z L)}{2\beta} + (q_z^2 + \beta^2 - q_L d_U)\frac{\sin(q_z L)}{2\beta q_z} = \pm 1 \tag{9}$$

(2) *Surface-type solutions* ($q_z = i\kappa$, $Q = iK$):

$$[\beta^2 + (\kappa - d_U)(\kappa + d_L)]\Big[\cosh(\kappa)[\beta^2 - (d^{SU} + d_U) \times (d_L - d^{SU})] + \frac{\sinh(\kappa)}{\kappa}[\beta^2 d^{SU} + (d^{SU} + d_U) \times (\kappa^2 - d_L d^{SU})]\Big] = 0 \tag{10}$$

$$\frac{\exp(-\kappa L)}{\beta(d^{SU} + \kappa)}[\beta^2 - (d^{SU} + d_U)(d_L + \kappa)] = -\exp(KL_0) \tag{11}$$

Now, solving Eqs. (10) and (11), we obtain the values of K and κ for a quasi-surface collective mode. Equation (10) holds in either of two cases:

(1) $\beta^2 + (\kappa - d_U)(\kappa + d_L) = 0$, which gives

$$\kappa_{1,2} = \frac{1}{2}[d_U - d_L \pm \sqrt{(d_U - d_L)^2 + 4(\beta^2 - d_U d_L)}], \tag{12}$$

(2)

$$\cosh(\kappa)[\beta^2 - (d^{SU} + d_U)(d_L - d^{SU})] + \frac{\sinh(\kappa)}{\kappa} \times [\beta^2 d^{SU} + (d^{SU} + d_U)(\kappa^2 - d_L d^{SU})] = 0. \tag{13}$$

Case (1) represents solutions independent of the value of the first layer surface anisotropy d^{SU}, while Case (2) accounts for it. The question of which solutions really exist in the system depends on the consistency condition for $K > 0$.

III. COMPARISON WITH FMR EXPERIMENTS

The above formalism is now applied to interpret the FMR results obtained by Zhang *et al.*[3] for Co/Pt multilayers with different values of the spacer (Pt) thickness.

We assume that pinning conditions on both sides of each individual layer are the same, $d^U = d^L \equiv d$. In this case the dispersion relation at $\mathbf{k}=0$, corresponding to the solution of Eq. (12), reads:

$$\omega = \omega_H - \alpha\omega_M(d + \beta(\ell))d, \tag{14}$$

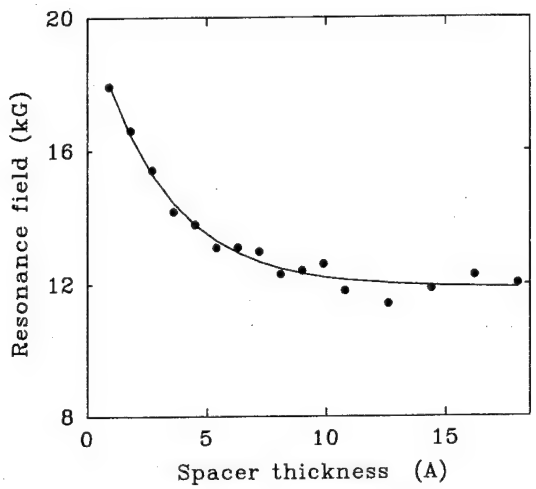

FIG. 1. FMR resonance field vs spacer thickness for a Co/Pt multilayer for a quasi-surface collective mode. Circles–experimental data [Ref. 3]; solid line–theory [Eq. (14)]. See text for the parameters.

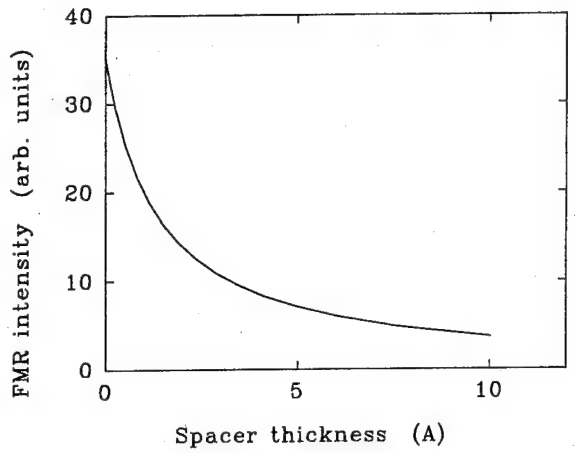

FIG. 2. Theoretical FMR response intensity vs spacer thickness for a Co/Pt multilayer. See text for the parameters.

where $\beta(\ell)=A_{12}(\ell)/A$ depends on the spacer thickness ℓ in accordance with Eq. (1).

Equation (14) describes correctly all the main features of the behavior of the quasi-surface collective FMR mode in a Co/Pt multilayer observed in Refs. 2 and 3. In particular, it accounts for the decrease of the resonance field with increasing spacer thickness, which was not explained by the theory of FMR presented in Ref. 3.

The results of fitting Eq. (14) to the experimental data[3] are shown in Fig. 1. We took $A=2.84\times10^{-6}$ erg/cm for the intralayer exchange constant in Co layers of thickness $L=25$ Å, the surface anisotropy constant at the Co/Pt interface to be $K_s\equiv Ad=0.4$ erg/cm^2, and $\omega/\gamma=3.5$ kG. The best fit was obtained for the following values of the parameters: $A_{12}^0=20$ erg/cm^2, $b=3.7$ Å, and $4\pi M_0=7900$ Oe. Differences in our values and the values quoted in Ref. 3 [$A_{12}^0=(70\pm5)$ erg/cm^2, $b=(7\pm1)$ Å] can be attributed to the fact that our theory accounts for the nonuniform distribution of variable magnetization within the magnetic layers, which effectively renormalizes the parameters of exchange coupling between the layers.

Another characteristic feature of the quasi-surface collective mode of FMR, for which the frequency is given by Eq. (14), is that its intensity, calculated as a normalized overlap integral of the magnetization distribution in this mode and the uniform magnetic field exciting the FMR in a multilayer, decreases with increasing spacer thickness (see Fig. 2). This is also in agreement with experiment.[3]

IV. CONCLUSION

By applying the transfer matrix formalism to semi-infinite magnetic multilayers, we obtained a simple analytical expression for the spectrum of a quasi-surface collective mode of FMR, which turns out to be in good qualitative agreement with the experimental data for the behavior of a quasi-surface collective mode of FMR in a Co/Pt multilayer when the spacer (Pt) thickness is varied.

Nonlinear magneto-acoustic waves in ferromagnets

G. T. Adamashvili
Tbilisi State University, Tbilisi, Republic of Georgia 380079

A. A. Maradudin
University of California, Irvine, California 92717

The nonlinear coherent interaction of a high-frequency acoustic wave pulse with a magnetically ordered medium is studied theoretically. We consider both microscopic and phenomenological theories of the formation of nonlinear magneto-acoustic waves in a ferromagnet. A self-consistent determination of the dispersion law for nonlinear magneto-acoustic waves in a ferromagnet is carried out. It is shown that in both of these theories nonlinear excitations arise which can be of the form of a periodic nonlinear wave, a soliton, or a kink. The nature of the change of polarization of transverse linearly polarized magneto-acoustic waves is also investigated. © *1996 American Institute of Physics.* [S0021-8979(96)75108-5]

I. INTRODUCTION

The propagation of an acoustic wave in a magnetically ordered medium (MOM) is accompanied by its interaction with spin waves, which leads to the formation of a bound magneto-acoustic wave (MAW). When the acoustic wave is weak, the degree of excitation of the magnetic system of the MOM is sufficiently low that properties of the MAW can be adequately described within the framework of the linear theory of these waves, which has been extensively developed.[1,2] With an increase of the intensity of the acoustic wave the situation changes significantly. Under the action of a strong acoustic wave a macroscopically large number of excitations occur, at least locally. In a MOM under strong excitation of the spin system various nonlinear phenomena can arise, which are due to nonlinear magneto-acoustic interactions. Some of them have been investigated in detail in Refs. 3 and 4. In addition to these nonlinear phenomena, great interest attaches to nonlinear effects which arise due to the nonlinear coherent resonant interaction of an acoustic wave with a MOM, and lead to the formation of nonlinear MAW of an invariable profile. Such a wave, for example, can have the form of a soliton. Some properties of these nonlinear waves have been investigated in considerable detail. In particular, in Refs. 5–7 a microscopic theory of nonlinear MAW was constructed on the basis of the Heisenberg model of a ferromagnet. In these papers, for a self-consistent determination of the dispersion law of these waves the method of Goll and Haken, applied earlier for the investigation of nonlinear optical waves in the exciton region of the optical spectrum,[8] was used. However, in the corresponding equations in Refs. 5–7 the speed of magnons was not taken into account. With the phase plane method it was shown that nonlinear waves having the forms of a soliton, a kink, and a nonlinear periodic wave can occur in this system, but explicit expressions for the forms of the parameters on which these waves depend were not presented. This was also the case in the presentation of a corresponding phenomenological theory that proceeded from the Landau–Lifshitz equations and the equations of the theory of elasticity.[9,10]

In the present paper we present microscopic and phenomenological theories of the formation of nonlinear MAW, and the nature of the change of their polarization, when the speeds of magnons as well as the speeds of coherent phonons are taken into account. Explicit expressions for the parameters of these nonlinear MAW are also presented.

II. MICROSCOPIC THEORY OF NONLINEAR MAW

For a microscopic determination of the basic features of the formation of nonlinear MAW in a ferromagnet we proceed from the Heisenberg model of a cubic ferromagnet. We assume that a transversely polarized MAW propagates in it along a constant magnetic field $\mathbf{H}_0$ which is parallel to the z-axis. The duration of the pulse is $T \ll T_{1,2}$, where T_1 and T_2 are the longitudinal and transverse relaxation times, and its frequency is $\omega \gg T^{-1}$. We consider the nonlinear coherent interaction of this pulse with the ferromagnet.

The Hamiltonian of the model investigated has the form

$$H=\hbar\omega_0\sum_i S_i^2-\Lambda\sum_i (S_i^z)^2+\hbar\sum_k \omega_k a_k^+ a_k$$

$$-\sum_{i\neq j} g_{ij}S_i^zS_j^z-\sum_{i\neq j}\eta_{ij}S_i^+S_j^-$$

$$-b\int_V\sum_{i\neq j}(S_i^+S_j^z\epsilon^-+S_i^-S_j^z\epsilon^+)dv, \tag{1}$$

where

$$g_{ij}=J_{ij}-I_{ij}^d, \quad \eta_{ij}=J_{ij}+1/2I_{ij}^d, \quad b=\gamma_2(\hbar\gamma/VM_0)^2,$$

$$\epsilon^{\pm}=\epsilon_{xz}\pm i\epsilon_{yz}=\pm i\sum_k \bar{\kappa}a_k^{\mp}\exp[\pm i(\omega_k t-kl)],$$

$$\bar{\kappa}=k\left(\frac{N_0\hbar}{8\rho\omega V}\right)^{1/2}, \quad \Lambda=2\mu\frac{\beta^2}{v_0}.$$

$\omega_0=\gamma H_0$ is the Zeeman frequency of the spins, where γ is the magnetomechanical ratio; $\mathbf{S}_i$ is the spin of the atom which is at the i^{th} site of the crystal; J_{ij} is the coefficient of the exchange interaction between spins ($J_{ij}>0$ for a ferromagnet); I_{ij}^d is the coefficient of the magnetic dipole-dipole interaction; β is the Bohr magneton; γ_2 is the magneto-acoustic coupling constant; M_0 is the saturation magnetization; $\epsilon_{ik}(i,k=x,y,z)$ are the components of the strain tensor; ρ is the mass density of the medium, v_0 is the volume of a

 0021-8979/96/79(8)/5727/3/$10.00

primitive unit cell of the crystal, and V is the volume of the crystal; a_k^+ and a_k are the creation and annihilation operators of the phonon with wave vector $\mathbf{k}$, while ω_k is the frequency of the k^{th} phonon mode; $\hbar$ is the Planck constant; μ is the anisotropy parameter; ℓ is the discrete coordinate along the z-axis; and N_0 is the number of lattice sites in the crystal.

From the expression (1), we obtain the equations of motion,

$$\begin{aligned}
&\alpha^*\dot{m}^{\pm}=\pm i(\omega_0-\omega-qN)m^{\pm}\pm i\beta_0[2N^2\mathscr{E}^{\pm}\\
&\qquad -m^{\pm}m^{\mp}\mathscr{E}^{\pm}-(m^{\pm})^2\mathscr{E}^{\mp}]\\
&\alpha^*\dot{N}=i\beta_0 N(m^+\mathscr{E}^- -m^-\mathscr{E}^+) \qquad (2)\\
&\alpha\dot{\mathscr{E}}^{\pm}=\mp i(\omega-c_t k)\mathscr{E}^{\pm}\mp i\beta_0\bar{\kappa}^2 N m^{\pm},
\end{aligned}$$

where $\alpha=1-c_t/v$, $\alpha^*=1-u_m/v$, with v the velocity of the nonlinear wave; c_t is the speed of transverse acoustic waves, and u_m is the speed of magnons; $\beta_0=b/\hbar;q=2[G(0)-M(k)]$, and $M(k)$ and $G(k)$ are the Fourier transforms of the quantities η_{il} and g_{il}, respectively.[7] The quantities $N, m^{\pm}$, and $\mathscr{E}^{\pm}$ are defined by $N=\langle S_l^z\rangle$, $\langle S_l^{\pm}\rangle=m^{\pm}e^{\pm i(\omega t-kl)}$, $\langle\epsilon^{\pm}\rangle=\mathscr{E}^{\pm}e^{\pm i(\omega t-kl)}$. The coordinate τ is defined by $\tau=t-l/v$, and the dot denotes differentiation with respect to τ. Using the initial conditions for the acoustic wave and magnetization that no magnons are excited before the acoustic wave impinges on the medium, i.e., at $t\to-\infty$, $\mathscr{E}^{\pm}\to 0$, $N=-1/2$, then from Eqs. (2) we obtain

$$m^+m^-+N^2=\frac{1}{4}, N=-\frac{1}{2}+g\mathscr{E}^+\mathscr{E}^-,$$

where $g=-\alpha/\alpha^*\bar{\kappa}^2$.

Taking into account these relations and decomposing the complex amplitudes $\mathscr{E}^{\pm}=ae^{\pm i\Phi}$ into their modulus a and phase Φ, from Eqs. (2) we obtain the following differential equation for the phase,

$$\dot{\Phi}=\frac{1}{2\alpha}\left(\tilde{\Delta}-\frac{\alpha}{\alpha^*}\Delta\right)-\mathrm{Ga}^2,$$

where $\tilde{\Delta}=\omega-c_t k$, $\Delta=\omega_0-\omega+q/2$, $G=q\alpha/4\bar{\kappa}^2\alpha^{*2}$. We assume that k is the central momentum and ω the central frequency of the pulse. Therefore $\dot{\Phi}$ must not contain a constant part. Consequently

$$\dot{\Phi}=-\mathrm{Ga}^2,$$

and

$$\frac{\tilde{\Delta}}{\alpha}=\frac{\Delta}{\alpha^*}, \qquad (3)$$

which is the dispersion law for the nonlinear wave.

From Eqs. (2) we also obtain the equation for the amplitude of the pulse

$$(\dot{a})^2=T^{-2}a^2+c_1a^4+c_2a^6+c_3a^8, \qquad (4)$$

where

$$T^{-2}=-\frac{G_0^2}{\alpha}-\left(\frac{\tilde{\Delta}}{\alpha}\right)^2,\quad c_1=-\frac{5}{4}\left(\frac{\beta_0}{\alpha^*}\right)^2-\frac{\tilde{\Delta}q}{2\bar{\kappa}^2\alpha^{*2}},$$

$$c_2=\frac{2\beta_0^2 g}{\alpha^{*2}}-G^2,\quad c_3=-\left(\frac{\beta_0 g}{\alpha^*}\right)^2,\quad G_0^2=\frac{\beta_0^2\bar{\kappa}^2}{4\alpha^*}, \qquad (5)$$

and the quantity G_0 is the magnon-phonon coupling constant. Expressions (3) and (5) contain the velocities u_m, v, and c_t as parameters. An analysis of Eq. (4) can be carried out in the same way as this was done in Ref. 7, where it was shown that nonlinear MAW having the form of a soliton, a kink, or a nonlinear periodic wave can occur.

III. PHENOMENOLOGICAL THEORY OF NONLINEAR MAW

In the phenomenological theory it is assumed that the state of a MOM can be described by the magnetic moment density $\mathbf{M}(z)$. The macroscopic energy density of the medium can be represented as $W=W_p+W_m+W_{mp}$, where W_p, W_m, W_{mp} are the densities of the elastic energy, the magnetic energy, and the energy of the magnon-phonon interaction, whose forms can be found in the monographs.[1,2]

The equations of motion for the magnetization $\mathbf{M}$ and for the acoustic wave have the forms

$$\begin{aligned}
&\frac{\partial M^{\pm}}{\partial t}=\pm i\omega_0 M^{\pm}\pm iF_1\left(\frac{\partial^2 M_z}{\partial z^2}M^{\pm}-M_z\frac{\partial^2 M^{\pm}}{\partial z^2}\right)\\
&\qquad \pm iF_2\left[\left(M_z^2-\frac{1}{2}M^+M^-\right)\epsilon^{\pm}-\frac{1}{2}(M^{\pm})^2\epsilon^{\mp}\right],\\
&\frac{\partial M_z}{\partial t}=i\frac{F_1}{2}\left(M^-\frac{\partial^2 M^+}{\partial z^2}-M^+\frac{\partial^2 M^-}{\partial z^2}\right)\\
&\qquad +i\frac{F_2}{2}M_z(M^+\epsilon^- -M^-\epsilon^+),\\
&\frac{\partial^2\epsilon^{\pm}}{\partial t^2}=c_t^2\frac{\partial^2\epsilon^{\pm}}{\partial z^2}+\tilde{G}\frac{\partial^2}{\partial t^2}(M_z M^{\pm}),
\end{aligned}$$

where

$$\tilde{G}=\frac{\gamma_2}{2\rho M_0^2},\quad F_1=\frac{2A\gamma}{M_0^2},\quad F_2=\frac{2\gamma\gamma_2}{M_0^2},$$

and

$$M^{\pm}=M_x\pm iM_y.$$

The constant A appearing in the definition of the coefficient F_1 is the coefficient of rigidity of the medium.

We can simplify these equations significantly by using the method of slowly changing profile. For this purpose, we represent the functions $M^{\pm}$, M_z, and $\epsilon^{\pm}$ in the forms

$$M^{\pm}=m^{\pm}e^{\pm i(\omega t-kz)},\quad M_z=M_0+m_z,\quad \epsilon^{\pm}=\mathscr{E}^{\pm}e^{\pm i(\omega t-kz)},$$

where $m^{\pm}$, m_z, $\mathscr{E}^{\pm}=ae^{\pm i\Phi}$ are slowly varying amplitudes.

Substituting these expressions in the equations of motion we obtain

$$\begin{aligned}
&\widetilde{\alpha^*}\dot{m}^{\pm}=\pm i(\omega_0-\omega+\tilde{q}M_z)m^{\pm}\\
&\qquad \pm i\tilde{\beta}[(2M_z^2-m^{\pm}m^{\pm})\mathscr{E}^{\pm}-(m^{\pm})^2\mathscr{E}^{\mp}],\\
&\widetilde{\alpha^*}\dot{M}_z=i\tilde{\beta}M_z(m^+\mathscr{E}^- -m^-\mathscr{E}^+), \qquad (6)
\end{aligned}$$

$$\tilde{\alpha}\dot{\mathscr{E}}^{\pm}=\mp i\Delta_0\mathscr{E}^{\pm}\pm i\tilde{g}M_z m^{\pm},$$

where $\tilde{q}=F_1k^2$, $\tilde{g}=\gamma_2k^2/4\rho\omega M_0^2$, $\tilde{\alpha}=1-c_t^2k/\omega v$, $\tilde{\alpha}^*=1-v_m/v$, $v_m=4A\gamma k/M_0$ is the magnon velocity, $\Delta_0=(\omega^2-c_t^2k^2)/(2\omega)$, and $\tilde{\beta}=F_2/2$. Using the initial conditions for the acoustic wave and magnetization in the same way as this was done in Sec. II, from the set of equations (6) we obtain the differential equation satisfied by the phase function

$$\dot{\Phi}=\tilde{G}a^2,$$

the dispersion law

$$\frac{\Delta_0}{\tilde{\alpha}}=\frac{\tilde{\Delta}_0}{\tilde{\alpha}^*}, \tag{7}$$

and the equation for the amplitude of the nonlinear wave

$$(\dot{a})^2=T_0^{-2}a^2+C_1a^4+C_2a^6+C_3a^8,$$

where

$$T_0^{-2}=-\frac{R^2}{\tilde{\alpha}^*\tilde{\alpha}}-\left(\frac{c_t^2k^2-\omega^2}{2\omega\tilde{\alpha}}\right)^2,$$

$$C_1=-\left(5g_0^2M_0^2\frac{\tilde{g}^2}{\tilde{\alpha}^2}-2\frac{\Delta_0}{\tilde{\alpha}}\tilde{G}\right),\quad C_2=4\frac{g_0^3M_0\tilde{g}^2}{\tilde{\alpha}^2}-\tilde{G}^2, \tag{8}$$

$$C_3=\left(\frac{\tilde{g}g_0^2}{\tilde{\alpha}}\right)^2,$$

$$\tilde{G}=\frac{\tilde{q}g_0^2\tilde{g}}{4\tilde{\beta}\tilde{\alpha}},\quad \tilde{\Delta}_0=\omega_0-\omega+\tilde{q}M_0,\quad R=2\tilde{g}\beta M_0^3,$$

$$\tilde{g}_0=-\frac{\tilde{\alpha}\tilde{\beta}}{\tilde{\alpha}^*\tilde{g}}.$$

Comparing Eqs. (3) and (5) with Eqs. (7) and (8) we see that the results of the microscopic and phenomenological theories are quite similar to each other.

IV. POLARIZATION OF NONLINEAR MAW

For describing the state of polarization of the nonlinear MAW we consider a linearly polarized transverse wave (LPTW) which propagates along an external constant magnetic field of magnitude H_0. By the use of the methods of Ref. 11, we obtain the following expression for the angle of rotation of the plane of polarization of the nonlinear MAW,

$$\psi_{n\ell}=-\frac{G_0^2}{2c_t}\frac{\tilde{\tilde{\Delta}}T^2}{1+\tilde{\tilde{\Delta}}^2T^2}z, \tag{9}$$

where

$$\tilde{\tilde{\Delta}}=\frac{\Delta}{\alpha^*}.$$

As the nonlinear MAW propagates, it becomes elliptically polarized as well. The ratio of the lengths of the small b and large a elliptic axes follows from

$$\left(\frac{b}{a}\right)_{n\ell}=\frac{|f_+-f_-|}{f_++f_-}, \tag{10}$$

where f_+ and f_- are to within a constant factor the forms (shapes) of the clockwise and counterclockwise polarized components of the LPTW pulse. In the linear limit the angle of rotation of the plane of polarization is

$$\psi_\ell=-\frac{G_0^2}{2c_t\tilde{\tilde{\Delta}}}z, \tag{11}$$

and the ratio of the lengths of the small and large elliptic axes in the absence of dissipation is equal to zero, i.e., the linear wave remains linearly polarized as it propagates. In the presence of dissipative effects $f_+=1$, $f_-=\exp(-\alpha_0z)$ (where α_0 is the absorption coefficient) and we have

$$\left(\frac{b}{a}\right)_\ell=\left(\frac{\cosh(\alpha_0z)-1}{\cosh(\alpha_0z)+1}\right)^{1/2},$$

i.e., in the general case elliptic polarization of the wave occurs.

From expressions (9) and (11) for the angle of rotation of the plane of polarization it is seen that the values of ψ in the linear and nonlinear limits differ considerably in their dependences on Δ. In particular, in the linear limit, with the frequency ω approaching $\omega_0+1/2q$, the angle ψ_ℓ increases and tends to its maximum value while, on the other hand, for a nonlinear magneto-acoustic wave, as $\Delta\to0$ the angle $\psi_{n\ell}$ tends to zero, i.e., there is no rotation of the plane of polarization.

The nature of the variation of the ratio *b/a* is also significantly different in the linear and nonlinear limits. From Eq. (10) it is seen that as the nonlinear LPTW propagates, it transforms into an elliptically polarized wave. In this case the nature of the transformation depends on the form of the pulse $f_\pm$. At the values of z for which $f_+=f_-$ the magneto-acoustic wave is linearly polarized.

V. CONCLUSION

In the present paper we have shown that, due to the nonlinear coherent interaction of an acoustic pulse with a ferromagnet, nonlinear MAW of the type of a soliton, kink, or nonlinear periodic waves can arise. The nonlinear dispersion laws (3) or (7) are valid for these waves, which contain the speed of the nonlinear wave as well as the speeds of magnons and coherent phonons.

The theory describing parametrical interaction of magnetostatic backward volume waves (MSBVW) in a space-time periodic magnetic field was developed. Forward and backward scattering of MSBVW propagating in a 20-μm-thick yttrium-iron-garnet film at a central frequency of 3 GHz was observed. A space-time periodic magnetic field with a spatial period of 500 μm, a frequency in the range 20–150 MHz, and a magnitude up to 10 Oe was created by ac current passing through a meander line placed on the film surface. An interaction bandwidth of 20 MHz and an efficiency of up to 10% have been obtained in accordance with theoretical predictions. © *1996 American Institute of Physics.* [S0021-8979(96)75208-1]

INTRODUCTION

Magnetostatic spin waves (MSW) propagating in ferrite films are very sensitive to conditions at the film surface and to the external magnetic field. These properties may be used to control the propagation and the interaction of MSWs by means of weak nonuniformities created in the film. The efficient reflection of MSW in a periodically corrugated[1] or periodically ion-implanted[2] films and the scattering in a static space-periodic magnetic field[3] have been demonstrated. A dynamic nonuniformity, such as surface acoustic wave, propagating in the same film may be used to control MSW propagation as well.[4]

This paper presents the theory describing parametrical interaction of magnetostatic backward volume waves (MSBVWs) in a ferrite film placed in a weak space-time periodic magnetic field. Such a field may be easily created by passing an ac current through a meander line conductor placed near the film surface.[5] The collinear MSBVW scattering accompanied by conversion of the wave number and the frequency has been investigated.

THEORY OF COLLINEAR MSBVW INTERACTION

Consider a y-z plane oriented ferrite film of the thickness d, saturation magnetization $4\pi M$, and FMR line width ΔH, which is saturated with an external dc magnetic field H along the z axis. A metal lattice of the period Λ, strip width a, and thickness b is placed at a distance t above the film surface.

The characteristics of MSW propagating in a free film are found by solving the Maxwell's equations (without retardation) and the linearized equation of motion of the magnetization with boundary conditions at the film surfaces.[6] The dispersion equation for MSBVW propagating along the z axis has the form:

$$tg(kd/\sqrt{-\mu}) = -2\sqrt{-\mu/(1+\mu)}, \tag{1}$$

where $\mu = 1 + \omega_H\omega_M/[\omega^2(k) - \omega_H{}^2]$, $\omega_0 = \sqrt{\omega_H(\omega_{H+}\omega_M)}$, $\omega_H = \gamma H$, and $\omega_M = \gamma(4\pi M)$, γ is the gyromagnetic ratio.

Equation (1) gives the dependence of the wave frequency $\omega(k)$ versus the wave number k for eigenmodes with numbers $n=1,2,...$ having symmetrical or antisymmetrical distributions of magnetostatic potential Ψ_n across the film thickness.

Let an ac current $I = I_0\cos(\Omega t)$ with the frequency Ω pass through the metal lattice so that currents in the neighboring strips flow in opposite directions. Such a current distribution creates a space-time periodic magnetic field in the film that may be represented as a sum of "magnetic waves" propagating in opposite directions along the z axis:

$$h(z,t) = \sum_{l=1}^{\infty} \sum_{s=\pm 1} h_{ls} e^{i(sK_l z - \Omega t)} + c.c., \tag{2}$$

where $K_1 = \pi l/\Lambda$ and s determines the direction of propagation.

The amplitudes of the magnetic waves $h_{l,s} = (h_x^{1,s}, 0, h_z^{1,s})$ are determined by the current magnitude I_0 and by the geometrical parameters of the structure.

In the presence of the modulating field the MSW potential Ψ should be represented as a sum of the harmonics:[7]

$$\Psi = \sum_{m=-\infty}^{m=\infty} \sum_{l=1}^{\infty} \sum_{s=\pm 1} A_{mls} e^{i(smK_l z - m\Omega t)} e^{i(kz - \omega t)} + c.c., \tag{3}$$

where A_{mls} are the amplitudes of the harmonics. The harmonics are shifted relative to each other in frequency and wave number by the vector $(smK_1,\ m\Omega)$. In the zero approximation for the small parameter $\varepsilon = h/H \ll 1$ the harmonics do not interact and their dispersion is given by Eq. (1). When terms which are first order in ε are considered, the modulating field results in the interaction of harmonics. The strongest interaction takes place for harmonics with the neighboring numbers $m = 0$ and $m = \pm 1$ and $K = \pi/\Lambda$, when the following phase-matching conditions are satisfied:

$$k_{\pm} = k \pm K, \quad \omega(k_{\pm}) = \omega(k) \pm s\Omega, \quad s = \pm 1. \tag{4}$$

Figure 1 shows the MSBVW dispersion curves and demonstrates that the character of interaction depends on the

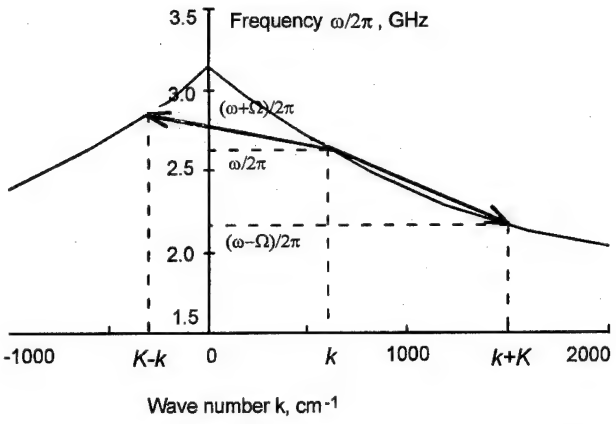

FIG. 1. Diagram for MSBVW scattering in a space-time periodic magnetic field.

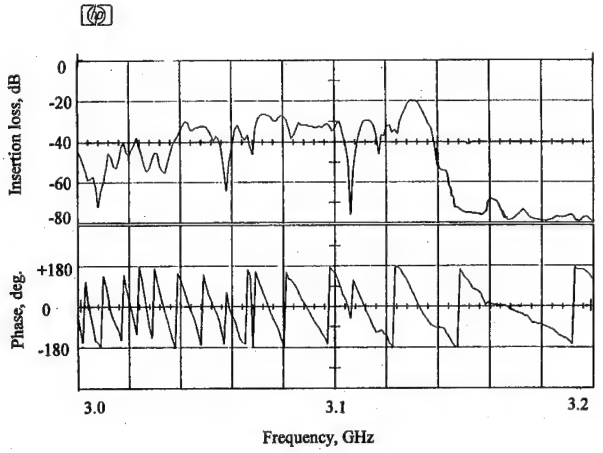

FIG. 2. Frequency response (a) and phase response (b) of the MSBVW transmission line containing a 500 μm-period meander imposed on the YIG film surface in the absence of modulation magnetic field.

value of the magnetostatic wave number k and the lattice wave number K. If $k>K$ only forward scattering takes place. If $k<K$ forward as well as backward scattering is allowed. In general the offsets of scattered wave frequencies ω_+ and ω_- from the incident wave frequency ω are different.

Interaction in a weak modulating field ($h/H \ll 1$) is well described by the theory of coupled waves. Solution of the problem to the first order in ε, gives the system of coupled equations:

$$i\frac{dA_+}{dt}+V_+\frac{dA_+}{dz}+i\delta\omega_+A_+ +\omega_C^+A_-=0, \tag{5a}$$

$$i\frac{dA_-}{dt}\pm V_-\frac{dA_-}{dz}+i\delta\omega_-A_- +\omega_C^-A_+=0, \tag{5b}$$

where $A_\pm$, $V_\pm=d\omega_\pm/dk$, $\delta\omega_\pm=\gamma\Delta H$, and $\omega_{C\pm}=\omega_C$ are the amplitudes, group velocities, damping coefficients, and coupling coefficients of interacting waves, respectively. The signs + and − in the second equation correspond to the forward and backward scattering, respectively.

The coupling coefficients for waves with identical (ω_{CS}) and different (ω_{CA}) symmetries are given by the expressions:

$$\omega_{CS}=\frac{h_z}{4\pi M}\frac{\omega_M(\omega_H^2+\omega_0^2)}{2\omega_H\omega_0}, \quad \omega_{CA}=\frac{ih_x}{4\pi M}\frac{\omega_M^2}{\omega_0}\sqrt{\frac{kd}{2}}. \tag{6}$$

From Eq. (6) one can see that coupling is strongest for identical modes and is almost independent on the frequency. The coupling for different modes, on the other hand, sharply decreases with decreasing wave number.

The efficiency η of the MSBVW interaction can be found by solving Eq. (6) with the proper boundary conditions at $z=0$ and $z=L$. For forward scattering and a strong coupling ($\omega_C \gg \delta\omega$) one can obtain the following expressions:

$$\eta_{F+}=\left|\frac{A_+(z=L)}{A(z=0)}\right| = \sqrt{\cos^2(\xi_1 L)+\frac{\Delta_\omega^2\Delta_V^2}{1+\Delta_\omega^2\Delta_V^2}\sin^2(\xi_1 L)}\cdot e^{-\xi_2 L}, \tag{7a}$$

$$\eta_{F-}=\left|\frac{A_-(z=L)}{A(z=0)}\right|=\frac{|\sin(\xi_1 L)|}{\sqrt{1+\Delta_\omega^2\Delta_V^2}}e^{-\xi_2 L}, \tag{7b}$$

where $\xi_1=(\omega_C/V)(1+\Delta_\omega^2\cdot\Delta_V^2)^{1/2}$, $\xi_2=\delta\omega V$, $\Delta_\omega=\Delta\omega/\omega$, $\Delta_V=\Delta V/V$, and $\Delta\omega=\omega_\pm-\omega$ and $\Delta V=V_\pm-V$ are the frequency detuning and difference in the group velocities of the interacting waves respectively, $V=(V_+ + V_-)/2$. The efficiency reaches its maximum at exact frequency matching condition $\Delta\omega=0$ for $\omega_C L \ll \pi/2$, and it may have a maximum at $\Delta\omega\neq 0$ when $\omega_C L \gg \pi/2$ is fulfilled. Amplitudes of the interacting waves decay and oscillate along the z axis as the group velocity V decreases due to the decrease of the effective interaction length. For the backward single-mode scattering on a long magnetic lattice ($L/V \gg \sqrt{\omega^2+\delta\omega^2}$), the efficiency is given as

$$\eta_B(L=\infty)\simeq\frac{\omega_B}{|\Delta\omega+i\delta\omega+\sqrt{(\Delta\omega+i\delta\omega)^2-\omega_C^2}|}. \tag{8}$$

From Eq. (8) it follows that the frequency detuning is $\Delta\omega\approx\omega_C$ in the case of strong coupling, and $\Delta\omega\approx\delta\omega$ in the case of strong damping. Estimation of the coupling coefficient and the efficiency of MSBVW scattering from Eqs. (6) and (7) and the values of parameters listed below give the following results: $\omega_C/2\pi\approx 30$ MHz, $\eta\approx 100\%$.

EXPERIMENTAL RESULTS AND DISCUSSION

The MSBVW transmission line containing an yttrium-iron-garnet (YIG) film ($d=20$ μm, $4\pi M=1750$ G, $\Delta H=0.5$ Oe), an alumina substrate with two microstrip transducers, and a meander line conductor deposited between them was used in the experiment. The length of the meander line was 7 mm with an aperture of 6 mm and a period of 100, 200, or

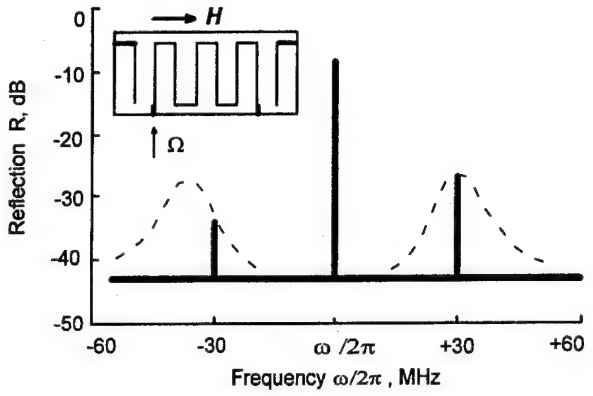

FIG. 3. Spectrum of a microwave signal reflected from the MSVBW line. The inset shows the geometry of experiment.

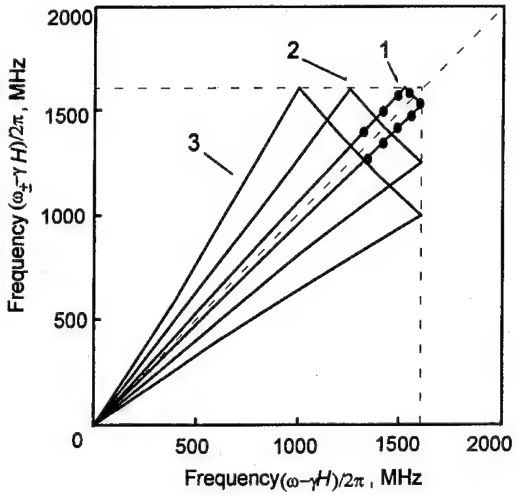

FIG. 4. Frequency synchronization curves for MSBVW scattering. Solid lines are calculation, dots are experimental data. Period of the lattice Λ is: 1–500 μm, 2–200 μm, and 3–100 μm.

500 μm. An ac current with magnitude up to 2 A and frequency of $\Omega/2\pi=20-150$ MHz was passed through the meander line, creating the modulation field with magnitude of up to $h\approx 10$ Oe. The structure was tangentially magnetized with an external dc magnetic field $H=550$ Oe. The MSBVW was excited by a continuous signal with a carrier frequency of $\omega/2\pi=2-3.5$ GHz. Spectra of transmitted and reflected signals were registered.

Figure 2 shows a frequency response (upper trace) and a phase response (lower trace) for the MSBVW line with the meander's period of 500 μm under stationary conditions (in the absence of modulating field). Imposing of the meander on the ferrite surface increased the ripple in the line frequency response and resulted in changes in the dispersion for the waves with wave numbers $k\Lambda<1$. One can see formation of rejection peaks resulting from MSBVW reflection by the meander conductors at the frequencies when the following condition is fulfilled:

$$k(\omega_N)=(\pi/2\ \Lambda)+2\pi N, \quad \text{where } N=1,2\ldots \tag{9}$$

Note, that the frequencies defined by Eq. (9) do not coincide with the frequencies defined by Eq. (4) for MSBVW scattering in a space-time periodic magnetic field.

Figure 3 shows a typical spectrum of a microwave signal reflected from the line in the presence of modulating magnetic field. Two lateral harmonics appeared in the spectrum due to MSBVW scattering in a space-time periodic magnetic field. The dashed curves in Fig. 3 show the resonance variation of the harmonics' power as a function of the modulation frequency. Different offsets of the harmonics' maxima from the input signal frequency were observed.

Figure 4 shows dependences of scattered wave frequencies $\omega_\pm$ versus the incident wave frequency ω (synchronization curves) calculated from Eq. (4) and Eq. (1). The main MSBVW mode and parameters which are corresponded to the experimental structure were used. Frequencies of backward scattered waves lie on the upper parts of the curves. The decrease of the meander line period leads to the broadening of the synchronization curve, so that the frequencies of the scattered waves $\omega_\pm$ are moved apart from the carrier frequency ω. The points in Fig. 4 correspond to experimentally observed MSBVW forward and backward scattering. Only the lower frequency ω_+ was observed in the spectrum of the transmitted signal when the input signal excited the wave with $k=K$. In this case the frequency ω_- corresponded to the wave with $k\approx 0$ and was not detected by the transducer.

The interaction bandwidth, defined as a half-height width of the resonance curve in Fig. 3, was equal to $\Delta\omega/2\pi\simeq 20$ MHz, which agrees with the calculation. The maximum interaction efficiency, calculated from experimental data and taking into account the MSBVW excitation losses, was equal to $\eta\simeq 10\%$.

Note that the considered effects may be used for effective excitation of higher order magnetostatic volume modes. From Eq. (7b) it follows that in the case of strong coupling ($\omega_C\gg\delta\omega$) the mode conversion with almost 100% efficiency takes place at the distance $L=(V/\Delta\omega_C)\ \text{arctg}(2\omega_C/\delta\omega)\simeq(\pi/2)(V/\omega_C)$. For the YIG film thickness of 20 μm and modulation field amplitude of $h=10$ Oe the conversion distance will be about $L\simeq 1$ mm.

This research was made possible in part by grant M6Q300 from the International Science Foundation and the Russian Government.

This paper is to use the spectral-domain technique to perform characteristic analysis of coupled microstrip patch resonators on ferrimagnetic substrates. Our formulation has been validated by comparing our result with the published data and showing an excellent agreement between them. Numerical computations have been performed to obtain dependence of resonant frequency on patch dimensions, offset and separation between the two patches, thicknesses of ferrimagnetic film and substrate. It has been seen that as the length of the patch increases the resonant frequency decreases. The larger the offset between the two patches the lower the resonant frequency. The separation between the two patches strongly affects the resonant frequency. It is also found that the resonant frequency increases as the width of the patch decreases. For the fixed dimensions, separation and offset, a thinner substrate results in a higher resonant frequency, and in contrast, a thinner ferrimagnetic film results in a lower resonant frequency. © *1996 American Institute of Physics.* [S0021-8979(96)75308-8]

I. INTRODUCTION

Recently there is a growing interest[1–4] in microwave integrated circuits (MICs) on ferrimagnetic substrates, especially on epitaxially grown yttrium iron garnet (YIG)/gadolinium gallium garnet (GGG) films due to rapid advances of material technology that makes it possible to contiguously grow and deposit magnetic thin films on different substrates. It is known that a variety of applications of MICs such as filters, oscillators, and tuned amplifiers are directly involved with utilizing microwave resonators.[5] It is the new material technology and demand of MICs on magnetized ferrites that drive investigation of microwave resonators on ferrimagnetic substrates. Great efforts have been made to study microwave resonators with different geometries on YIG/GGG structures.[6,7] It is of our interest in this work to investigate a new configuration of coupled microstrip patch resonators on YIG/GGG with an offset between the two coupled patches as illustrated in Fig. 1.

This paper is to use the spectral-domain technique[8] to study the coupled microstrip patch resonators on YIG/GGG structures. The boundary value problem of the coupled patch resonators is formulated in the spectral domain by the two-dimensional (2D) Fourier-transform. Then Galenkin's method is applied to obtain a system of matrix equations. As a result a secular equation is generated based on the determinant of the system equation and the resonant frequency of the coupled patch resonator can be solved for a given set of dimensions. To assure accuracy of numerical results and efficiency of numerical computations, a set of basis functions is chosen, which accurately represent expected resonant currents on each patch. Numerical computations have been performed. Our results have revealed that resonant frequency depends on patch dimensions, offset and separation between the two patches, and thicknesses of YIG and GGG.

II. FORMULATION

The geometry of the shielded structure of the coupled microstrip patch resonator on YIG/GGG is illustrated in Fig.

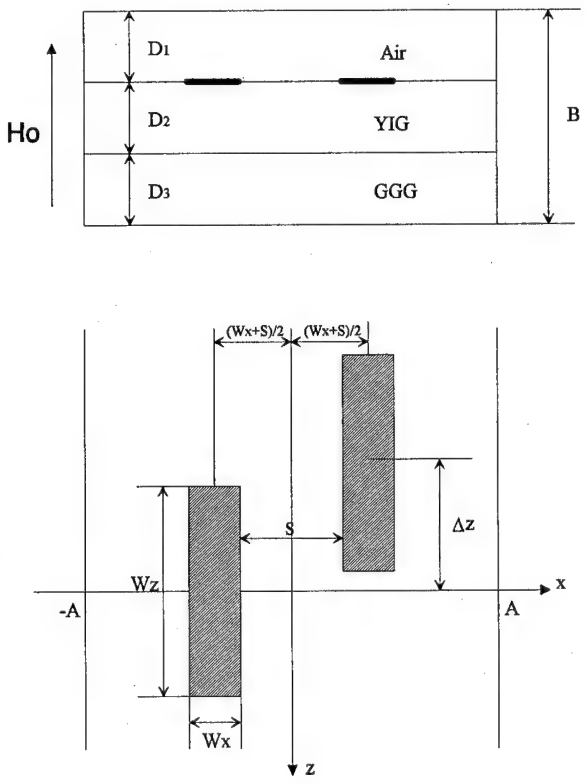

FIG. 1. Cross section and top views of coupled microstrip patch resonator. $2A$ and B the waveguide dimensions, (W_x, W_z) the patch width and length, S the separation between the two patches, Δz the offset between the two patches along the z-axis, and D_1, D_2, and D_3 thicknesses of air region, YIG, and GGG, respectively.

 0021-8979/96/79(8)/5733/3/$10.00

1. Two rectangular patches have dimensions of W_x and W_z, and are separated by a distance of S with an offset of Δz. Thicknesses of YIG and GGG are D_2 and D_3, respectively. A dc magnetic field is applied normal to the plane of YIG film, which is characterized by its static magnetization. Accordingly the permeability tensor of YIG is given as

$$\vec{\vec{\mu}}=\mu_0\begin{bmatrix}\mu & 0 & -j\kappa\\ 0 & 1 & 0\\ j\kappa & 0 & \mu\end{bmatrix} \tag{1}$$

with $\mu = 1 + \omega_h\omega_m/\omega_h^2 - \omega^2$, $\kappa = \omega\omega_m/\omega_h^2 - \omega^2$, where $\omega_h=\gamma\mu_0 H_0$, $\omega_m=\gamma\mu_0 M$, and γ, μ_0, ω, and H_0 are the gyromagnetic ratio, the free-space permeability, the operating frequency, and the internal field, respectively.

In order to formulate the boundary problem in the spectral-domain, the 2D Fourier transforms of every field component and patch currents in xz plane are taken:

$$\tilde{f}(\alpha_n,\gamma,\beta)=\int_{-\infty}^{\infty}\int_{-a}^{a} f(x,y,z)e^{j\alpha_n x+j\beta z}dxdz. \tag{2}$$

In this case summation index n takes on all integer values from minus to plus infinity, since the symmetry of the Green's function is perturbed by the off-diagonal terms in $\vec{\vec{\mu}}$ of YIG. The above definition of the transform allows the first derivatives with respect to x and z in the space domain to be converted to multiplicative factors in the spectral-domain.

With the transformation defined in Eq. (2) field components of E_x and E_z in YIG film are transformed into the spectral-domain and two coupled equations for $\tilde{E}_x$ and $\tilde{E}_z$ can be obtained to determine the solution to Maxwell's equation. Other field components can be found based on $\tilde{E}_x$ and $\tilde{E}_z$. The electric and magnetic fields in regions of air and GGG can be written as a superposition of TEy and TMy modes.[10] By enforcing the boundary conditions at each of interfaces the Green's function is yielded as follows:

$$\begin{bmatrix}\tilde{E}_z(\alpha_n,\beta)\\ \tilde{E}_x(\alpha_n,\beta)\end{bmatrix}=\begin{bmatrix}\tilde{Z}_{zz}(\alpha_n,\beta) & \tilde{Z}_{zx}(\alpha_n,\beta)\\ \tilde{Z}_{xz}(\alpha_n,\beta) & \tilde{Z}_{xx}(\alpha_n,\beta)\end{bmatrix}\begin{bmatrix}J_z(\alpha_n,\beta)\\ J_x(\alpha_n,\beta)\end{bmatrix}. \tag{3}$$

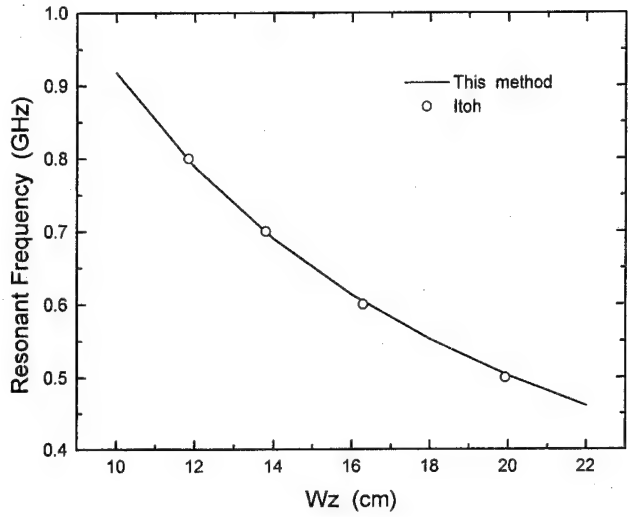

FIG. 2. Resonant frequency vs the patch length W_z with $\epsilon_{xx}=\epsilon_{yy}=\epsilon_{zz}=2.65$, $D_1=8.89$ cm, $D_2=1.27$ cm, $D_3=0$, $B=15.5$ cm, and $W_x=2$ cm.

The remaining task is to employ Galerkin's method along with Paserval's theorem to set up a system equation which includes two sets of homogeneous linear equations. These equations can be solved by setting the determinant of coefficients to zero and searching for the root to find the resonant frequency.

To successfully solve the system equation one must have a proper choice of basis functions that satisfy the edge conditions and have fast convergence properties. In this study the basis functions which are chosen to expand the patch currents are presented below:

$$\begin{aligned}J_x^{(e/o)}(x,z)&=J_x^-(x,z)\mp J_x^+(x,z),\\ J_z^{(e/o)}(x,z)&=J_z^-(x,z)\pm J_z^+(x,z),\end{aligned} \tag{4}$$

with

$$\begin{cases} J_x^-(x,z)=\dfrac{\sin\{(2\pi/W_x)[x+\frac{1}{2}(S+W_x)]\}}{\sqrt{1-\{(2\pi/W_x)[x+\frac{1}{2}(S+W_x)]\}^2}}\times\dfrac{\sin(\pi z/W_z)}{\sqrt{1-(2z/W_z)^2}}, & -\left(\dfrac{S}{2}+W_x\right)<x<-\dfrac{S}{2} \text{ and } -\dfrac{W_z}{2}<z<\dfrac{W_z}{2}\\ J_x^+(x,z)=\dfrac{\sin\{(2\pi/W_x)[x-\frac{1}{2}(S+W_x)]\}}{\sqrt{1-\{(2\pi/W_x)[x-\frac{1}{2}(S+W_x)]\}^2}}\times\dfrac{\sin[(\pi/W_z)(z-\Delta z)]}{\sqrt{1-[(2(z-\Delta z)/W_z)]^2}}, & \dfrac{S}{2}<x<\dfrac{S}{2}+W_x \text{ and } \Delta z-\dfrac{W_z}{2}<z<\Delta z+\dfrac{W_z}{2}\end{cases}$$

$$\begin{cases} J_z^-(x,z)=\dfrac{1}{\sqrt{1-\{(2\pi/W_x)[x+\frac{1}{2}(S+W_x)]\}^2}}\times\dfrac{\cos(\pi z/W_z)}{\sqrt{1-(2z/W_z)^2}}, & -\left(\dfrac{S}{2}+W_x\right)<x<-\dfrac{S}{2} \text{ and } -\dfrac{W_z}{2}<z<\dfrac{W_z}{2}\\ J_z^+(x,z)=\dfrac{1}{\sqrt{1-\{(2\pi/W_x)[x-\frac{1}{2}(S+W_x)]\}^2}}\times\dfrac{\cos\left[\dfrac{\pi}{W_z}(z-\Delta z)\right]}{\sqrt{1-[2(z-\Delta z)/W_z]^2}}, & \dfrac{S}{2}<x<\dfrac{S}{2}+W_x \text{ and } \Delta z-\dfrac{W_z}{2}<z<\Delta z+\dfrac{W_z}{2}\end{cases}$$

where the superscription (e/o) denotes even and odd modes, respectively.

III. NUMERICAL RESULTS

In order to validate our formulation and numerical results we simplify the configuration, in which the thickness of GGG is reduced to zero, $S+W_x$ is set to be zero such that the two patches overlap, permeability tensor of YIG is chosen to be that utilized in Ref. 9. Comparison is made between our results and those in Ref. 9 and illustrated in Fig. 2. It is clear that our results agree very well with the published data.

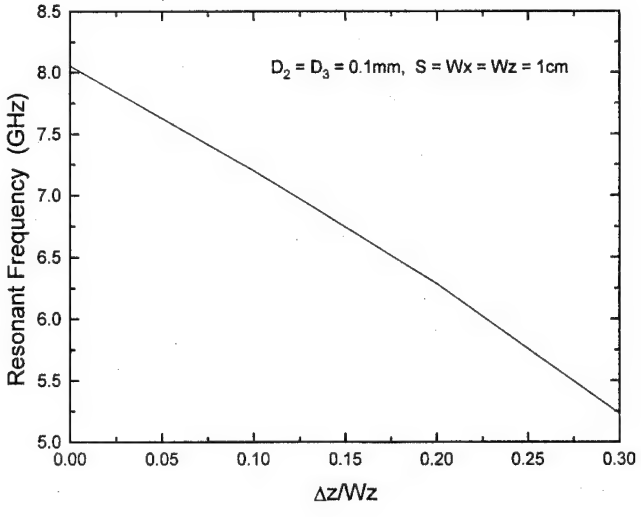

FIG. 4. Resonant frequency vs offset Δz.

Numerical computations have been performed with $\mu_0 H_0=0.1T$, $\mu_0 M=0.175T$, permittivity for YIG and GGG $\epsilon_r=12.3$, $A=7.75$ cm and $B=6$ cm throughout this paper unless stated elsewhere. Both even and odd modes of resonance were calculated. Since there is a slight difference between them, only is the even mode presented in this paper. Figure 3 demonstrates dependence of resonant frequency on the patch length W_z. It is observed that the resonant frequency decreases with W_z. Impacts of thicknesses of YIG and GGG on resonant frequency are illustrated in Fig. 3. For a given set of patch dimensions (W_x, W_z), separation (S) and offset (Δz), a thinner substrate GGG results in a higher resonant frequency, and in contrast, a thinner YIG film results in a lower resonant frequency. Influence of offset between the two patches on resonant frequency was investigated. Figure 4 shows that the resonant frequency decreases with Δz for a given set of (W_x, W_z), S, and thicknesses (D_2 and D_3) of YIG and GGG. Width (W_x) of the resonant patch has the same impact on the resonant frequency as W_z except for $W_x<0.2$ cm (see Fig. 5). The resonant frequency slightly increase with W_x as W_x is less than 0.2 cm, and then decreases with W_x rapidly.

We have studied the physical properties of a high directivity microstrip directional coupler on a single-layered ferrite substrate under the influence of an external dc magnetic field H_0. We also present an analysis of the coupled microstrip lines on a ferrite-dielectric substrate. Our method of calculation, which is done in the spectral domain, is based upon a combination of the Hertz vector potentials and the Galerkin numerical technique. The dyadic Green functions for the coupled microstrip lines are also obtained. We consider the even and odd modes of propagation, with the characteristic impedances and normalized phase constants of these artificial structures obtained as a function of their geometry. Special attention is given to the determination of a high directivity for the coupler, by equating the phase velocity of the even and odd modes of propagation which, in turn, is obtained throughout the variation of the applied magnetic field H_0. © *1996 American Institute of Physics.* [S0021-8979(96)75408-X]

The development of microstrip circuits on magnetized ferrimagnetic layers, such as microstrip antennas and resonators, is presently receiving a growing interest. This is mainly due to the fact that these devices/circuits performance can be tailored by changing the external dc magnetic field magnitude or orientation.[1] In this context, many works were devoted not only to the analysis of finlines and slotlines, but also to study microstrip lines with several layers, including magnetic ones (see Refs. 2 and 3, and the references therein). Furthermore, the study of microstrip lines and its application in the development of planar phase shifters was reported and discussed by Bolioli *et al.*,[4] taking into account the advantage of the nonreciprocal transmission effects, which could be controlled by an externally dc magnetic bias field.

The aim of this work is to study the properties of a microstrip directional coupler on a single-layered ferrite substrate under the influence of an external dc magnetic field H_0, with a special attention to the case depicted in Fig. 1, which guarantees its high directivity. Our analysis is done in two steps: in the first one, we characterize the coupled microstrip lines in order to determine the characteristic impedances and the normalized phase constants as a function of the frequency and its geometry. We achieve these expressions by using a combination of the Hertz vector potentials, Parseval's theorem and the Galerkin method within the spectral domain.[3,5] The analysis is performed by considering that the ferrite substrate is magnetized by an external dc magnetic field applied perpendicularly to the ground plane. The symmetry of the structure allows us to study the even and odd modes of propagation. In the second step, the theory of transmission lines is used to express the main parameters of the directional coupler, namely the coupling factor and the directivity, in terms of its physical characteristic and geometry. Numerical results are then shown to illustrate our theoretical predictions.

The multilayered geometry under consideration is depicted in Fig. 1. The coupled strips of width w and uniform spacing s are assumed to be infinitely thin and perfectly conducting. Region 1 is occupied with the ferrite layer, and it has thickness d, scalar permittivity ϵ_1 and a tensor permeability $\vec{\mu}$. We also assume that a uniform external magnetic field H_0 is applied perpendicularly to the substrate to saturate the sample, and then removed, so that the magnetic permeability tensor is given by:

$$\mu=\begin{bmatrix} \mu & 0 & ik \\ 0 & \mu_0 & 0 \\ -ik & 0 & \mu \end{bmatrix}, \tag{1}$$

where the components μ and k depend on the ferrite characteristics and operating frequency, i.e.:

$$\frac{\mu}{\mu_0}=1-\frac{\gamma^2 H_0 4\pi M_s}{\omega^2-(\gamma H_0)^2}; \quad \frac{k}{\mu_0}=\frac{\gamma 4\pi M_s}{\omega^2-(\gamma H_0)^2}. \tag{2}$$

Here, the saturation magnetization of the ferrite is $4\pi M_s$, and γ and ω are the gyromagnetic ratio and the operating frequency, respectively. Region 2, which has a thickness h, is filled up with a dielectric material, whose permittivity is given by ϵ_2. Region 3 is the air with parameters ϵ_0 and μ_0 denoting the free-space values of permittivity and permeability, respectively.

The analysis in the spectral domain is carried out initially for the determination of the impedance matrix, through the use of the Hertz vector potentials oriented along the y-axis (the same orientation of the magnetic field H_0). The components of the electrical field can be given in terms of the current density at one of the conducting lines. Taking into

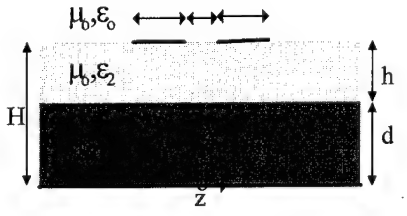

FIG. 1. Schematic representation of the coupled microstrip line supported by a ferrite substrate used in this paper.

 0021-8979/96/79(8)/5736/3/$10.00

account the spectral domain formulation, these components can be determined after using the appropriate continuity and boundary conditions in Fourier transform domain, i.e.:

$$\begin{bmatrix}\tilde{E}_x(\alpha,H)\\ \tilde{E}_z(\alpha,H)\end{bmatrix}=\begin{bmatrix}\tilde{Z}_{xx}(\alpha,H) & \tilde{Z}_{xz}(\alpha,H)\\ \tilde{Z}_{zx}(\alpha,H) & \tilde{Z}_{zz}(\alpha,H)\end{bmatrix}\begin{bmatrix}\tilde{J}_x(\alpha,H)\\ \tilde{J}_z(\alpha,H)\end{bmatrix}, \quad (3)$$

where α represents the spectral variable, $\tilde{E}_x$, $\tilde{E}_z$, and $\tilde{J}_x$, $\tilde{J}_z$ are the Fourier transforms of the tangential electrical field and the current density components in the conducting strip. The elements of the dyadic impedance Green's function can now be found, and are given by:

$$\tilde{Z}_{xx}(\alpha,\beta,H)=i\frac{\alpha\beta}{\omega(\alpha^2+\beta^2)}\left[F_1+\frac{\beta}{\alpha}F_2-F_3+\frac{\alpha}{\beta}F_4\right], \quad (4)$$

$$\tilde{Z}_{xz}(\alpha,\beta,H)=-i\frac{\alpha\beta}{\omega(\alpha^2+\beta^2)}\left[\frac{\beta}{\alpha}F_1+F_2-\frac{\beta}{\alpha}F_3+F_4\right], \quad (5)$$

$$\tilde{Z}_{zx}(\alpha,\beta,H)=i\frac{\alpha\beta}{\omega(\alpha^2+\beta^2)}\left[\frac{\alpha}{\beta}F_1-F_2+\frac{\beta}{\alpha}F_3-F_4\right], \quad (6)$$

$$\tilde{Z}_{zz}(\alpha,\beta,H)=i\frac{\alpha\beta}{\omega(\alpha^2+\beta^2)}\left[-F_1-\frac{\alpha}{\beta}F_2+F_3+\frac{\beta}{\alpha}F_4\right], \quad (7)$$

where β is the single microstrip phase constant, and

$$F_1=i\omega^2\mu_0\epsilon_1\frac{k}{\mu}\frac{g_3g_5}{g_1g_2};\quad F_2=\omega^2\mu_0\frac{g_5}{\gamma_0 g_2} \quad (8)$$

$$F_3=i\omega^2\mu_0\epsilon_1\frac{k}{\mu}\frac{\gamma_0}{\gamma_2\gamma_{e1}g_1}\coth(\gamma_{e1}d)\tanh(\gamma_2h);$$

$$F_4=\frac{\gamma_0 g_4}{g_1}\coth(\gamma_{e1}d)\tanh(\gamma_2h). \quad (9)$$

Also, the remaining parameters appearing in Eqs. (4) to (9) are given by

$$g_1=\epsilon_0+\frac{\epsilon_1}{\gamma_{e1}}\left[\frac{\epsilon_0}{\epsilon_2}\gamma_2\tanh(\gamma_2h)+\gamma_0\right]\coth(\gamma_{e1}d)+\epsilon_2\frac{\gamma_0}{\gamma_2}\tanh(\gamma_2h), \quad (10)$$

$$g_2=\frac{\mu}{\mu_0}+\gamma_{h1}\left[\frac{1}{\gamma_2}\tanh(\gamma_2h)+\frac{1}{\gamma_0}\right]\coth(\gamma_{h1}d)+\frac{\mu}{\mu_0}\frac{\gamma_2}{\gamma_0}\tanh(\gamma_2h), \quad (11)$$

$$g_3=\frac{1}{\gamma_{e1}}\left[1+\frac{\gamma_0}{\gamma_2}\tanh(\gamma_2h)\right]\coth(\gamma_{e1}d), \quad (12)$$

$$g_4=\frac{\gamma_2}{\gamma_{e1}}\left[\frac{\epsilon_1}{\epsilon_2}+\frac{\gamma_{e1}}{\gamma_2}\tanh(\gamma_{e1}d)\coth(\gamma_2h)\right];$$

$$g_5=\left[\frac{\mu}{\mu_0}+\frac{\gamma_{h1}}{\gamma_2}\coth(\gamma_{h1}d)\tanh(\gamma_2h)\right]. \quad (13)$$

Here,

$$\gamma_0^2=(\alpha^2+\beta^2-k_0^2);\quad \gamma_{h1}^2=\frac{\mu}{\mu_0}(\alpha^2+\beta^2-k_1^2);$$

$$\gamma_e^2=(\alpha^2+\beta^2-k_2^2) \quad (14)$$

$$\gamma_1^2=(\alpha^2+\beta^2-k_3^2);\quad k_0^2=\omega^2\mu_0\epsilon_0;\quad k_1^2=\omega^2\mu_0\epsilon_1 \quad (15)$$

$$k_2^2=\omega^2\left(\frac{\mu^2-k^2}{\mu}\right)\epsilon_1;\quad k_3^2=\omega^2\mu_0\epsilon_2. \quad (16)$$

In order to obtain the characteristic equation for the propagation constants, we use Galerkin's procedure along with Parseval's theorem. The solution of Eq. (3) depends upon a reasonable choice of basis functions, and they should contain the edge conditions of the currents. It is considered that the current distribution on each strip is the same as those given for a single strip.[6] Once the propagation constant is available, the characteristic impedance can be evaluated based on the power-current definition.[7]

The study of the coupling among transmission lines, as the microstrips shown in Fig. 1, requires the coupling factor in a frequency-dependent form be written like:[8]

$$C(\theta)=\frac{iC\sin\theta}{(1-C^2)^{1/2}\cos\theta+i\sin\theta}, \quad (17)$$

where C, the coupling factor at the central frequency, is given by

$$C=\frac{Z_{0e}-Z_{0o}}{Z_{0e}+Z_{0o}}. \quad (18)$$

Here, Z_{0e} and Z_{0o} are the even and odd mode characteristic impedances, respectively, and $\theta=\beta l$, l being the length of the coupled region which is determined from the average of the even and odd phase constants, β_e and β_o.

The directivity, which is the coupling which can occur to the theoretically isolated port, is:[8]

$$D=\left|\frac{\chi Z_{0e}-\psi Z_0 Z_{0o}}{\chi(Z_{0e}Z_0\cos\Theta_e+iZ_{0e}^2\sin\theta_e)-\psi(Z_{0o}Z_0\cos\theta_o+iZ_{0o}^2\sin\theta_o)}\right|, \quad (19)$$

where

$$\chi=2Z_{0o}Z_0\cos\theta_o+i(Z_{0o}^2+Z_0^2)\sin\Theta_o, \quad (20)$$

$$\psi=2Z_{0e}Z_0\cos\theta_e+i(Z_{0e}^2+Z_0^2)\sin\theta_e, \quad (21)$$

with Z_0 being the characteristic impedance of each individual line and θ_e and θ_o being the even and odd electrical lengths, respectively.

We show now numerical results for microstrip directional couplers containing a magnetized ferrite perpendicu-

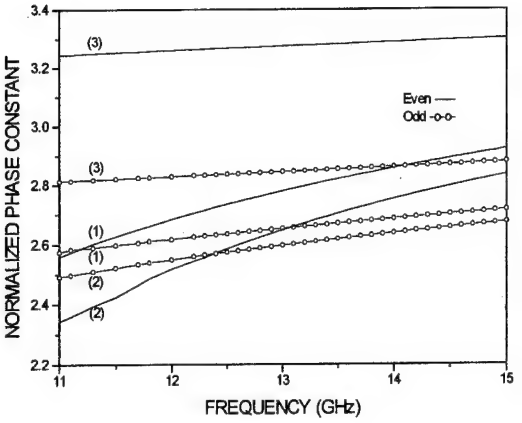

FIG. 2. Normalized phase constant as a function of the frequency for the parameters given in the main text. The labels (1), (2), and (3) refer to the cases where H_0=900 Oe, H_0=1300 Oe, and the isotropic situation.

larly to the substrate surface. We present results for the even and odd modes of propagation as well as for the coupler's parameters as a function of the frequency, various structural parameters, and the biasing magnetic field.

A ferrite substrate, with a saturation magnetization $4\pi M_s$=2150 G, a gyromagnetic ratio γ=2.855 MHz/Oe, a relative dielectric permittivity $\epsilon_{rl}=\epsilon_l/\epsilon_0=12.7$, and a thickness d=1.0 mm, was considered. The coupled strips have w=1.0 mm and s=0.5 mm.

Figure 2 presents the normalized phase constants for the odd and even modes of propagation in parallel coupled microstrip lines. The cases labeled (1) and (2) correspond to the utilization of a ferrimagnetic substrate with h=0 in Fig. 1, and the external magnetic field equal to 900 and 1300 Oe, respectively. The case with the label (3) corresponds to a numerical convergence for the isotropic case, which is obtained from (1) provide $\mu=\mu_0$ and k=0. Observe that the utilization of a ferrite substrate permits a reduction, and even an equalization, in the difference between the values of the phase velocities of the coupled modes. This represents a very

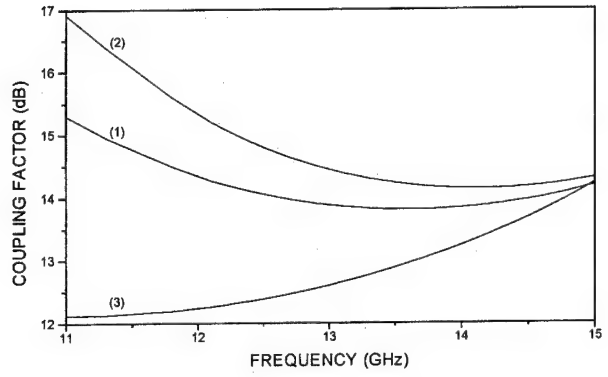

FIG. 3. Coupling factor as a function of the frequency for the same parameters and cases presented in Fig. (2).

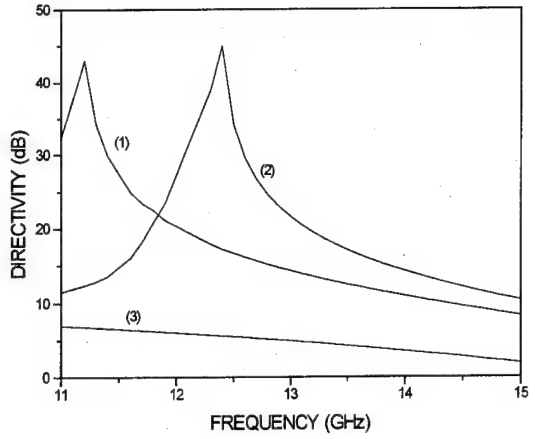

FIG. 4. Directivity as a function of the frequency for the same parameters and cases presented in Fig. (2).

interesting result, mainly if one is interested on the project of high directivity couplers.

In Fig. 3 we show the behavior of the coupling factor against the frequency, for the same cases discussed in Fig. 2. The coupled region length is 2.35 mm. As we expected, the strength of the coupling shows a significant dependence with the frequency, particularly for lower frequencies.

Figure 4 shows the curves obtained for the directivity as a function of the frequency, considering again the same three situations discussed in the previous figures. The best values of the directivity were obtained when it was considered a ferrite substrate, especially in the vicinities of the frequencies which equalize the phase velocities of the even and odd modes of propagation, observed in Fig. 2.

We have performed an analysis, within the spectral domain regime, for microstrip directional couplers supported by a ferrite material. It was shown that the utilization of this kind of substrate allows the development of high directivity couplers, through the variation of the magnitude of H_0. Agreement was observed when we compare our results with those presented by Janiczak and Kitlinski[9] for coupled symmetric microstrip lines, and by Alexópoulos[10] for the coupling factor and directivity.

We thank the Brazilian Research Agency CNPq for partial financial support.

We have included losses in the analysis of a $3N$-port stripline/microstrip circulator and have reformulated the circulation conditions previously postulated for the lossless case. Our calculations have been compared to three published data on circulator designs biased below and above ferrimagnetic resonance. Scattering parameters at each port have been calculated as a function of assumed material losses and coupling capacitance of a multiport circulator. Wide transmission band or wide stop bands may be possible for a six port circulator biased above ferrimagnetic resonance.
 [S0021-8979(96)75508-6]

INTRODUCTION

The present theory is able to calculate reasonably well the required external magnetic field and operating frequency at which the circulation condition of a stripline/microstrip circulator is obeyed. However, the present theory is not able to predict insertion loss or the coupling efficiency between ports at circulation. Clearly, the insertion loss must somehow be related to the intrinsic losses of the ferrite, both magnetic and electric losses. In this paper, we want to elevate this qualitative notion to a more precise quantitative prediction of insertion loss at circulation based upon intrinsic loss of the ferrite and external microwave loading to the circulator. We have avoided the traditional approach which relies on the use of Bessel functions which take only real numbers as arguments, since in the previous calculations intrinsic losses are assumed to be zero. Instead, new computational algorithms have been developed which directly process complex numbers upon which the circulator's interport impedances can be conveniently calculated. Also, previous theoretical formulations was based upon the assumption that at the circulation condition the transmission efficiency between the input and the circulation ports was 100% and the isolation port was zero. This assumption cannot be applied here. We need to relax this principle by allowing the circulation transmission to be a maximum, since there may be dissipation included in the ferrite. This suggests a theoretical formalism in which some sort of mathematical extremum conditions are derived from the equation of motion of the magnetization. We find that our formulation predicts exactly the same circulation conditions as derived by previous papers using the conventional formalism.[1–3] Once we were able to predict the circulation conditions calculated by others, we then calculated the insertion loss, isolation efficiency, and circulation transmission efficiency for various cases by including the ferrite losses in the formalism. Calculations compare quite well with measurements.[1–3]

FORMULATION

In this paper we define a $3N$-port circulator to be a multi-port ferrite-junction circulator in which three ports are through ports capable of signal circulation in the normal sense and the other $(3N\text{-}3)$ ports are open-circuited ports which are used to provide additional capacitance tuning. The threefold symmetry of the junction requires ports m, $m+N$, and $m+2N$ to be characterized by the same parameters. Here m is an integer and $1\leqslant m\leqslant N$. The azimuthal angle at the center of port α is denoted as ϕ_α and $\phi_\alpha=2\pi(\alpha-1)/3N$ for $1\leqslant\alpha\leqslant 3N$. The port suspension angle at port α is $2\theta_\alpha$. Port 1 will be considered as the input port, and ports $1+N$ and $1+2N$ are either the transmission port or the isolation port, respectively.

The ferrite disk is of radius R, height h, whose dielectric constant, dielectric loss tangent, saturation magnetization, ferrimagnetic resonance (FMR) linewidth are denoted as ϵ_i, $\tan\delta$, $4\pi M_i$, ΔH, respectively. The ferrite disk is surrounded by a dielectric matching material filling the space between the metal strip and the ground plane(s) making up for the stripline/microstrip feeder lines. The dielectric constant of the dielectric filling material is denoted as ϵ_i.

The six-port circulator has been previously formulated and reported in Ref. 3. We derive in this paper the formulation of a general $3N$-port circulator in which the ports may not necessarily have the same port angles. Denote a_{in} as the incident rf-magnetic field at port 1 and a_α, $1\leqslant\alpha\leqslant 3N$, as the average rf-magnetic field at port α. Analogous to the derivations in Ref. 3 a_α can be solved in terms of a_{in} from the following $3N$ coupled linear equations:

$$\sum_{\beta=1}^{3N}(Z_\alpha\delta_{\alpha\beta}+G_{\alpha\beta})a_\beta=2a_{\text{in}}Z_a\delta_{\alpha 1},\qquad \text{for } 1\leqslant\alpha\leqslant 3N, \tag{1}$$

where $G_{\alpha\beta}$ are the interport impedances given by

$$G_{\alpha\beta}=-iZ_f\left(\frac{\theta_\beta}{\pi}\right)\sum_{n=-\infty}^{\infty}\left[\frac{n}{x}\left(1-\frac{\kappa}{\mu}\right)-\frac{J_{n+1}(x)}{J_n(x)}\right]^1\left(\frac{\sin n\theta_\alpha}{n\theta_\alpha}\right)\left(\frac{\sin n\theta_\beta}{n\theta_\beta}\right)e^{\text{in}(\phi_\alpha-\phi_\beta)},$$

$$x=kR,\quad k=\omega(\mu_{\text{eff}}\epsilon_f)^{1/2}/c,$$

$$Z_d=(\mu_0/\epsilon_d\epsilon_0)^{1/2},\quad Z_f=(\mu_{\text{eff}}\mu_0/\epsilon_f\epsilon_0)^{1/2},$$

$$\mu_{\text{eff}}=(\mu^2-\kappa^2)/\mu, \quad \mu=1+f_0 f_m(f_0^2-f^2),$$
$$\kappa=f f_m/(f_0^2-f^2),$$
$$f_m=4\pi\gamma M_s, \quad f_0=\gamma H_i. \tag{2}$$

H_i is the internal dc magnetic field, c denotes the speed of light in vacuum, γ the gyromagnetic ratio, and $\delta_{\alpha\beta}$ is the Kronecker delta function. Finally, the wave impedance viewed at port α is

$$Z_\alpha=iZ_d \cot(x_\alpha\omega\sqrt{\epsilon_{re}}/c).$$

For stripline port $\epsilon_{rc}=\epsilon_d$, and for microstrip port $\epsilon_{rc}=1+q(\epsilon_d-1)$, where q denotes the filling factor of the dielectric in the microstrip transmission line.

We note that Eq. (2) can be evaluated only if $x(=kR)$ is real. However, when material becomes lossy, both dielectric and magnetic imperfections need to be accounted for explicitly. For lossy ferrites the dielectric constant ϵ_f shall be replaced by $\epsilon_f(1+i\tan\delta)$ and the internal field H_i by $H_i-(i\Delta H/2)f/f_i$, where f_i denotes the frequency at which the linewidth ΔH was measured (usually at 10 GHz). As such, x becomes a complex number and Eq. (2) can no longer be appropriate for numerical evaluation. Other numerical schemes have to be used as an alternative. Actually, Eq. (2) has been purposely cast in the form which facilitates complex-number calculation. That is, the ratio between two Bessel functions of subsequent orders can be expressed in a form involving continued fractions:[4]

$$\frac{J_\nu(z)}{J_{\nu-1}(z)}=\frac{1}{2\nu z^{-1}-}\,\frac{1}{2(\nu+1)z^{-1}-}\,\frac{1}{2(\nu+2)z^{-1}-}\cdots, \tag{3}$$

in which z can be a complex number and ν a real number (not necessarily an integer). Equation (3) converges rather rapidly and the radii of convergence in the z and the ν variables are both infinite.

The scattering parameters can now be calculated as

$$S_{11}=1-a_1/a_{\text{in}}, \quad S_{(1+N)1}=-a_{1+N}/a_{\text{in}},$$
$$S_{(1+2N)1}=-a_{1+2N}/a_{\text{in}}. \tag{4}$$

The circulation conditions in the presence of material imperfections are rephrased as

$$|a_{11}|=\text{maximum},$$
$$|a_{1+N}|=\text{minimum (or maximum)}, \tag{5}$$
$$|a_{1+2N}|=\text{maximum (or minimum)}.$$

Equation (5) describes the case when port $1+N$ is the transmission (isolation) port and port $1+2N$ is the isolation (transmission) port. We note that Eq. (5) needs to be maximized/minimized for at least two conditions, the third one will hold automatically due to the three-fold symmetry of the ferrite junction. Optimization of scattering parameters, or searching for circulation conditions, Eq. (5), needs to be performed with respect to, at least, two independent circulator variables with others being treated as parameters. Traditionally, ϵ_i and R were used as variables to solve for the "lossless" circulation conditions, $|a_{11}|=1$ and, say, $|a_{1+N}|=0$, other parameters are specified beforehand, such as the desired circulation frequency, port suspension angle(s), internal field, and other parameters characterizing the ferrite material. In this paper we may use any of the quantities, f, θ_α, ϵ_i, R, and/or H_i as the independent variables exploiting the so-called multidimensional simplex method in optimizing the circulation conditions, Eq. (5). Multidimensional simplex method,[5] although it is relatively slow in comparison with other slope-related methods, is quite robust and efficient in the present calculations.

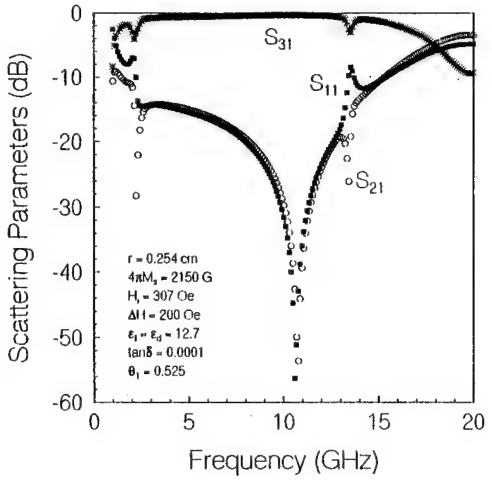

FIG. 1. Optimization of Wu and Rosenbaum's circulator design for better isolation and insertion loss.

RESULTS

Figure 1 shows the calculated scattering parameters of the optimized design of the three-port circulator proposed by Wu and Rosenbaum.[1] In this design the ferrite used was magnesium ferrite (TT1-390, Trans-Tech, MD) possessing the following parameters: $4\pi M_i=2150$ G, $\Delta H=540$ Oe, $\epsilon_f=12.7$ $(=\epsilon_d)$, and tan $\delta=2.5\times10^{-4}$. In the calculation we also use $r=0.254$ cm, and $\theta_1=0.525$ rad. After optimization of Eq. (5) with respect to H_i and f, we obtain $H_i=307$ Oe

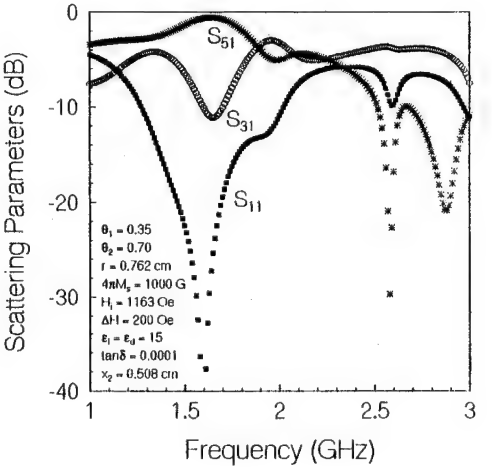

FIG. 2. Optimization of Riblet's sixport circulator design allowing for wideband transmission operation.

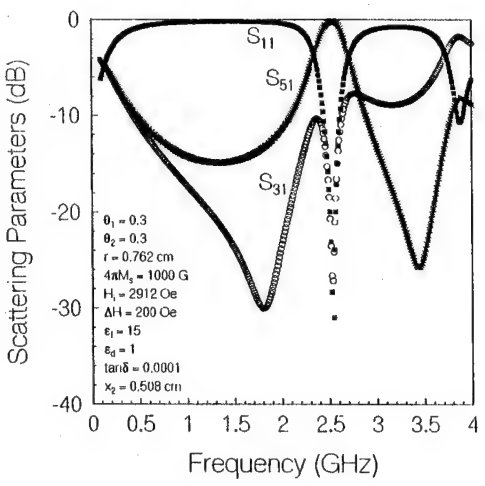

FIG. 3. Optimization of Riblet's sixport circulator design allowing for wide stop band protection.

with an insertion loss -0.255 dB at the central circulation frequency $f_0=10.629$ GHz. The transmission band extends from 2.615 to 12.97 GHz with insertion loss -1.01 and -0.595 dB, respectively. The measured absorption peak in S_{11} at 13.2 GHz due to excitation of second-order harmonic can also be identified in Fig. 1. However, the wide-band feature of the above circulator was not measured experimentally. It was realized that the internal field has to be uniformized before the real bandwidth of the circulator can be measured.[6]

Figure 2 shows the calculated scattering parameters for a six-port stripline circulator operating above FMR. This design was originally proposed by Riblet which was intended for high power wideband operation.[2] For this design $r=0.762$ cm, $4\pi M_i=1000$ G, $\epsilon_1=\epsilon_d=15$, $\Delta H=200$ Oe, $\tan\delta=0.0001$, and $x_1=0.508$ cm. The external field used by Riblet was 2000 Oe and the port suspension angles were $\theta_1=\theta_2=0.425$. However, we found that Riblet's design has not been optimized. After optimizing the circulation conditions, Eq. (5), using H_i, θ_1, θ_2, and f as the independent variables we found that $\theta_1=0.35$ rad, $\theta_2=0.70$ rad, $H_i=1163$ Oe with the central transmission frequency located at 1.64 GHz (-0.56 dB insertion loss). The transmission band extends from 1.37 to 1.77 GHz and the bandwidth is about 24.4% of the transmission frequency.

Another circulator design using Riblet's parameters which may have potential applications is shown in Fig. 3. In this design $\theta_1=\theta_2=0.3$, $\epsilon_d=1$ ($\neq\epsilon_1$), and $H_i=2912$ Oe. As shown in Fig. 3 the calculated insertion loss minimum locates at 2.528 GHz with a value of -0.193 dB. The design does not show wideband operation, since the bandwidth is only about 6.1% of the transmission frequency. However, the advantage of using the design of Fig. 3 is that it is easy to be fabricated, since air can be conveniently used as the dielectric filling material providing the greatest dielectric breakdown voltage. Furthermore, it is seen in Fig. 3 that the transmission band is surrounded by two wide stopbands where the circulator becomes highly reflective (reflection loss -0.3 and -1 dB, respectively). The circulator can be thus deployed in front of a frequency selective radome which, while it is intended to transmit/receive signals at the desirable frequencies near 2.528 GHz, blocks effectively other unwanted jamming/interfering signals above and below the transmission band in wide frequency ranges to protect the electronics inside the radome.

Experimental determination of an effective demagnetization factor for nonellipsoidal geometries

Guobao Zheng, M. Pardavi-Horvath, and Xiaohua Huang
Institute for Magnetics Research, The George Washington University, Washington, DC 20052

B. Keszei and J. Vandlik
Institute for Materials Science, H-1525 Budapest, P.O.B. 49, Hungary

For a nonellipsoidal magnetic sample, the internal magnetic field $\mathbf{H}_{\text{int}}(\mathbf{r})$ is inhomogeneous even when a uniform external magnetic field $\mathbf{H}_{\text{app}}$ is applied to it. In such a case the elements of the demagnetizing tensor become position-dependent, $\mathbb{N}=\mathbb{N}(\mathbf{r})$. The knowledge of the *local* demagnetization tensor is important for the analysis and design of devices using finite size and shape magnetic elements. The demagnetizing tensor elements can be calculated analytically and/or numerically, however, often a quick check of the extent of the inhomogeneity of the magnetization distribution of a sample, or a single approximate value of the demagnetizing factor for the given non-ellipsoidal geometry, would be satisfactory. Therefore a method to define and measure an effective demagnetizing tensor element N_{eff} for rectangular and circular shapes has been developed. Experiments, performed on 2×4 mm^2 yttrium iron garnet samples up to 220 μm thickness, show that the analytical approximation can be used to define an N_{eff}. But even for a length/thickness ratio of 200, the thin film approximation still is in an error of 3.7%. © *1996 American Institute of Physics.* [S0021-8979(96)75608-9]

I. INTRODUCTION

Ferrite elements are widely used in microwave devices, isolators, circulators, and phase shifters. The traditional elements have a spherical shape and uniform magnetization.

As the industry turns to monolithic integrated/hybrid nonreciprocal microwave devices, planar geometries have to be used. At microwave frequencies, the size of a distributed microstrip circulator is related to the wavelength in the ferrite ($\sim r/2$).

The magnetization distribution in modern planar ferrite elements, due to the nonellipsoidal shape of the ferrite, is no more uniform. This gives rise to nonuniform internal fields, affecting the operation of the device. In planar microwave devices, the thickness of the layers is in the range of 100 μm, and the lateral dimensions are comparable to the thickness so, the aspect ratio cannot be regarded as infinite. As a result, demagnetizing effects cannot be neglected. Due to inhomogeneous demagnetizing fields, the value of the external bias field in general has to be increased as compared to the case of the spherical geometry. Another problem, arising from the fact that the ferrite element is not a thin film, is that one has to solve the problem in three dimensions. The distribution of the internal magnetization of the ferrite and the electromagnetic field around the edges has a great important for device performance.[4] In designing magnetic devices, the range of N_{zz} is the measure of the inhomogeneity of the internal field in the sample.

The inhomogeneity of magnetization should be taken into account in device design, i.e., the knowledge of *local* distribution of demagnetization factors $N_{ij}(x,y,z)$ is necessary. If the *local* demagnetizing tensor is known, the equilibrium distribution of the magnetization can be calculated by micromagnetic methods.

The demagnetizing correction is nontrivial for samples in open magnetic circuits. An exact correction can be obtained only for ellipsoids, where both the magnetization $\mathbf{M}$ and the demagnetizing field $\mathbf{H}_d$ are uniform under a uniform applied field $\mathbf{H}_{\text{app}}$.[5–7] If the three principal ellipsoid axes coincide with the x, y, and z axes, then the internal field is:

$$\mathbf{H}_{in}=\mathbf{H}_{\text{app}}+\mathbf{H}_d=\mathbf{H}_{\text{app}}-\mathbb{N}\mathbf{M} \tag{1}$$

where $\mathbb{N}$ is a diagonal demagnetizing tensor, and $N_{xx}+N_{yy}+N_{zz}=1, 0\leqslant N\leqslant 1$ in SI units, and $0\leqslant N\leqslant 4\pi$ in CGS units.

For nonellipsoidal samples, if the sample is placed in a uniform applied field $\mathbf{H}_{\text{app}}$ along its axis, a demagnetization factor N can be defined as the ratio of the average demagnetizing field to the average magnetization of the entire sample:[8]

$$\int_S \mathbf{H}_d(\mathbf{r})d\mathbf{S}=-N\int_S \mathbf{M}(\mathbf{r})d\mathbf{S}. \tag{2}$$

But now N is the function of the aspect ratio, $m=L/D$ (length to diameter). So, the ellipsoidal approximation is no longer suitable and a relationship between the shape and size of the ferrite element and the demagnetizing factors should be developed. The demagnetizing factors, and/or the local demagnetizing tensor elements have been calculated analytically in Refs. 1–3 using various approximations. Nonuniform demagnetizing factors have been calculated in Ref. 1, based on a first order approximation, that the direction of the magnetization coincides with the direction of the local magnetic field at any point within the sample. This approximation may cause a 20% error. It is desirable to know the difference between the real demagnetizing factors and that calculated by Ref. 1.

In the present work an experimental method was developed to determine an *effective* demagnetizing factor N_{eff} for thick, small rectangular and circular ferrite samples. The results are compared to N_{eff}, derived from Ref. 1, based on a technique of statistical averaging over the volume.

 0021-8979/96/79(8)/5742/3/$10.00

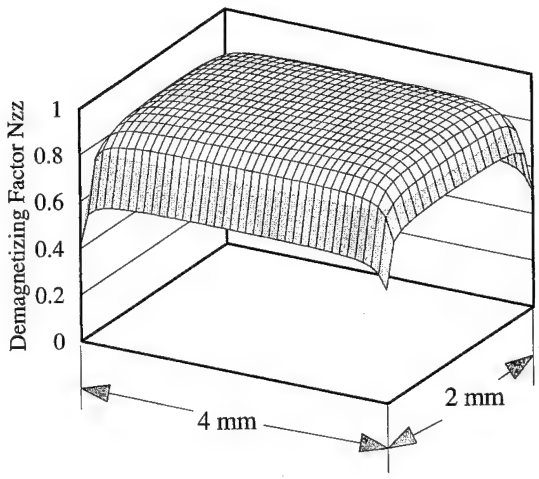

FIG. 1. Calculated distribution of local demagnetization factors $N_{zz}(x,y)$ on the center plane, $z=0$, of a $2\times4\times0.135$ mm^3 YIG sample.

II. EXPERIMENTS

The method to determine an *effective* demagnetizing factor for a nonellipsoidal sample is based on the measurement of the in-plane and out-of-plane major hysteresis loops using a vibrating sample magnetometer (VSM). Experiments were performed on 4×2 mm^2 rectangular yttrium iron garnet (YIG) films ($4\pi M_s$ = 1780 G), in the thickness range from 4.7 to 220 μm; on 3–5 mm square YIG films of 140 μm thickness; and on round polycrystalline MnMg ferrites ($4\pi M_s$ = 2350 G) of 0.15 in. diameter, thickness from 0.005 in. to 0.025 in. The measured YIG samples were grown by liquid phase epitaxy on (111) GGG substrates. All samples were cut from the same wafer, and polished to the final thickness. The measured magnetization curves have been corrected for the paramagnetic contribution of the GGG substrate.

The procedure is illustrated for the case of the rectangular geometry. The dimensions of the rectangular sample are: $2a\times2b\times2h=2\times4\times0.135$ mm^3. For this configuration, the 3D distribution of demagnetizing factors, $N_{ij}(x,y,z)$ has been calculated. Figure 1 illustrates $N_{zz}(x,y)$ in the central plane ($z=0$) of the YIG sample. For this geometry the distribution of the magnetization is mostly uniform; inhomogeneous fields occur only around the edges of the sample.

The maximum N_{zz} is at the center on the top surface. The smallest value is at the corners of the sample. If $N_{zz}(x,y)$ is calculated over planes, corresponding to different z, then after averaging $N_{zz}(x,y)$ over the plane, the maximum average Max N_{zz} will appear on the top and bottom planes of sample, while the minimum N_{zz} will be on the center plane of the sample. We expect that the experimentally determined $N_{zz,\mathrm{eff}}$ will correspond to the average of $N_{zz}(x,y,z)$ all over the sample.

N_{eff} can be determined from in-plane and out-of-plane hysteresis loops. For the case of negligible anisotropy (as compared to $4\pi M_s$), the loops are expected to be congruent after correcting for the demagnetizing factors. Based on this assumption, the expression $H_{\mathrm{in}} = H_{\mathrm{app}} - 4\pi M_s N_{\mathrm{eff}}$ has been used to find N_{eff}, i.e., to correct the in-plane and out-of-plane loops until they coincide. First, it is assumed that the samples are thin enough, therefore, N_{xx} approaches zero; i.e., the in-plane hysteresis loop is not corrected. Then, the out-of-plane loop should be corrected with a proper N_{zz} until it overlaps with the in-plane loop. This procedure gives the minimum of N_{zz}. Next, it is considered that the inhomogeneous field exists not only in the out-of-plane direction, but also in-plane. So, both hysteresis loops should be corrected by N_{zz} and N_{xx} to arrive to the same loop. The final hysteresis loops, after corrected by demagnetizing factors, should not "overshoot," i.e., have a negative slope. This limiting N_{zz} is the maximum N_{zz}, and Max N_{zz} = Min $N_{zz} + N_{xx}$. The values of Max N_{zz} and Min N_{zz}, determined experimentally, are used to verify the numerical results of Refs. 1–3.

TABLE I. Thickness dependence of demagnetizing factors for MgMn-ferrite discs, diameter: $D=0.15$ in., height: $L=0.010$, 0.015, and 0.020 in.

	N	$D/L=15$	$D/L=10$	$D/L=7.5$
N_{xx}	Theory (2)	0.0482	0.0696	0.0894
	Measured	0.0562	0.0785	0.0955
N_{zz}	Theory (2)	0.904	0.861	0.821
	Theory (3)	0.8478	0.7967	0.7533
	Measured	0.758	0.725	0.698

III. RESULTS AND DISCUSSION

The correction procedure has been applied to a series of YIG samples of same size, but having different thickness, and same thickness but different size; and circular MgMn ferrites of different thickness.

A. Circular ferrite samples

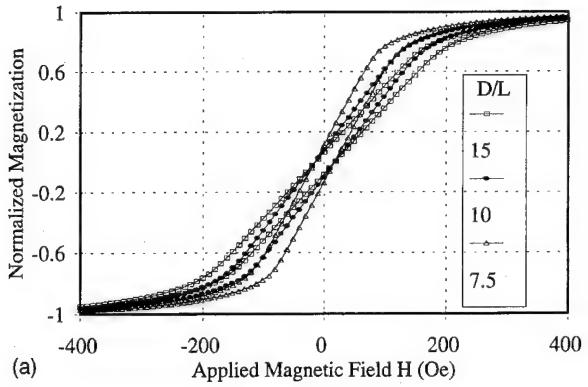
Figures 2(a) and 2(b) illustrate the in-plane hysteresis loops before and after the correction was performed for circular ferrite samples of different aspect ratios ($D=0.15$ in.) and are given in Table I. Theoretical values for N_{xx} in Table 1 are calculated by Eq. (2), and the corresponding $N_{zz} = 1-2N_{xx}$ are given in Table I. The difference between the experimental data and the theoretical results of the ellipsoidal approximation (2) is much larger than expected. Therefore, the solenoid approximation of Eq. (3) has been used to calculate the effective demagnetizing factors of circular samples:

$$N_{zz}=1-4LL_s/(\mu_0\pi D^2), \tag{3}$$

where L_s contains the complete elliptic integrals, and μ_0 is the permeability of vacuum. Table I shows that both Eqs. (2) and (3) underestimate the effect of the shape, i.e., the inhomogeneity of the internal field for disk shaped samples.

B. Rectangular YIG samples

Measurements were done on 4×2 mm^2 YIG films up to 220 μm thickness. The theoretical results for the local demagnetizing tensor element $N_{zz}(x,y,z)$, are based on the first order approximation of Ref. 1. Calculated and measured demagnetizing factors are given in Table II and Fig. 3. In the theoretical estimation column, Max N_{zz} is the average of



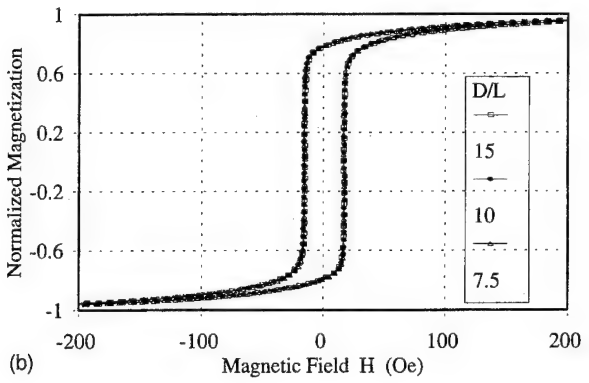


FIG. 2. In plane hysteresis loops for MnMg ferrite disks, D=0.15 in., L=0.010, 0.015, and 0.020 in.; (a) as measured, (b) after correcting by the demagnetizing factors N_{xx} and N_{zz}.

demagnetization factors on the top (bottom) plane, min N_{zz} is on the center plane; Avg N_{zz} is the average all over the sample. The agreement between the averaged values of the first order approximation of Ref. 1 and the measured demagnetization factors is in good agreement with Ref. 1, however the experimental data suggest a different slope of the curve.

C. Shape dependence of the demagnetizing factor

Measurements of the shape dependence of the magnetization curves are performed on h=140-μm-thick square (L=3, 4, and 5 mm) YIG samples with aspect ratio of $20 \leqslant L/h \leqslant 200$. The calculated and measured values of N_{zz} are given in Table III. The difference between the measured Max N_{zz} and the calculated value is 3% for the smallest

		Ave	0.828	0.830	0.831	0.960
	Measured	Max	0.840	0.856	0.873	
		Min	0.798	0.820	0.843	
	Error		3.0%	1.2%	0.6%	...

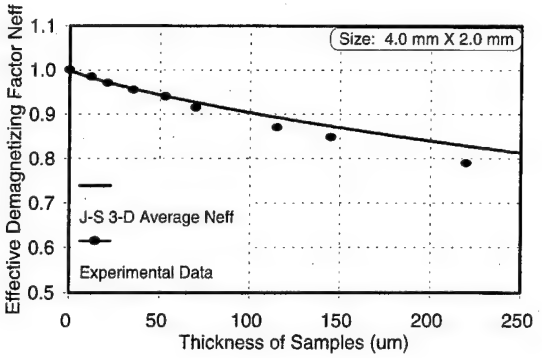

FIG. 3. Thickness dependence of the measured effective demagnetizing factor N_{zz} of 2×4 mm^2 epitaxial YIG films (solid circles), compared to the averaged values calculated from Ref. 1 (solid line).

sample, and it is less than 1% for the 5 mm sample. However, for L/h=214 the calculated Max N_{zz} is only 0.964, i.e., the validity of the thin film approximation is still worse than 3%.

V. CONCLUSIONS

The internal field of a finite size, finite thickness magnetic material is nonuniform, which affects the operation of microwave ferrite devices. The knowledge of the *local* demagnetizing tensor elements $N_{ij}(x,y,z)$ is necessary to analyze and design such devices. Analytical calculations of the demagnetizing tensor elements are based on approximations. To investigate the applicability of these theories, a method, based on in-plane and out-of-plane hysteresis loop measurements, has been developed to define and measure an effective demagnetizing factor for nonellipsoidal samples. The measurements dependence of the effective N_{zz}, N_{xx} on thickness, sample size, and shape have been performed on rectangular YIG and circular MgMn ferrite samples. The measured data have been compared to the properly averaged, calculated results, and it is concluded, that the agreement between the calculated and measured N_{eff} values for rectangular YIG samples is very good, however, the available analytical calculations underestimate the inhomogeneity for the case of disc-shaped samples.

Quantum fluctuations in antiferromagnets of the BX_2 family (abstract)

E. Rastelli and A. Tassi
INFM, Dipartimento di Fisica, Università di Parma, 43100 Parma, Italy

The hexagonal antiferromagnets of the BX_2 family, where B is a magnetic ion, and X a halogen, are characterized by an in plane exchange interaction J much stronger than the exchange interaction J' along the c axis, so that some features of the triangular antiferromagnet (TA) could survive in these real compounds. In particular we are interested to investigate a possible "planar" phase with the spins lying in the c plane supported by quantum fluctuations when an external magnetic field H is applied perpendicular to the c axis. We find that such a phase is stable for sufficiently small interplane coupling owing to the zero point motion energy, whereas an "umbrella" phase would be expected on the basis of the classical approximation for any nonzero interplane coupling. Notice that for the TA model the planar and umbrella configurations are degenerate in classical approximation for any H and infinite isoenergetic planar configurations exist. Quantum fluctuations select a planar configuration with a spin over three opposite to the field.[1] We find that the classical scenario itself is substantially different for any $j=J'/J\neq 0$, because only a planar configuration with a spin over three nearly perpendicular to the field and the umbrella configuration minimize the energy of the model and the umbrella is stable. However, quantum fluctuations stabilize the planar configuration for any H below a critical interplane coupling j^*. For intermediate j the planar configuration is stable for low and high fields, whereas only the umbrella phase is stable of j large enough. © *1996 American Institute of Physics.* [S0021-8979(96)69808-3]

Spin configurations in VBr_2 supported by uniaxal anistropy and quantum fluctuations (abstract)

E. Rastelli and A. Tassi
INFM, Dipartimento di Fisica, Università di Parma, 43100 Parma, Italy

Small single ion anisotropy is believed to play an important role in selecting the plane where the spins lie in hexagonal anitferromagnets on the basis of the classical approximation. For instance, in VBr_2 a small easy-axis single ion anisotropy is expected to force the spins in a plane containing the c axis and the classical approximation suggests that the spin configuration should be an "umbrella" configuration with axis along the external magnetic field perpendicular to the c axis.[1] However, the classical expectation is questionable because the zero point motion energy supports spin configurations with the spins lying in a plane containing the magnetic field. We find that the "planar" configuration with the spins in the plane containing the c-axis and the external magnetic field is stable for interplane coupling and anisotropy sufficiently small. Since this is the case of VBr_2, our results rise some doubts about the interpretation of experimental data in VBr_2 when an external magnetic field is applied. © *1996 American Institute of Physics.*

Henkel plots and the Preisach model of hysteresis

C. J. Buehler and I. D. Mayergoyz
Department of Electrical Engineering, University of Maryland, College Park, Maryland 20742

Interpretation of Henkel plots in terms of the Preisach model is revisited. The Preisach model is treated as a purely phenomenological one and the Henkel plots are directly related to experimental data, namely, to the first-order transition curves. © *1996 American Institute of Physics.* [S0021-8979(96)20208-4]

Henkel plots have been the focus of considerable research in magnetics in recent years. This is because these plots can provide some insights concerning interaction mechanisms that govern magnetization processes.[1,2] In a ground breaking paper of Basso and Bertotti,[3] the classical Preisach model has been used for the interpretation of Henkel plots. This line of research has been further extended in subsequent publications (see, for instance, Refs. 4 and 5). In all of these publications, the Preisach model has been viewed as a physical model. For this reason, the distribution (weight) function $p(\alpha,\beta)$ [or $\mu(\alpha,\beta)$] has been given a probabilistic interpretation, and it has been assumed to be positive. It has been shown by Basso and Bertotti that, under this assumption, the classical Preisach model imposes some restrictions on the possible configurations of Henkel plots. It has been suggested that these restrictions on Henkel plots can be removed by using the moving Preisach model.[6]

In this paper, the interpretation of Henkel plots in terms of the Preisach model is revisited. The Preisach model is treated as a purely phenomenological one for which the question of its applicability can be posed and answered on solely mathematical grounds without invoking any physical arguments. For this reason, no *a priori* assumptions are made concerning the weight function $\mu(\alpha,\beta)$ except those that are imposed by the experimental data used for the identification of the model. By using this approach, we relate the Henkel plots directly to first-order transition curves. These curves constitute the experimental data used for identification.[7] In this way, it is demonstrated that under some conceivable conditions on the first-order transition curves, the classical Preisach model can yield Henkel plots that may lie outside the constrained region established by Basso and Bertotti. Another (and probably more important) benefit of this approach is the ability to compute the Henkel plots directly in terms of first-order transition curves without numerical "preparation" of the ac demagnetized state. This is important because the shape of the Henkel plots is very sensitive to the precise method by which the ac demagnetized state is prepared.[4] This sensitivity has been one reason (among other things) why a "thermally" demagnetized state has been introduced.[5]

To start the discussion, we recall that Henkel plots represent the $\tilde{f}_d$ vs $\tilde{f}_r$ relationship, where $\tilde{f}_d=f_d/f_\infty$ and $\tilde{f}_r=f_r/f_\infty$ and where the physical meaning of f_d, f_r and f_∞ is demonstrated by Fig. 1. It is customary to associate the linear Wohlfarth relation

$$f_d(u)=f_\infty-2f_r(u) \tag{1}$$

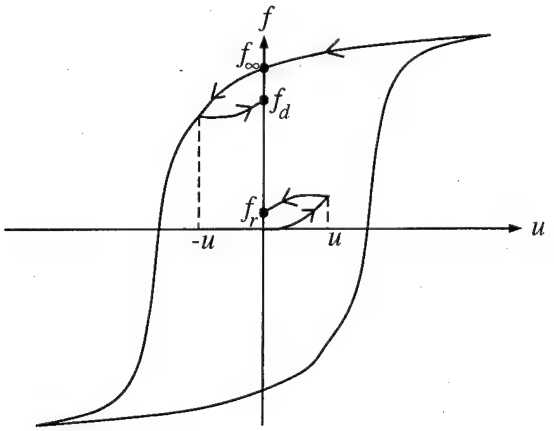

FIG. 1. Definition of Henkel plot variables f_d, f_r, and f_∞.

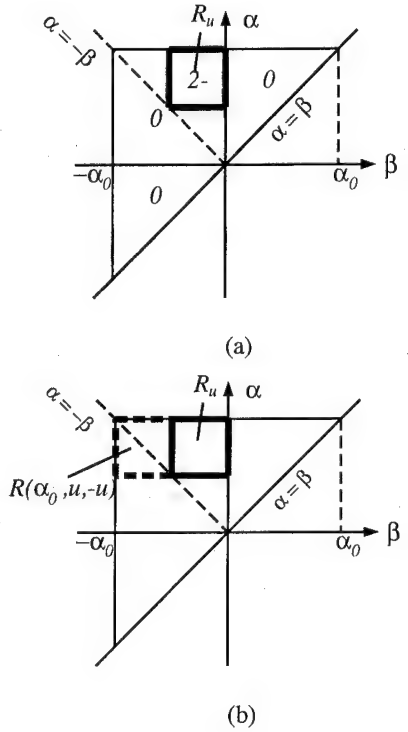

FIG. 2. Rectangular regions of integration.

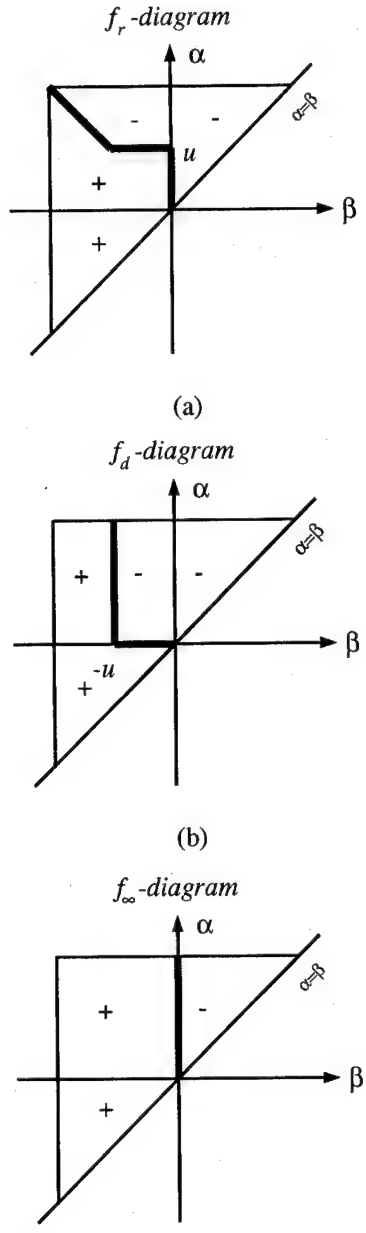

FIG. 3. (a) f_r diagram, (b) f_d diagram, and (c) f_∞ diagram.

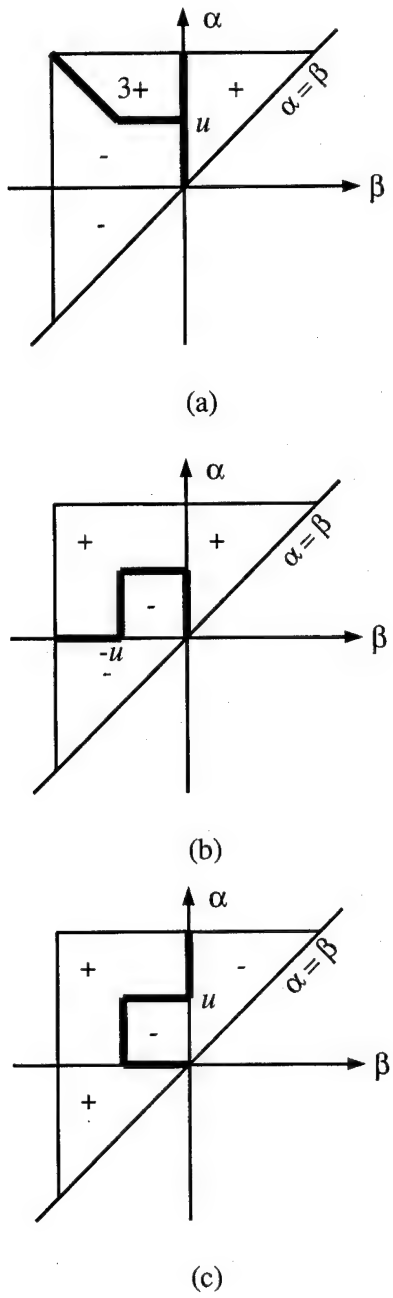

FIG. 4. Intermediate steps in manipulations of $(f_\infty - 2f_r)$ diagrams.

with noninteracting "particles," while inequalities

$$f_d(u) > f_\infty - 2f_r(u), \tag{2}$$

$$f_d(u) < f_\infty - 2f_r(u) \tag{3}$$

are associated with positive (magnetizing-like) and negative (demagnetizing-like) interactions, respectively. It has been shown[3] that the classical Preisach model,

$$f(t) = \iint_{\alpha \geqslant \beta} \mu(\alpha,\beta)\hat{\gamma}_{\alpha\beta}u(t)d\alpha\, d\beta, \tag{4}$$

imposes the restriction (3) on Henkel plots under the assumption that $\mu(\alpha,\beta)$ is positive. To revisit this issue, we introduce

$$\Delta f = f_d - (f_\infty - 2f_r), \tag{5}$$

and shall next derive the expression for Δf in terms of first-order transition curves. To this end, we first show that

$$\Delta f = -2\iint_{R_u} \mu(\alpha,\beta)d\alpha\, d\beta, \tag{6}$$

where R_u is the rectangle pictured in Fig. 2(a).

The proof of (6) is based on the symmetry of the weight function,

$$\mu(\alpha,\beta) = \mu(-\beta,-\alpha), \tag{7}$$

and the careful manipulation of Preisach diagrams that correspond to f_r and f_d "states," respectively. Diagrams shown

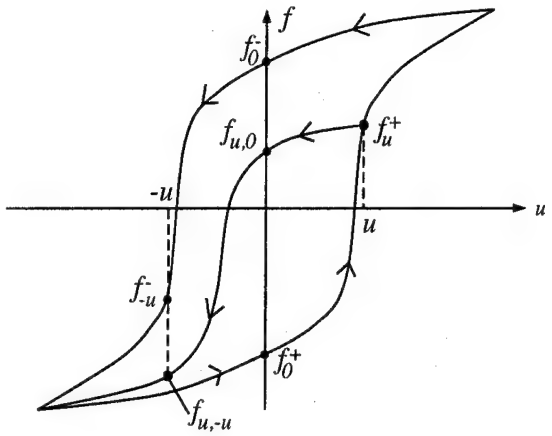

FIG. 5. Illustration of relevant first-order transition curve values.

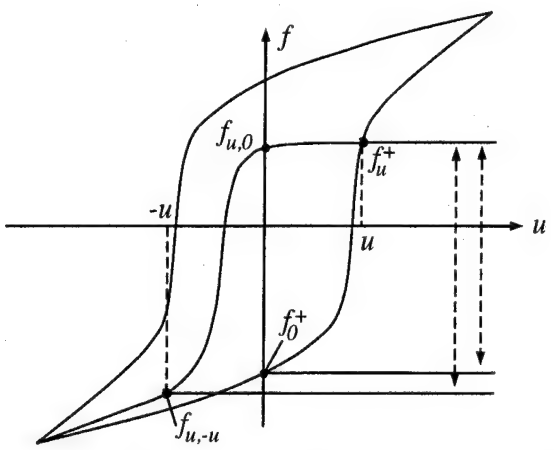

FIG. 6. Example first-order transition curves, which satisfy the conditions for a demagnetizing-like Henkel plot.

in Figs. 3(a)–3(c) correspond to f_r, f_d, and f_∞ "states." Subtracting twice the f_r diagram from the f_∞ diagram yields the intermediate result shown in Fig. 4(a). By using the symmetry property of $\mu(\alpha,\beta)$, we can simplify this diagram to the one shown in Fig. 4(b). By using transposition about the symmetry line $\alpha=-\beta$, we end up with the diagram shown in Fig. 4(c). Now, we notice that the f_d diagram and the $(f_\infty-2f_r)$ diagram differ only in a rectangular region. By performing one more subtraction, we arrive at the final Preisach Δf diagram [Fig. 2(a)]. This diagram leads to the expression (6).

Clearly, if $\mu(\alpha,\beta)$ is assumed to be positive, then the integral in (6) must always be negative, leading to the conclusion[3] that the classical Preisach model always produces demagnetizing-like Henkel plots. However, we shall not use any *a priori* assumption concerning $\mu(\alpha,\beta)$, but rather relate the integral in (6) directly to first-order transition curves.

To achieve this, we transform Eq. (6) as follows:

$$\Delta f=-2\left(\iint\limits_{R(\alpha_0,u,0)}\mu(\alpha,\beta)d\alpha\,d\beta-\iint\limits_{R(\alpha_0,u,-u)}\mu(\alpha,\beta)d\alpha\,d\beta\right), \tag{8}$$

where rectangles $R(\alpha_0,u,0)$, $R(\alpha_0,u,-u)$, and R_u are related by the expression $R(\alpha_0,u,0)=R(\alpha_0,u,-u)+R_u$ and rectangle $R(\alpha_0,u,-u)$ is outlined in Fig. 2(b).

It can be shown (see Ref. 7 p. 68) that the integrals in (8) can be directly related to the first-order transition curves as follows:

$$2\iint\limits_{R(\alpha_0,u,0)}\mu(\alpha,\beta)d\alpha\,d\beta=f_0^--f_{u,0}, \tag{9}$$

$$2\iint\limits_{R(\alpha_0,u,-u)}\mu(\alpha,\beta)d\alpha\,d\beta=f_{-u}^--f_{u,-u}, \tag{10}$$

where the meaning of f_0^-, f_{-u}^-, $f_{u,0}$, and $f_{u,-u}$ is demonstrated by Fig. 5. By substituting (9) and (10) in (8), we obtain

$$\Delta f=(f_{-u}^--f_0^-)+(f_{u,0}-f_{u,-u}). \tag{11}$$

By using symmetry, we easily find

$$f_{-u}^--f_0^-=-(f_u^+-f_0^+). \tag{12}$$

From (11) and (12), we derive the final expression:

$$\Delta f=(f_{u,0}-f_{u,-u})-(f_u^+-f_0^+). \tag{13}$$

It is clear that the classical Preisach model can produce a magnetizing-like Henkel plot if

$$f_{u,0}-f_{u,-u}>f_u^+-f_0^+. \tag{14}$$

As shown in Fig. 6, it is conceivable to have the first-order transition curves, which satisfy inequality (14).

Next, we shall demonstrate that the Henkel plots can be directly computed in terms of the first-order transition curves. The calculation of these plots in terms of the first-order transition curves is based on the following observations. First, f_d can be construed as $-f_{u,0}$, and f_∞ as $-f_0^+$. Second, by using these facts and substituting (5) into (13), we derive the following expression for f_r in terms of the first-order transition curves:

$$f_r=f_{u,0}-\frac{1}{2}(f_{u,-u}+f_u^+). \tag{15}$$

Thus, f_r can be computed by using first-order transition curves, i.e. without numerical preparation of the demagnetized state.

Kinetic Ising systems as models of magnetization switching in submicron ferromagnets

Howard L. Richards,[a] Scott W. Sides,[a] Mark A. Novotny,[b] and Per Arne Rikvold[a]
Supercomputer Computations Research Institute, Florida State University, Tallahassee, Florida 32306-3016

Experimental techniques, such as magnetic force microscopy (MFM), have recently enabled the magnetic state of individual submicron particles to be resolved. Motivated by these experimental developments, we use Monte Carlo simulations of two-dimensional kinetic Ising ferromagnets to study the magnetic relaxation in a negative applied field of a grain with an initial magnetization $m_0=+1$. The magnetostatic dipole–dipole interactions are treated to lowest order by adding to the Hamiltonian a term proportional to the square of the magnetization. We use droplet theory to predict the functional forms for some quantities, which can be observed by MFM. One such quantity is the probability that the magnetization is positive, which is a function of time, field, grain size, and grain dimensionality. The relaxation is characterized by the number of droplets larger than a field-dependent critical size, which form during the switching process. Our simulations of the kinetic Ising model are in excellent agreement with droplet-theoretical predictions. The qualitative agreement between experiments and our simulations of switching in individual single-domain ferromagnets indicates that the switching mechanism in such particles may involve local nucleation and subsequent growth of droplets of the stable phase. © *1996 American Institute of Physics.* [S0021-8979(96)20308-0]

I. INTRODUCTION

The processes by which magnetization reversal occurs in the nanoscale ferromagnets that will make up the next-generation recording media are the subject of active research. One quantity for which theory and experiment often disagree is the lifetime τ, which is the time required for a particle with initial magnetization $m_0=+1$ to reach $m=0$ when a magnetic field in the $-\hat{z}$ direction is applied. Micromagnetics,[1] a theoretic technique in which differential equations are numerically solved on a lattice that is coarse grained compared to the physical lattice, predicts that the lifetime is given by the Arrhenius equation,

$$\tau \propto \exp(\beta\, \Delta F), \tag{1}$$

with $\Delta F \propto L^d$. Here d is the dimension, β^{-1} is the temperature in units of energy, ΔF is the free-energy barrier between the stable and metastable phases, and L is the linear system size. [Equation (1) must be appropriately generalized if there is more than one barrier or path between the stable and metastable states.] This same prediction is made by the standard Néel–Brown theory of single-domain ferromagnets.[2,3] The evident failure of Eq. (1) with $\Delta F \propto L^d$ for somewhat larger grains is ascribed to the existence of more than one domain in larger particles, as is a corresponding peak in plots vs. L of the switching field $H_{\rm sw}$, which is the field required to yield a given lifetime.

Recently, techniques such as MFM have been used to resolve the magnetic properties of *isolated, well-characterized* single-domain particles (see, e.g., Ref. 4). This is an important advance, since previous experiments on ferromagnetic powders left uncertainties due to the range of grain sizes and orientations and the local magnetic environments. Observations of individual particles by MFM have made it clear that even for many *single-domain* particles, Néel–Brown theory is inadequate.

We have applied the statistical-mechanical droplet theory of metastable decay to nanoscale ferromagnets with large uniaxial anisotropy, and compared Monte Carlo simulations of square-lattice Ising systems with droplet-theory predictions.[5] (For a review of droplet theory, see Ref. 6.) The agreement between theory and simulation is quite good, and despite the crudeness of the Ising model as a model for real magnets, it shows good qualitative agreement with the MFM experiments. We find rich L-dependent behavior in the standard Ising model, even though its equilibrium structure is a single domain for all L. This suggests that for some strongly anisotropic magnetic materials, magnetization reversal may occur through the nucleation and growth of nonequilibrium droplets. Details of our work are given in Refs. 5 and 7, including formulas for general dimensionality. For simplicity, we only discuss the two-dimensional case here.

II. APPLIED DROPLET THEORY

To be concrete, consider a kinetic Ising ($s_i=\pm 1$) ferromagnet evolving under Metropolis single-spin-flip dynamics on a square lattice ($d=2$) with periodic boundary conditions. In addition to terms arising from the nearest-neighbor (n.n.) coupling J and applied field H, the Hamiltonian, $\mathcal{H}=-J\Sigma_{\rm n.n.}s_i s_j - H\Sigma_i s_i + L^{-d}D(\Sigma_i s_i)^2$, includes a term ($\propto D$) representing a mean-field approximation for the dipole–dipole interaction energy. Unless noted, we set $D=0$. The critical radius of a "droplet" of $s_i=-1$ spins surrounded by $s_i=+1$ spins occurs when the free energy of the droplet ($2\pi R\sigma - \pi R^2 2|H|$) is maximum: $R_c \approx \sigma/2|H|$, where σ is the surface tension per unit length. Droplets smaller than this will very probably shrink and vanish; larger droplets will very probably grow and reverse the magnetiza-

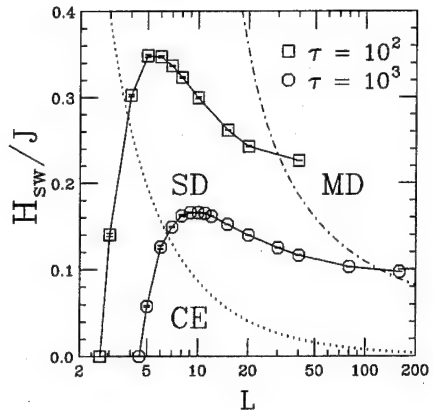

FIG. 1. The relation between the switching field H_{sw} and the system width L for two different fixed lifetimes (solid curves), calculated by kinetic Ising model simulations at $k_BT=0.8k_BT_c\approx 1.815$ J. The dotted curve is near the crossover between the CE and SD regions;[5] the dash–dotted curve is near the crossover between the SD and MD regions.[5]

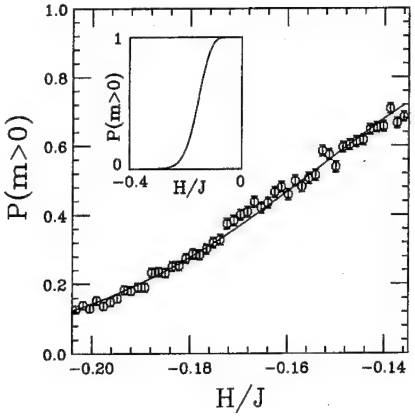

FIG. 2. The probability that $m>0$ for a kinetic Ising system in the SD region. $T=0.8T_c$, for fixed time $t=914$ Monte Carlo steps per spin (MCSS) and $L=10$. The solid curve is a fit of $\exp(-t/\tau)$ to the MC data, where τ is given by Eq. (4). The inset figure shows the fitted curve over a wider range in H.

tion of the system. In a sufficiently large system, the probability per unit time that a critical droplet forms, centered at a given site, is given by droplet theory as[6]

$$I\propto|H|^3\exp(-\beta\pi\sigma^2/2|H|). \tag{2}$$

The details of the magnetization reversal depend on the number of critical droplets the system forms.

For weak fields or small systems ($L<R_c$), no critical droplet can form. This is called the coexistence (CE) Region, and since two interfaces (remember periodic boundary conditions) must form to reverse the magnetization,

$$\tau\propto\exp\{\beta[2\sigma L-O(HL^2)]\}. \tag{3}$$

For slightly larger L, the first supercritical droplet will grow to the size of the system before another one can form. The lifetime in this Single Droplet (SD) Region is

$$\tau\approx[L^dI]^{-1}. \tag{4}$$

In both the CE and SD regions, switching is a Poisson process, so the standard deviation of the lifetime is comparable to τ. Both Eq. (3) and Eq. (4) are actually special cases of the Arrhenius equation, Eq. (1), but in neither case is ΔF proportional to L^d. Note that if τ is held constant and the system size is increased, Eq. (3) implies that the magnetic field must *increase*, whereas Eq. (4) implies that the magnetic field must *decrease*. This shows that the peak in H_{sw} occurs near the crossover between the CE and SD regions (see Fig. 1).

The probability that the magnetization is greater than zero $P(m>0)$ is shown as a function of field in Fig. 2 for a system in the SD region. This probability is what is most easily observed in MFM experiments, and it decays exponentially with time in both the CE and SD regions. In the SD region, the system is very unlikely to return to the metastable state from the stable state, so

$$P(m>0)=\exp(-t/\tau). \tag{5}$$

In the CE region such backward switching takes place on a time scale comparable with the initial decay, so the situation is more complicated.

For sufficiently large L or H, several supercritical droplets may form before any one of them has grown to the size of the system. This is the Multi-Droplet Region (MD). Such systems were first studied by Kolmogorov,[8] Johnson and Mehl,[9] and Avrami,[10] and have a lifetime

$$\tau\approx[I\pi v^2/3\ln 2]^{-1/3}, \tag{6}$$

where the radial growth velocity v is assumed to be proportional to $|H|$. Although τ is independent of L, the variance of the lifetime is proportional to $(v/L)^2$. Measuring $P(m>0)$ as a function of H or t thus provides a means of estimating the proportionality constant between v and H (see Fig. 3). Details are given in Ref. 5.

To first approximation, the effects of dipole–dipole interactions on the switching behavior can be studied through inclusion of the term $L^{-d}D(\Sigma_i s_i)^2$ in the Hamiltonian. The system then evolves in an *effective* field, $H_{\text{eff}}\equiv H-2Dm$. In the CE and SD regions, the values of m that enter in H_{eff} depend only on the volume of the critical fluctuation, and the modified ΔF in Eq. (1) can be easily evaluated through a

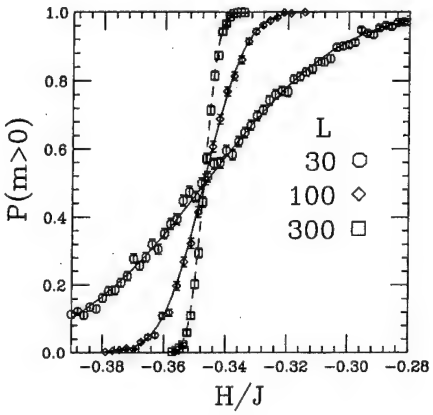

FIG. 3. The probability that $m>0$ for a kinetic Ising system in the MD region. $T=0.8T_c$, $\tau=40.7$ MCSS and $L=30$, 100, and 300. The solid curves are fits of droplet theory predictions to the MC data. The dashed curve is the fit of the droplet-theory prediction for $L=100$ extrapolated to $L=300$.

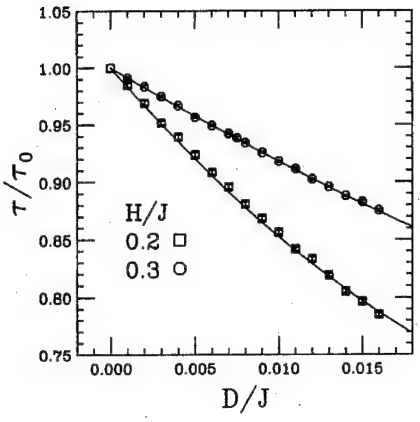

FIG. 4. The lifetime τ for a kinetic Ising system in the MD region, normalized by the lifetime in a similar system with $D=0$. $T=0.8T_c$, and $L=100$. The solid curves are droplet-theory predictions.

continued-fraction expansion. The switching remains a Poisson process, so Eq. (5) still applies in the SD region. In the MD region, H_{eff} involves the time-dependent magnetization $m(t)$. This can be evaluated analytically to $O(D)$. The resulting analytic expression for τ to $O(D)$, plus small nonlinear corrections obtained by a numerical iteration procedure, give very good agreement with simulation results (Fig. 4). A detailed treatment of the $D>0$ case is given in Ref. 7.

III. CONCLUSION

We have used Monte Carlo methods to simulate magnetization switching in two-dimensional kinetic Ising ferromagnets. The results of the simulations can be well explained by droplet theory and show good qualitative agreement with experiments, despite the comparative simplicity of the Ising model. This simplicity, in turn, allows us to develop an understanding of the underlying statistical mechanics. Particular features to make the model more realistic, such as appropriate boundary conditions, quenched randomness, and less rigorous anisotropy will be added in later studies.

Simple function for a complex domain configuration

A. S. Arrott and J.-G. Lee
Department of Physics, Simon Fraser University, Burnaby, British Columbia, V5A 1S6, Canada

A complex domain configuration found in an iron whisker can be generated by a function with three parameters. The configuration is generated by passing a current along the axis of a {100} whisker with a square cross section. It has four domains in which the magnetization circulates about a central domain magnetized along the z axis. There are four {110} 90° walls and four {100} 90° walls separating these domains. Two of the parameters are known *a priori* from micromagnetics: a_1 describes type I 90° walls between two domains with in-plane magnetization; and a_2 describes type II 90° walls between the domains with in-plane magnetization and the central domain with the magnetization out of the plane. The third parameter h, which determines the width of the central domain, is adjustable to minimize the total micromagnetic energy in response to magnetic fields. The magnetization pattern is generated from a vector potential $A(x,y)\hat{z}$. Calculating M_s curl $A(x,y)\hat{z}$ produces M_x and M_y. Then M_z is found from $M_x^2+M_y^2+M_z^2=M_s^2$. The potential has four parts: $A(x,y)=A_x+A_z+A_h+A_c$, where A_x and A_y are the same function (with x and y interchanged) used to create the in-plane domains and the type I walls, A_h generates the type II walls, and A_c describes the outer corners. The resulting magnetization is divergence free. The analytic functions are convenient for calculation of the magnetic response to applied fields.
 [S0021-8979(96)20408-7]

When a {100} iron whisker with a square cross section is fitted with lead wires to pass a current along its axis, it is possible to achieve the structure illustrated in Fig. 1. This is a conjecture for which there is considerable experimental evidence from measurement of the ac response of the magnetization to ac fields along the whisker axis (z axis) for values of the currents and dc fields, also along the whisker axis.[1] The change in these responses on application of additional fields perpendicular to the z axis also supports this picture.

The description of the magnetization in the cross section midway between the ends of the whisker is simpler than for the cross sections away from the midplane. By symmetry there are no first derivatives with respect to z. Furthermore, there is no need to have any magnetic charge; that is, div $\mathbf{M}=0$ within the whisker and $\hat{\mathbf{n}}\cdot\mathbf{M}=0$ at the four surfaces. For the midplane cross section one can pretend that the whisker is infinitely long, except for considerations of the demagnetizing fields coming from the charges away from the midplane. The pattern has four domains in which the magnetization circulates about a central domain magnetized along the z axis. There are four {110} 90° walls and four {100} 90° walls separating these domains. In addition, the magnetization lies along the edges of the whisker at the corners of the central cross section.

The magnetization at one of the corners is illustrated in Fig. 1 and Fig. 2. There are eight distinct patterns depending on the directions of the magnetization at the corners. As the magnetic responses of these are almost identical, the only cases considered are where all four corners have their magnetization parallel or antiparallel to the magnetization of the central domain. The in-plane components of the conjectured magnetization pattern are shown in Fig. 2. With standard expressions from one-dimensional models it is possible to describe this pattern by dividing it into the five domains and the eight walls, but this does not take into account either the four outside corners or the four inside corners. Because the experiments[1] indicate quite singular behavior as the area of the central domain approaches zero, one might wonder if the energetics of the inside corners are responsible. This possibility led to the detailed study of this configuration.[2] The cause of the singular behavior is the magnetoelastic energy[3] and is not due to the energetics of the inside corners. Nevertheless, this did lead to the description of the configuration presented here.

Because there have been no direct observations of the inner domain pattern it is necessary to rely on agreement between model calculations and experiments. There are many terms in the expression for the energy of a whisker with such a domain pattern. There are the magnetostatic terms of interaction between the magnetization and the various applied fields, including the field from the current. There are the micromagnetic terms from the wall energies, including exchange and anisotropy, the magnetoelastic energy from the strains resulting from the conflicting directions of magnetization in the five domains, and the demagnetizing field energy from the interaction of the magnetization with itself.

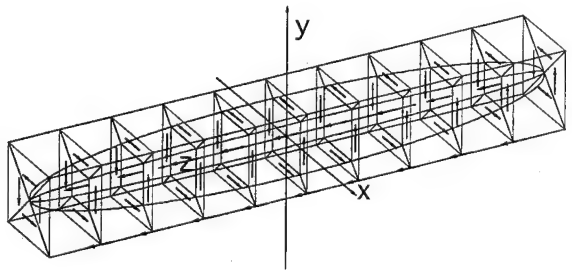

FIG. 1. Domain structure for a {100} iron whisker fitted with lead wires to pass a current along its axis.

 0021-8979/96/79(8)/5752/3/$10.00

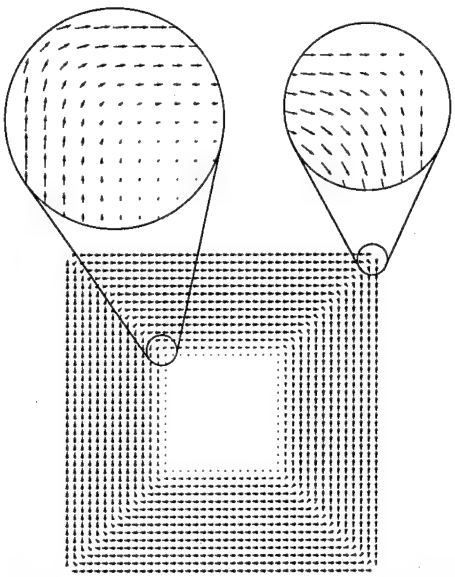

FIG. 2. In-plane components of the conjectured magnetization pattern.

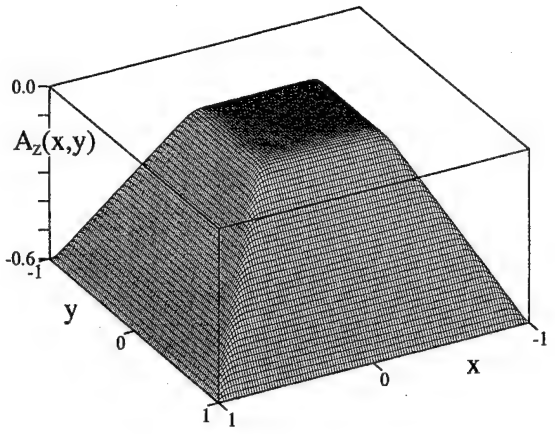

FIG. 3. Vector potential used to generate the complex domain pattern. Equation (9) is illustrated for greatly exaggerated ratios of a_1/d and a_2/d, taken here to be 1/20 and 1/30, respectively, whereas they should be two orders of magnitude smaller for a typical whisker.

To describe all of these terms analytically it is convenient to have a mathematical description of the conjectured magnetization pattern. Such a pattern can be characterized by three parameters. These are the area of the central domain $A_c=h^2$, the thickness of the {110} walls $a_2=a_{110}$ and the thickness of the {100} walls $a_1=a_{100}$. As the wall thicknesses are already known, the pattern is a function of h.

A functional form for this pattern is given here using a vector potential $\mathbf{A}=f(x,y)\hat{\mathbf{z}}$ to generate the in-plane components of the magnetization from $\mathbf{M}=\text{curl}\,\mathbf{A}$. The z components are found by the condition that $M_s^2=M_x^2+M_y^2+M_z^2$. The functional form $f(x,y)$ is illustrated in Fig. 3. The main structure is a truncated pyramid. The coordinates (x',y') used to generate the pyramid are rotated by 45° with respect to the edges of the whisker and the pyramid. This puts the edges of the pyramid (and the {110} walls) in the planes $x'=0$ or $y'=0$. The total function has four parts. The main part is given by

$$f_m(x',y') = a_1 \ln\left(\tan\left\{\frac{\pi}{4}+\frac{1}{2}\arctan\left[\exp\left(\frac{|x'|+|y'|-h}{a_1}\right)\right]\right\}\right), \quad (1)$$

which can also be expressed as

$$f_m(w)=a_1 \ln\left\{\frac{\sqrt{e^{2w}+1}+e^w}{\sqrt{e^{2w}+1}-e^w}\right\}, \quad (2)$$

where $w=(|x'|+|y'|-h)/a_1$ and $|x'|+|y'|=h$ is the equation of the center of the 90° {100} domain wall. The function $f_m(w)$ is zero for sufficiently negative argument and is asymptotic to $w+\ln 2$ for sufficiently positive argument. The crossover occurs for $w=0$ where $|x'|+|y'|=h$. The parameter a_1 makes the truncation smooth and determines the width of the {100} domain walls.

The main function would produce infinitely sharp {100} domain walls corresponding to the edges of the truncated pyramid. The domain wall widths are made finite by rounding the edges of the pyramid using the functions $f_{x'}(x',y')$ and $f_{y'}(x',y')=f_{x'}(y',x')$, where

$$f_{x'}(x',y')=a_2 \sin(\arctan e^{(|y'|-h)/a_1}) \times\left\{\ln\left(2\cosh\frac{|x'|}{a_2}\right)-\frac{|x'|}{a_2}\right\}. \quad (3)$$

The sin (arctan u) function appears in the theory of 90° {100} walls. It is also the derivative of the principal term in the function for the truncated pyramid. It is replaced by using the relation $\sin(\arctan u)=u/\sqrt{u^2+1}$.

The term in brackets { } in Eq. (3) produces sharp edges that cancel the sharp edges of the pyramid. The parameter a_2 determines the width of the {110} domain walls. The function sin(arctan u) turns off the rounding functions for $|y'|<h$ and $|x'|<h$.

Finally, one adds a function that flattens the potential in the corners so that the in-plane components of the magnetization will vanish there as they do in the central region:

$$f_c(x',y')=a_2 \ln\left[\frac{\cosh[(x'-\sqrt{2}d)/a_2]\cosh[(x'+\sqrt{2}d)/a_2]\cosh[(y'-\sqrt{2}d)/a_2]\cosh(y'+\sqrt{2}d)/a_2}{\cosh^4(2\sqrt{2}d/a_2)}\right]. \quad (4)$$

The vector potential **A** has only a z component given by

$$A_z=\frac{1}{\sqrt{2}}[f_m(x',y')+f_{x'}(x',y')+f_{y'}(x',y') +f_c(x',y')], \tag{5}$$

where $x'=(x+y)/\sqrt{2}$ and $y'=(-x+y)/\sqrt{2}$, with the boundaries of the whisker cross section at $x=\pm d$ and $y=\pm d$.

It should be noted that a_1 and a_2 will be the wall widths as normally determined in one-dimensional domain theory. There are no extra parameters to describe the four corners of the whisker cross section. There are no extra parameters to describe the details of the intersection of the {100} walls with the {110} walls. The model is highly constrained, with only the area of the inner domain h^2 as a parameter to change with application of applied fields or changes in the current along the whisker. We show elsewhere that the energy has terms in h^4, h^3, h^2, h, and $h \ln h$ coming from the demagnetizing field, the field from the current, the applied field, the wall energy, and the magnetoelastic energy, respectively. All are important in one range or another as the applied field and the current are varied.

The magnetization is given by

$$M_x=\frac{1}{2}(\sqrt{2}M_{x'}-\sqrt{2}M_{y'}),$$
$$M_y=\frac{1}{2}(\sqrt{2}M_{x'}+\sqrt{2}M_{y'}), \tag{6}$$

where the components in the rotated coordinate system are given by

$$\sqrt{2}M_{x'}=(M_1+M_{2x'}+M_{3x'})\operatorname{sgn} y'-M_{cx'}$$
$$\sqrt{2}M_{y'}=-(M_1+M_{2y'}+M_{3y'})\operatorname{sgn} x'+M_{cy'}, \tag{7}$$

where

$$M_1=\frac{e^{(|x'|+|y'|-h)/a_1}}{\sqrt{e^{[2(|x'|+|y'|-h)/a_1]}+1}}, \tag{8}$$

$$M_{2x'}=\frac{a_2}{a_1}\frac{e^{(|y'|-h)/a_1}}{(e^{2(|y'|-h)/a_1}+1)^{3/2}} \times\left(\ln\left(2\cosh\frac{|x'|}{a_2}\right)-\frac{|x'|}{a_2}\right), \tag{9}$$

$$M_{3x'}=\frac{e^{(|x'|-h)/a_1}}{\sqrt{e^{2(|x'|-h)/a_1}+1}}\left(\tanh\frac{|y'|}{a_2}-1\right), \tag{10}$$

and

$$M_{cx'}=\tanh\frac{y'-d\sqrt{2}}{a_2}+\tanh\frac{y'+d\sqrt{2}}{a_2}. \tag{11}$$

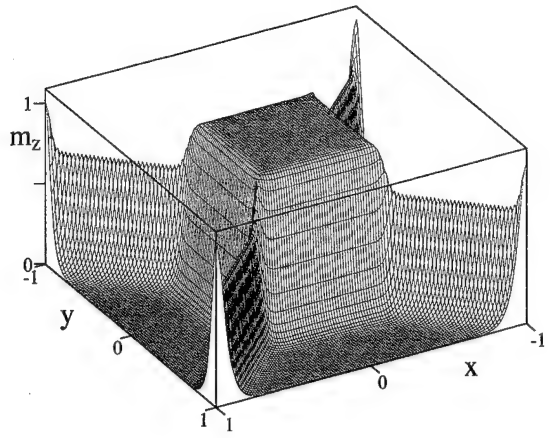

FIG. 4. Analytic expressions Eqs. (6)–(11) are used to plot M_z for the same parameters as Fig. 3.

Equations for the $M_{y'}$ functions in Eq. (7) are not shown. They are given by interchanging x' and y' in Eqs. (9), (10), and (11). These analytic expressions were used to draw Fig. 2 for the in-plane components and Fig. 4 for M_z. In order to demonstrate the geometry it was necessary to greatly exaggerate the ratios of a_1/d and a_2/d taken here to be 1/20 and 1/30, respectively, whereas for a typical whisker they should be two orders of magnitude smaller.

This is a fully analytic expression. It has just one variable h, as long as $d \gg a_1$ and $d \gg a_2$, so that a_1 and a_2 are not affected by the energy of the corners at each end of the {110} domain walls. Such a simple function is not a solution of the full micromagnetic equations. For example, the function chosen for the {110} walls is not the solution for the one-dimensional wall. The analytic expression is the first step in developing a Ritz method for calculating the energy of this complex structure. It incorporates the constraint that div $M=0$, which is an approximation that takes into account the dominance of magnetostatic energies as long as $d \gg a_1$ and $d \gg a_2$. (In relaxation calculations it would be necessary to consider all the dipole–dipole interactions in order to recover the effects that are legislated by the functions used here.)

For each choice of h one can calculate each of the terms in the micromagnetic energy. The total energy can be compared with models where the energy is assumed to be the energy per unit length of the walls times the lengths of the wall sections. It was found that the effects of the intersections can be safely ignored. As mentioned above, there was a strange effect that was unaccounted for when this calculation was carried out, but which later was found to be the result of magnetostriction. The approach given here may be useful in describing the entire three-dimensional structure shown in Fig. 1, but this has not been done.

Dynamical micromagnetics of a ferromagnetic particle: Numerical studies

Bo Yang and Donald R. Fredkin
Department of Physics, University of California, San Diego, La Jolla, California 92093

We have developed a general purpose dynamical micromagnetic code to solve the damped Gilbert equation using the finite element method. We report a study of magnetization switching in a ferromagnetic prolate ellipsoid with aspect ratio of 4.6:1. Switching starts with curling at the middle of the particle, then continues with more complex magnetization configurations, heavily influenced by the damping constant. In general, lighter damping produces more sharply defined domain walls. The critical field for switching has a mild dependence on the damping constant. © *1996 American Institute of Physics.* [S0021-8979(96)20508-3]

We solve Gilbert's equation[1] for a continuous magnetic medium, including all interactions in standard micromagnetic theory in three-dimensional regions of arbitrary geometrical and physical properties. We handle submicrosecond to nanosecond processes. In this paper we use the code to study magnetization switching in an ellipsoidal particle. We concentrate on dynamical aspects of the processes: Larmor precession and Gilbert damping.

I. NUMERICAL MODEL

We start with Gilbert's equation,[1] written here as

$$\frac{1}{\gamma}\frac{\partial \mathbf{M}}{\partial t}=\mathbf{M}\times\mathbf{H}_{\text{eff}}-\eta\mathbf{M}\times\frac{\partial \mathbf{M}}{\partial t}, \tag{1}$$

where $\mathbf{M}$ is the magnetization density with constant magnitude M_s and η is a positive constant associated with dissipation. The effective field $\mathbf{H}_{\text{eff}}=-\delta E/\delta\mathbf{M}$ is defined as the variational derivative of the free energy,[2]

$$E=\int\left[\frac{A}{2M_s^2}|\nabla\cdot\mathbf{M}|^2-\frac{1}{2}\mathbf{H}_d\cdot\mathbf{M}-\mathbf{H}_0\cdot\mathbf{M}\right]dV.$$

The first term is the exchange energy. $\mathbf{H}_0$ is the applied magnetic field and $\mathbf{H}_d$ is the demagnetizing field. For simplicity we omit crystalline anisotropy energy; its inclusion does not lead to any complications. Appropriate boundary conditions are imposed. At constant $\mathbf{H}_0$ and in the absence of random thermal noise, E decreases until an equilibrium is reached.[2]

Gilbert's equation (1) is discretized by the Galerkin method, using the piecewise linear basis functions associated with a tetrahedral mesh as test functions. Let $\varphi_i(\mathbf{r})$ be the basis function at node i that is linear in each element and such that $\varphi_i(\mathbf{r}_j)=\delta_{ij}$. The magnetization can be approximately represented as $\mathbf{M}(\mathbf{r})=\Sigma_i\mathbf{M}_i\varphi_i(\mathbf{r})$ and, similarly, the potential for the demagnetizing field ($\mathbf{H}_d=-\nabla\phi$) can be approximated by $\phi(\mathbf{r})=\Sigma_i\phi_i\varphi_i(\mathbf{r})$. This is the same representation of $\mathbf{M}(\mathbf{r})$ as was used by Chen, Fredkin, and Koehler[3] for static micromagnetic calculations using the finite element method. The dynamical equation is then discretized with the Galerkin method with φ_i as test functions,

$$\frac{1}{\gamma}\int\varphi_i\frac{\partial \mathbf{M}}{\partial t}\,dV=\int\varphi_i\mathbf{M}\times\left(\mathbf{H}_{\text{eff}}-\eta\frac{\partial \mathbf{M}}{\partial t}\right)dV,$$

where i runs from 1 to the number of nodes, N. All the dependence on geometry is included in integrals of products of $\varphi_i(\mathbf{r})$, and these are computed analytically. The boundary conditions are brought in by a partial integration of the exchange term. This leads to a system of coupled ordinary differential equations that are solved with a custom variant of LSODI.[4]

Demagnetization fields are computed on the fly by the solution of Poisson's equation with absorbing boundary conditions[5] using a finite element method and a preconditioned conjugate gradient method. Because of space limitations, details will be given elsewhere. We mention here that, for an N point mesh, our method has time complexity $O(N\log N)$ and storage cost $O(N)$. Our use of the finite element method with a tetrahedral mesh gives us the flexibility to handle any finite magnetic region of arbitrary shape, morphology, and connectivity, with possibly inhomogeneous physical properties.

II. RESULTS

The first application of our code is a study of switching of an ellipsoid modeled after a γ-Fe_2O_3 particle used in an experimental study.[6] It is a prolate ellipsoid 3000 Å long and 650 Å wide, with $M_s=350$ emu/cm^3. The exchange constant A is unknown experimentally, and an approximate value is used such that the exchange length $A^{1/2}/M_s=338$ Å. The field direction $\hat{\mathbf{n}}_H$ is along the long axis of the ellipsoid, $\hat{\mathbf{z}}$, tilted 0.1° to a short axis, $\hat{\mathbf{x}}$, to break the initial symmetry around $\hat{\mathbf{z}}$. The initial state is prepared by applying a large ($6M_s$) external field along $-\hat{\mathbf{n}}_H$ until saturation is reached. Then the field is reversed and kept at a constant value H_0 along $\hat{\mathbf{n}}_H$. To avoid excessive transients, the reversal of $\mathbf{H}_0$ is completed in time τ with a cosine function for the transition. The field switching time, τ, is relatively short at this stage of the study (up to $10/\gamma M_s$), so switching of the magnetization occurs mostly after the field is reversed.

Little is known about the value of η and its effect.[7] To investigate both over-damped and lightly-damped systems, we have set η to values ranging from $3.0/\gamma M_s$ to $0.01/\gamma M_s$. Different values of H_0 are used, and for each η we found one field value H_c below which the particle is not switched. Figure 1 is a linear-log plot of the component of total magnetization, $\mathcal{M}$, along $\hat{\mathbf{n}}_H$ as a function of time at various values of H_0 and η. On most of the curves three segments are found with distinctive slopes, which suggests that we divide the dynamics of switching into three stages, each found to be

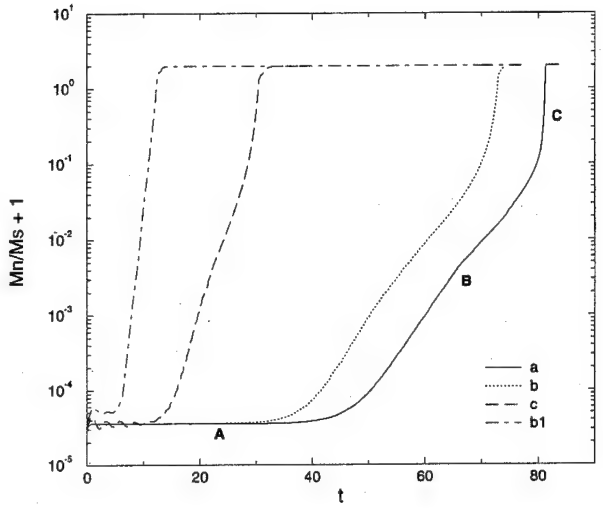

FIG. 1. Component of total magnetization along the applied field versus time in units of $1/\gamma M_s$. $M_n = \mathscr{M}_n/V$, V is the volume of the particle. Note that one has been added to permit a logarithmic axis. (a) $\eta = 3/\gamma M_s$, $H_0 = 3.493 M_s$. (b) $\eta = 0.3/\gamma M_s$, $H_0 = 3.493 M_s$. (c) $\eta = 0.1/\gamma M_s$, $H_0 = 3.493 M_s$. (b1) $\eta = 0.3/\gamma M_s$, $H_0 = 3.700 M_s$.

characterized by one physical process: (A) precursor, (B) curling, and (C) switching and damping.

The precursor stage is characterized by small movements of $\mathbf{M}$, and almost stationary $\hat{\mathbf{n}}_H$ component of total magnetization $\mathscr{M}$. Motion of $\mathscr{M}$ can best be illustrated by tracing the projection of $\mathscr{M}$ on the xy plane. We found that when η is small, $\mathscr{M}$ initially precesses around what looks like a local minimum of the energy, designated by $\mathscr{M}_s$, while moving toward it. The direction of $\mathscr{M}_s$ is very close to $-\hat{\mathbf{n}}_H$. When H_0 is lower than a critical value, H_c, $\mathscr{M}$ eventually settles at $\mathscr{M}_s$, and the particle is not switched [Fig. 2(a)]. When $H_0 > H_c$, after some revolutions, $\mathscr{M}$ is able to escape from the trap and exits to the curling stage [Fig. 2(b)], which, without observed exception, leads to switching. We found that the exit point is closer to $\mathscr{M}_s$ when H_0 is closer to

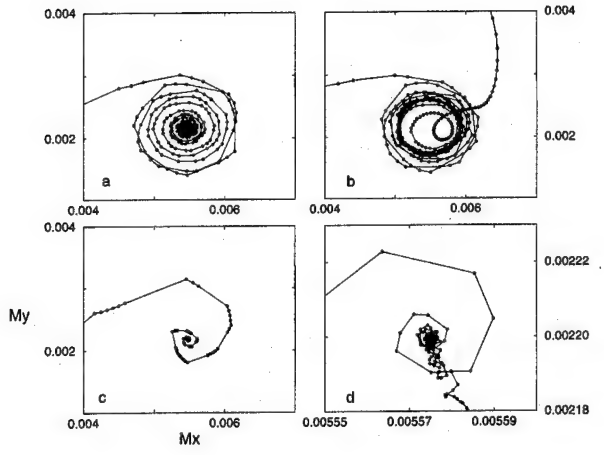

FIG. 2. Small movements of total magnetization. $\mathscr{M}_x$ and $\mathscr{M}_y$ in units of $M_s V$. The vector enters from left when the field is being switched. (a) $\eta = 0.03/\gamma M_s$, $H_0 = 3.469 M_s$. (b) $\eta = 0.03/\gamma M_s$, $H_0 = 3.475 M_s$. The vector exits to the top, starting a curling process. (c) $\eta = 0.3/\gamma M_s$, $H_0 = 3.475 M_s$. (d) $\eta = 0.3/\gamma M_s$, $H_0 = 3.486 M_s$. Note the change in scale.

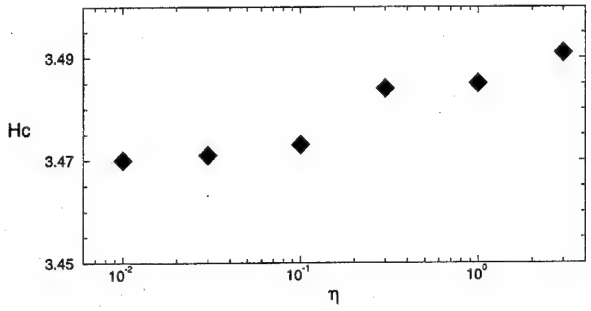

FIG. 3. Critical switching field as a function of damping constant, H_c/M_s vs $\gamma M_s \eta$.

H_c. At higher η, the path to $\mathscr{M}_s$ is shorter, as energy is quickly dissipated. At some field values causing switching, if η is increased the particle can no longer exit from the trap [Fig. 2(c)].

We need a criterion to mark a system as being in equilibrium so that we can decide if a value of H_0 eventually causes a reversal. We have chosen the total free energy, since it is consistently decreasing until equilibrium is reached. However, when the system is close to equilibrium, energy changes become small and are subject to numerical errors, which we believe are responsible for some switching when H_0 is very close to H_c [Fig. 2(d)]. This may correspond to thermal noise in a real particle, but the exact relation between the two, and the possibility of using this relation to

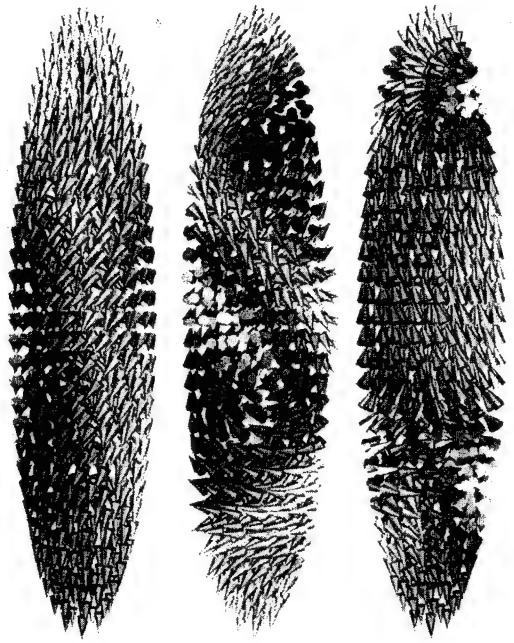

FIG. 4. Magnetization at switching, viewed from $+\hat{\mathbf{x}}$. $\mathbf{H}_0$ is pointing up. (a) curling pattern before switching. This is found for all values of H_0 and η for which switching occurs. (b) $H_0 = 3.493 M_s$, $\eta = 3/\gamma M_s$. During switching a vortex with an axis on the xz plane is formed in the middle of the ellipsoid; it travels transversely along $+\hat{\mathbf{y}}$. A smaller vortex forms closer to the top and travels along $-\hat{\mathbf{y}}$. When both vortices exit, magnetization of the whole particle is reversed. (c) $H_0 = 3.492 M_s$, $\eta = 0.3/\gamma M_s$. The middle part switches first, followed by the two ends.

simulate thermal noise, remains to be investigated. For the present we compute a moving average of the free energy and consider the system to be in equilibrium when that average stops decreasing for a fixed period of time. We estimate the error of H_c caused by this choice of criterion to be less than $0.01M_s$. Figure 3 shows H_c found as a function of η. We conclude that over-damping slightly increases the switching field. And that damping has no observable effect on the critical switching field when η is lower than one-tenth of $1/\gamma M_s$.

The curling stage starts with an exponential increase of $\mathcal{M}_n$, the component of the total magnetization along the applied field. The magnetization moves to a configuration that mostly resembles curling, with M_z gradually increasing, but stops before it switches. This curling process starts from center of the ellipsoid and expands to the whole middle part [Fig. 4(a)]. Curling stops at this configuration, and other more complicated processes take over. Parts of the ellipsoid, usually close to the center, switch first. This results in the appearance of domain walls and the subsequent events vary with the values of H_0 and η. The behavior can be best described as a continuous spectrum between two extreme cases. In a highly damped system ($\gamma M_s \eta > 1$), when H_0 is only slightly higher than the critical switching field, vortices with axes close to $\hat{\mathbf{x}}$ are formed [Fig. 4(b)]. This is similar to a configuration found in a static calculation.[8] When the damping is light ($\gamma M_s \eta < 1$), or H_0 is much higher than critical value, the whole middle part suddenly switches, and produces two sharp domain walls parallel to the xy plane [Fig. 4(c)], which eventually leave the particle through the surface. Generally speaking, the switching patterns at lower η are configurations with higher exchange energy, characterized by abrupt changes of magnetization in space.

In conclusion, we remark that, since the computational cost, both in time and in memory, of our method scales almost linearly with geometric size, it is quite feasible to treat larger systems than the one discussed here.

Anomalous time-induced curvature in Henkel plots based on the Preisach model

We have used a finite-temperature version of the Preisach model, in which thermally activated switching events supplement those induced by an applied field h_a, to calculate the magnetizing and demagnetizing remanences, $i_r(h_a)$ and $i_d(-h_a)$, respectively, assuming a Preisach distribution that is Gaussian in both the coercive field h_c and the shift field h_s. Since $T\neq 0$, the time t that the magnetization is permitted to relax influences the shape of the hysteresis loop and the Henkel plots constructed from the remanences. If the effective time for relaxation is specific to a given branch of the cycle, due perhaps to the way the system reacts to a given experimental procedure, it is possible to generate Henkel plots with curvature suggestive of mean field interaction effects, even if no such effects are actually present, or with such extreme demagnetizing-like curvature that the plot actually crosses the nominal lower boundary $i_d=-i_r$. Experimental instances of this behavior are discussed.
 [S0021-8979(96)20608-X]

I. INTRODUCTION

The Henkel plot[1] was originally proposed as an experimental technique for analyzing a magnetic system for the presence of interparticle interaction effects. If the magnetizing remanence, $i_r(h_a)$ of a system of single-domain particles is measured by applying and then removing positive fields h_a to the unmagnetized state until the remanence is saturated at $i_\infty \equiv i_r(h_a\rightarrow\infty)$, and then the demagnetizing remanence $i_d(-h_a)$ is measured by applying and removing negative fields $-h_a$ to the saturated remanence state i_∞ until negative saturation $-i_\infty$ is reached, then, according to Wohlfarth,[2] *noninteracting* systems will be characterized by the linear relation $i_d(-h_a)=i_\infty-2i_r(+h_a)$. Thus, a Henkel plot of i_d/i_∞ vs i_r/i_∞ with h_a as the matching variable, which curves above or below the Wohlfarth straight line $i_d/i_\infty=1-2i_r/i_\infty$, may be interpreted as evidence of either magnetizing-like or demagnetizing-like interactions, respectively, between the particles. This technique is now widely used, even in continuous systems,[3] which are only figuratively particulate by virtue of their domain wall motions,[4] and its interpretation has been formalized[5–7] through numerical calculations based on the Preisach model[8] of hysteresis. This model treats macroscopic hysteresis phenomena as a superposition of elementary rectangular hysteresis loops with individual coercive fields (or half-widths) h_c, with centers offset from the origin $h_a=0$ by a shift field h_s due to interactions between loops, and with two possible outputs, ± 1. The fields h_c and h_s are generally assumed to be distributed independently according to the Preisach distribution, $p(h_c,h_s)=f(h_c)g(h_s)$, and symmetry arguments[9] require that $g(h_s)$ be symmetric about $h_s=0$. In the moving Preisach model,[10] $h_s\rightarrow h_s+km$, where m is the magnetization and k is the mean field constant, in order to account, in an average sense, for the effect on the interaction field distribution of magnetizing the system. Numerical calculations have shown that, for ac and dc demagnetized systems,[5,6] curvature in a Henkel plot is produced by *both* mean field effects ($k\neq 0$) *and* by "disorder," that is, by a nonzero width to the shift field distribution $g(h_s)$. Only in the case of thermal demagnetization[7] is curvature produced *only* by a nonzero mean field parameter k. Furthermore, as long as $T=0$, all Henkel plots must lie above a lower boundary $i_d(-h_a)=-i_r(+h_a)$, independent of the details of their initial demagnetized state.

In this paper, we will use a generalized, finite-temperature version of the Preisach model[11,12] to show that the time that the system is permitted to relax may have a profound influence on the shapes of Henkel plots, and that varying this relaxation time from one branch to another of a given hysteresis cycle can produce spurious mean field-like curvature or even violations of the nominal lower boundary $i_d=-i_r$, as observed in some canonical spin glasses.

II. MODEL CALCULATIONS

Figure 1(a) shows the effect of applying a positive field h_a to an initially unmagnetized Preisach plane at $T=0$. For purposes of reference we have included both the (h_c,h_s) axes and the alternate (α,β) axes, where $\alpha=h_c+h_s$ and $\beta=h_c-h_s$ are the up and down switching fields, respectively, for an elementary loop. The signs indicate the current state of each loop. All the loops with $\alpha>h_a$ *and* $\beta<h_a$ are double well potentials like that illustrated in Fig. 1(a), while the rest of the loops outside this region are single well potentials. The symbol $\pm$ in the fourth quadrant means that one or both of the wells may have been occupied in the initial unmagnetized state, depending on the specific demagnetization technique; ac demagnetization leaves only the $-(+)$ well occupied above (below) the h_c axis, while for a thermally demagnetized system,[7] the $+$ and $-$ wells are both occupied with equal probability, $p(h_c,h_s)/2$.

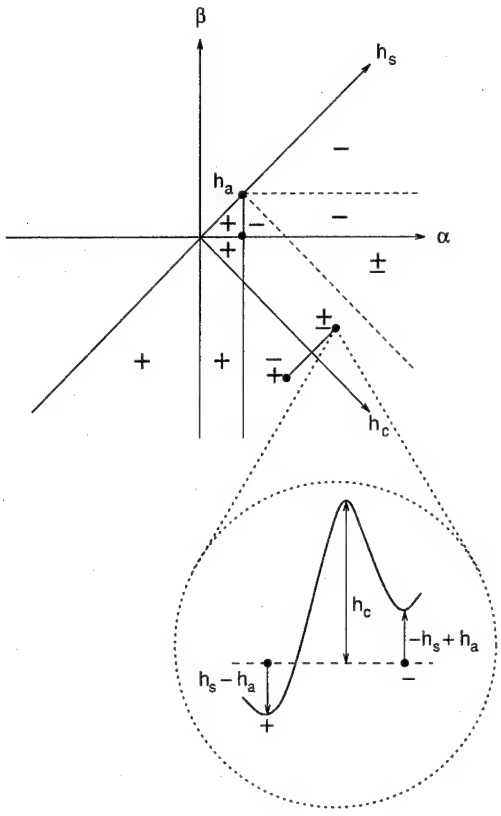

FIG. 1. (a) The effect of applying a positive field h_a to an initially unmagnetized Preisach plane at $T=0$. The double well representation of one of the elementary loops is shown on the right. (b) The same plane at a finite temperature $T\neq 0$. FL is the frontier line and h_T^* is the thermal field.

If the temperature T is not zero, we must take account of the effect of thermal overbarrier activation on the state of each loop.[11] More specifically, if an elementary loop is "trapped" in the higher-energy state of the double well potential in Fig. 1(a), this is regarded as an unstable configuration, and it is assumed that a transition will eventually occur over the smaller of the two barriers, which "switches" the loop to its lower-energy (or ground) state. Since the time τ for a thermally activated transition over an energy barrier W is

$$\tau=\tau_0 \exp(W/k_BT), \tag{1}$$

where τ_0^{-1} is a microscopic attempt frequency, then we expect that in a finite observation time t, all of the smaller barriers $W=h_c\pm h_s\mp h_a<W^*\equiv k_BT\ln(t/\tau_0)$ will have been overcome. This defines a frontier line,

$$h_c=W^*\pm h_s\mp h_a, \tag{2}$$

with its vertex on $h_s=h_a$, as shown in Fig. 1(b), which separates those regions "behind" the line that have reached equilibrium within the observation time t, from those "in front" of the line that have not. From a technical perspective the effect of the critical barrier height W^* on the Preisach plane is equivalent to an *effective thermal field* $h_T^*=W^*$ (since the loop moment is unity), which can act simultaneously along the α and β axes via two coupled flipping lines, to supplement the switching events induced by the applied field h_a.

Numerical calculations[12] of the remanences $i_r(h_a)$ and $i_d(-h_a)$, which assume that the Preisach distribution is a product of two Gaussians:

$$p(h_c,h_s)=\frac{1}{2\pi\sigma_c\sigma_s}\exp\left[-\frac{(h_c-\bar{h}_c)^2}{2\sigma_c^2}\right]\exp\left[-\frac{(h_s+km)^2}{2\sigma_s^2}\right], \tag{3}$$

and that all branches of a given hysteresis cycle have a common thermal field parameter h_T^* corresponding, for example, to a fixed temperature T and a single time constant t, have shown that the Henkel plots for a thermally demagnetized system with no mean field interactions ($k=0$) are Wohlfarth straight lines, independent of h_T^*, while those for an ac demagnetized system with $k=0$ always have demagnetizing-like curvature, which increases with increasing h_T^*, but never violates $i_d=-i_r$.

If, however, a common *experimental* time constant does *not* imply a common relaxation rate for the magnetization, then the effective time constant for relaxation t_{eff} may vary from branch to branch of the cycle, as will the effective thermal field parameter, h_T^*, and the Henkel plots will show anomalous structure. Field cooled spin glasses are a particularly good instance of this temporal "asymmetry." It is now widely accepted that, if a spin glass is cooled from above to below its ordering temperature T_{SG} in the presence of a field, it attains its equilibrium magnetization essentially instantaneously, independent of the actual measuring time t, as if the effective time constant for relaxation was infinite. However, all subsequent field reversals, such as those required to reach the remanent state or the demagnetizing branch, are governed by a necessarily much shorter time constant, close to the actual, finite experimental one. We have replicated this behavior in the finite temperature Preisach model by assigning a very large value $h_{T1}^*\gg\bar{h}_c$ to the thermal field parameter along the virgin magnetizing curve, and another smaller value $h_{T2}^*<h_{T1}^*$ to the remanence (in this case the thermoremanence or TRM), the descending branch of the major loop, and the demagnetizing remanence.

Figure 2 shows a sequence of Henkel plots generated for a *thermally demagnetized* system with a Preisach distribution

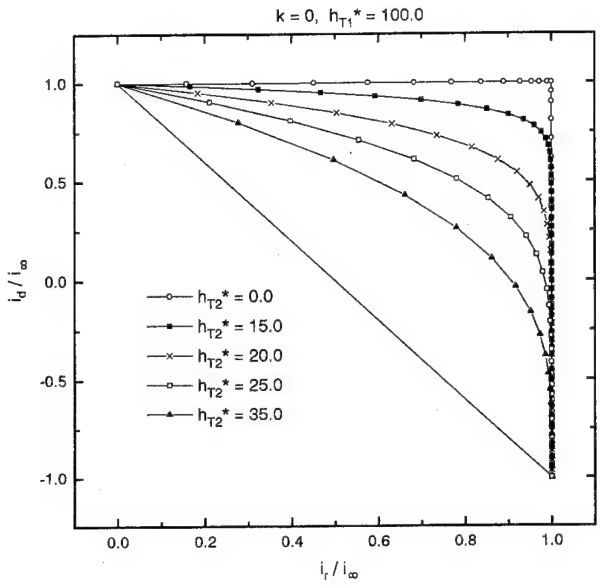

FIG. 2. Henkel plots for a thermally demagnetized, field cooled system with Preisach distribution parameters $\bar{h}_c=12$, $\sigma_c=4$, $\sigma_s=1$, $k=0$, for thermal fields $h_{T1}^* = 100$ and $h_{T2}^* = 0, 15, 20, 25, 35$.

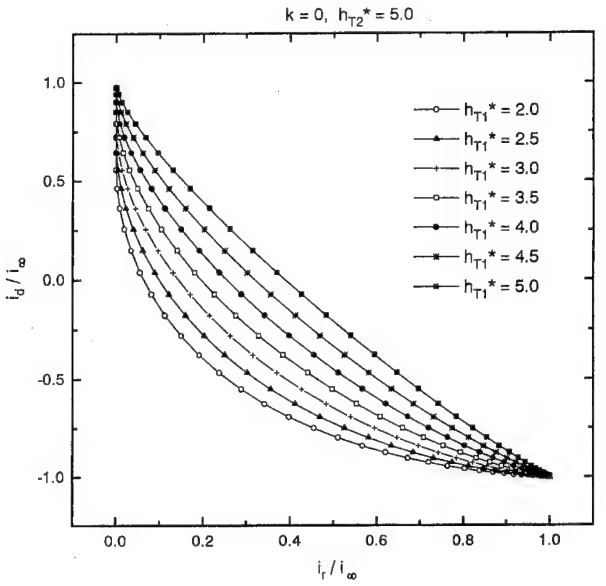

FIG. 3. Henkel plots for an ac demagnetized system with Preisach distribution parameters $\bar{h}_c=10$, $\sigma_c=3$, $\sigma_s=1$, $k=0$, for thermal fields $h_{T1}^* = 2.0$, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, and $h_{T2}^* = 5.0$.

with parameters $\bar{h}_c=12$, $\sigma_c=4$, $\sigma_s=1$, $k=0$, for thermal fields $h_{T1}^* = 100$ and $h_{T2}^* = 0, 15, 20, 25, 35$. All the Henkel plots show magnetizing-like curvature, which for thermally demagnetized systems would be unambiguous evidence of positive mean field interactions $k>0$, but that is actually an artificial consequence of the variation in time constants related to the experimental procedure of field cooling. In real spin glasses, the situation is further complicated by the existence of a peak in the field dependence of the TRM, which is difficult to accommodate within the usual Henkel analysis.

The inverse configuration of time constants yields anomalous structure of a different kind and may also be physically relevant to spin glasses. If we assume that the relaxation time constant is shorter along the virgin magnetizing curve than it is for the rest of the cycle, corresponding to $h_{T1}^* < h_{T2}^*$, then, in the absence of mean field effects, Henkel plots will always show demagnetizing-like curvature, as illustrated in Fig. 3 for an ac demagnetized system with Preisach distribution parameters $\bar{h}_c=10$, $\sigma_c=3$, $\sigma_s=1$, $k=0$, for thermal field parameters $h_{T1}^* = 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0$, and $h_{T2}^* = 5.0$. Moreover, if the difference between the two thermal fields (or time constants) is sufficiently large, the Henkel plots will actually cross the nominal $T=0$ lower boundary $i_d=-i_r$, as observed in canonical spin glass systems like AgMn[13] and CuMn[14] at low reduced temperatures T/T_{SG}, when they have been *zero field cooled* through their glass temperature. As $h_{T1}^* \to h_{T2}^*$, this effect becomes weaker and eventually disappears, which is precisely what happens experimentally with increasing temperature. If the theoretical and experimental behaviors are indeed related, then it would mean that zero field cooling has essentially the opposite effect of field cooling, and "traps" the system in a region of its complicated configuration space, which requires relatively long times and high reduced temperatures for "escape."

In summary, numerical calculations based on a finite temperature version of the Preisach model show that, when $T\neq 0$, the effective time in which the magnetization relaxes becomes an important factor in shaping Henkel plots, and may lead to anomalous curvature that imitates mean field effects, or that violates zero temperature boundaries.

Magnetization reversal and small lancettes calculated by statistic domain behavior (abstract)

Paul L. Fulmek and Hans Hauser
Institut für Werkstoffe der Elektrotechnik, Technische Universität Wien Gusshausstrasse 27–29, A-1040 Wien, Austria

The energetic model of ferromagnetic hysteresis calculates the magnetic state of anisotropic ferromagnetic materials by minimizing the total energy function $E_T = E_H + E_M$. The energy of the material E_M is divided into reversible (statistic domain behavior) and irreversible terms.[1,2] The applied field H (energy E_H) causes reversible domain wall displacements s_i until an individual Barkhausen jump starting position s_A is reached. The probability density $p_a(s_A)$ is assumed to be decreasing with increasing s_A: $p_a = (K_a/K_c)\exp[-(K_a/K_c)s_A]$ (adaptive constant K_a). K_c describes the influence of the total magnetic state on p_a at points of magnetization reversal; $K_c = 1$ for the initial magnetization curve. The losses E_r during an irreversible Barkhausen jump (wall friction K_r) are increasing with s_i: $E_r = K_r[s_i - s_A - (K_c/K_a)(K_c - 1)]$ and K_c depends on the covered displacements s_i at a point of field reversal: $K_c^{\text{new}} = 2 - K_c^{\text{bold}}\exp[-(K_a/K_c^{\text{old}})s_i]$. This follows from the condition of steadiness at these points. The physical constants of this model are derived from anisotropic energy contributions, initial susceptibility, coercivity, and saturation magnetization. The approach shows a good agreement to measurements to the stability of small lancettes of (110)[001] 3.5% FeSi steel sheets, magnetized in the rolling direction. © *1996 American Institute of Physics.* [S0021-8979(96)82508-9]

Surface anisotropy of a fine γ-Fe_2O_3 particle

Kezhao Zhang and Donald R. Fredkin
Physics Department, University of California, San Diego, La Jolla, California 92093

We investigate the effects of surface anisotropy of a single-domain γ-Fe_2O_3 fine particle (length 3000 Å, aspect ratio 4.6:1) using micromagnetics and the finite element method. We add surface anisotropy energy, axially symmetric about the surface normal, to the total magnetic energy of the particle. We show that surface anisotropy of the appropriate sign enhances the coercivity. Further, the surface magnetization tends to be tangential to the surface and the magnetization reversal starts from the surface. Our simulation suggests that surface anisotropy might be an important mechanism for the coercivity enhancement in the surface-modified iron oxides. © *1996 American Institute of Physics.* [S0021-8979(96)20708-6]

I. INTRODUCTION

Surface effects of fine particles in high density magnetic recording media become very pronounced because of the large surface-to-volume ratio. Experiments have shown that modification of fine γ-Fe_2O_3 particles with Co[1,2] or sodium polyphosphate[3,4] can enhance the coercivity. A variety of possible mechanisms for and numerical simulations of the enhancement of coercivity have been discussed. For example, the particle volume can be divided into a low crystalline anisotropy core region and a high crystalline anisotropy shell region.[5–7] In another approach, a mechanism for surface anisotropy is suggested[8] and a quantum theory of the surface anisotropy of ferrimagnetic γ-Fe_2O_3 has been developed.[9] Dimitrov and Wysin[10] have numerically investigated the effects of surface anisotropy on hysteresis in a simplified case where the magnetic particles are spins on two- and three-dimensional finite lattices; each element in the system represents a single magnetic ion rather than a finite volume as in micromagnetics. In their simulation, magnetic dipole interactions are neglected.

In this paper we describe our micromagnetic study of the effects of surface anisotropy of a fine single-domain γ-Fe_2O_3 particle.

II. MICROMAGNETIC MODEL

We formulate the problem in terms of micromagnetics.[11] To investigate the effects of surface anisotropy, we add surface anisotropy energy to the total magnetic energy,

$$E_{\text{total}}=E_{\text{ex}}+E_{\text{demag}}+E_{\text{anis}}+E_{\text{Zeem}}+E_{\text{surface}}, \tag{1}$$

where E_{ex} is the exchange energy, E_{demag} is the magnetostatic interaction energy, E_{anis} is the crystalline anisotropy energy in the bulk of the particle, and E_{Zeem} is the Zeeman energy describing the interaction of the magnetization in the particle and an applied field. The surface anisotropy energy is

$$E_{\text{surface}}=K_s'\int [\mathbf{M}(\mathbf{r})\cdot\hat{\mathbf{n}}]^2\, dS=K_s\int \cos^2\theta\, dS, \tag{2}$$

where $\mathbf{M}(\mathbf{r})$ is the magnetization vector, $\hat{\mathbf{n}}$ is the unit vector normal to the surface, θ is the angle between $\mathbf{M}$ and $\hat{\mathbf{n}}$, and the surface anisotropy constant is $K_s = K_s'|\mathbf{M}|^2$. The integration is carried out over the surface of the particle.

We use the finite element method (FEM) to discretize the continuous magnetization field.[12,13] The magnetic region is decomposed into tetrahedral elements and the magnetization within an element is interpolated linearly from its values at the nodes of the mesh. The magnitude of the magnetization is fixed, $|\mathbf{M}(\mathbf{r})|=M_s$, where M_s is the saturation magnetization. Finally, the total magnetic energy is expressed as a quadratic polynomial of the magnetization vectors on the nodal points of the FEM mesh,

$$E_{\text{total}}=\sum_{i,j}\tfrac{1}{2}\mathbf{M}_i\cdot\mathbf{K}_{ij}\cdot\mathbf{M}_j-\sum_i Z_i\mathbf{M}_i\cdot\mathbf{H}_{\text{ext}}. \tag{3}$$

The $\mathbf{K}$ matrix contains all information about the long range magnetostatic interaction, the anisotropy energy (including surface and crystalline anisotropies), and the exchange energy. Z_i gives the weights of external field on the nodes.

We use the Landau–Lifshitz equation without the procession term to monotonically reduce the system energy to a local minimum, corresponding to a metastable magnetization configuration.

III. RESULTS

We investigate a fine single-domain ellipsoidal γ-Fe_2O_3 particle with a long axis of 3000 Å and a short axis of 650 Å. The saturation magnetization $M_s=350$ emu/cm^3; the crystalline anisotropy constant $K_1=-4.6\times10^4$ ergs/cm^3.[14] The crystalline anisotropy constant is negligible compared to the shape anisotropy energy of an ellipsoid with an aspect ratio of 4.6:1 which is $0.81\pi M_s^2=3.2\times10^5$ ergs/cm^3.[15] Therefore we neglect crystalline anisotropy, $K_1=0$. The value of the exchange constant is known only approximately; we use $A=5.0\times10^{-7}$ ergs/cm in our calculation.

We calculate the hysteresis loops (Fig. 1) with different surface anisotropy constants. Surface anisotropies on the order of 1 erg/cm^2 have been reported for iron.[16,17] We choose K_s within the range of 0–50 ergs/cm^2.

Figure 1 shows the increase of coercivity due to the surface anisotropy. The relationship of these two quantities is summarized in Fig. 2. For $K_s\approx20$ ergs/cm^2, the coercivity is about double of the value when $K_s=0$.

The computed magnetization configuration just before the switching indicates that magnetization reversal starts from the surface where the magnetization vectors form a wavelike pattern [Fig. 3(b)], while in the bulk magnetization is almost pointing in the same direction [Fig. 3(a)]. Surface

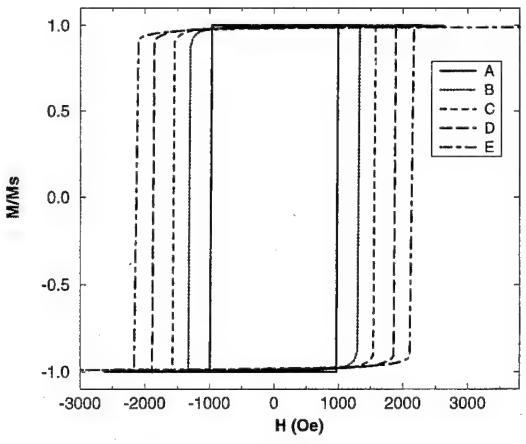

FIG. 1. Hysteresis loops of an ellipsoidal γ-Fe_2O_3 particle (aspect ratio 4.6:1) with various surface anisotropy constants K_s. The magnetization is along the long axis of the particle. The angle between the external field and the long axis is 1°. (A) $K_s=0$; (B) $K_s=3.98$ ergs/cm^2; (C) $K_s=7.96$ ergs/cm^2; (D) $K_s=19.91$ ergs/cm^2; (E) $K_s=39.81$ ergs/cm^2.

magnetization tends to be tangential to the surface, which requires a larger applied field during the switching, hence the enhancement of coercivity.

We have also investigated the effects of $K_s<0$. Negative K_s is found experimentally to be much smaller than the positive K_s for iron.[16] Our simulation shows that negative surface anisotropy does not effectively enhance the coercivity and in many cases decreases it. However, $K_s<0$ makes the surface magnetization perpendicular to the surface and aids formation of nucleation centers on the surface.

IV. CONCLUSION

We added a surface anisotropy energy term to the total magnetic energy in the micromagnetic model in order to understand the effects of the surface anisotropy in a fine surface-modified γ-Fe_2O_3 particle. Our simulation shows that with positive surface anisotropy ($K_s>0$), magnetization reversal starts from the surface. Coercivity is doubled when $K_s\approx 20$ ergs/cm^2 for an ellipsoidal particle with a 3000-Å-long axis. This suggests that surface anisotropy might be an important mechanism for the coercivity enhancement in fine surface-modified iron oxide particles. The increase of coercivity can be attributed to the energy barrier, which requires a larger applied field during the switching, due to the positive surface anisotropy. For smaller particles that have a larger surface-to-volume ratio, the effects of surface anisotropy could be more prominent.

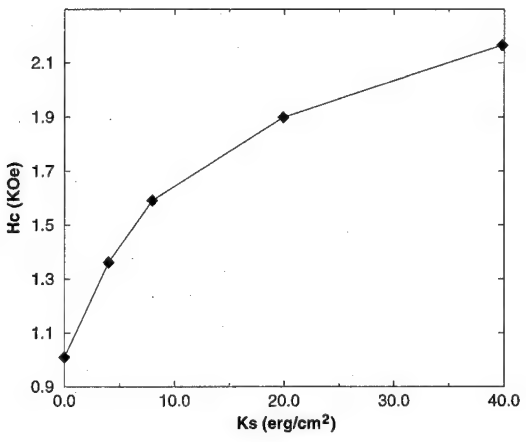

FIG. 2. Coercivity vs surface anisotropy constant. The values of the coercivity are obtained from the computed hysteresis loops.

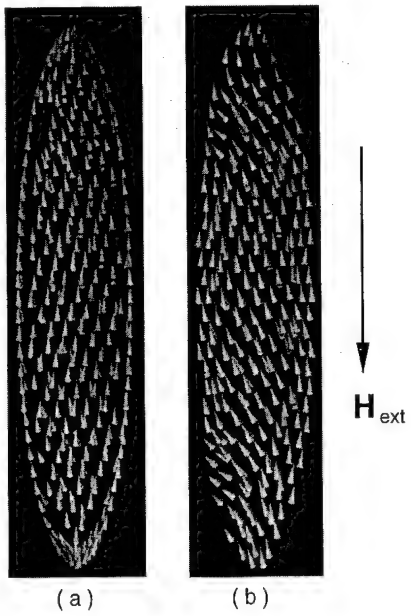

FIG. 3. Magnetization configurations on different cross sections just before switching. The surface anisotropy $K_s=19.91$ ergs/cm^2 and the applied magnetic field $H_{ext}=1869$ Oe. Random free energy model for the description of hysteresis

G. Bertotti, V. Basso, and G. Durin
IEN Galileo Ferraris, INFM and GNSM, Corso M. d'Azeglio 42, I-10125 Torino, Italy

The connection between hysteresis phenomena and free energy metastable states in magnetic systems is discussed. A random free energy model is introduced, which leads to a stochastic differential equation for the evolution of magnetization in time. We show that the solutions of this equation are equivalent to the Preisach model of hysteresis. The analytical form of the Preisach distribution is calculated. © *1996 American Institute of Physics.* [S0021-8979(96)20808-2]

I. INTRODUCTION

Hysteresis, and in particular ferromagnetic hysteresis, has its origin in the multiplicity of metastable states in the system free energy. The consequences of such a general statement are usually very difficult to translate into quantitative predictions. An intermediate, more viable approach pursued by several authors has been to introduce phenomenological models, where all the basic hysteretic features are a direct consequence of a few simple initial assumptions. In this respect, a powerful tool is the Preisach model,[1] where hysteresis is described by a collection of a large number of elementary bistable units, each characterized by the values α and β, $\alpha>\beta$, at which the external field H_a makes the unit switch up or down. A given system is fully described by the switching field distribution $p(\alpha,\beta)$. The Preisach model clarifies several important aspects of hysteresis phenomena, but its relation to the system free energy properties still presents several unresolved aspects. The most remarkable result in this respect is still perhaps Néel's derivation of the Rayleigh law of ferromagnetic hysteresis,[2] where he showed that the behavior of a magnetic domain wall under small fields is approximately equivalent to a Preisach description with a constant Preisach density.

In this paper we analyze the properties of a simple single-degree-of-freedom system which sheds new light on this problem. The model is based on a stochastic description of the system free energy $F(I)$ as a function of the magnetization I, characterized by the presence of a great number of local minima. We will show that the evolution of the system through the metastable states landscape results in a random sequence of irreversible jumps and that the associated hysteresis properties, once averaged over a proper statistical ensemble, are equivalent to a Preisach description with an exponential Preisach distribution of the form $p(\alpha,\beta) \propto \exp[-(\alpha-\beta)/2A\chi]$, where A and χ are suitable constants. The model shows how the Preisach description arises from the stochastic dynamics of the system and thus represents an important result in the direction of clarifying the physical meaning and limits of the Preisach model itself.

II. MODEL

We will consider a ferromagnetic system, described by its magnetization I, evolving under the action of a time-dependent external field $H_a(t)$, where internal heat is produced as a consequence of irreversible processes. The rate of heat production per unit volume during a given isothermal transformation is

$$\frac{dQ_i}{dt}=H_a(t)\frac{dI}{dt}-\frac{dF}{dt}=\left[H_a(t)-\frac{\partial F}{\partial I}\right]\frac{dI}{dt}, \tag{1}$$

where $H_a dI/dt$ is the power injected into the system and $F(I)$ is the system free energy. We consider the case where the system is not brought too far from equilibrium, so that there exists a linear relationship between the thermodynamic flux dI/dt and the thermodynamic force $H_a(t)-\partial F/\partial I$,

$$\gamma\frac{dI}{dt}=H_a(t)-\frac{\partial F}{\partial I}. \tag{2}$$

In the case of a quadratic dependence of F on I, i.e., $F=I^2/2\chi$, Eq. (2) gives the well-known exponential relaxation equation $\gamma dI/dt=H_a-I/\chi$. This equation predicts a linear quasistatic behavior of the form $I=\chi H_a$ (no hysteresis). Under stationary conditions, if H_a increases at constant rate, $dI/dt=\chi dH_a/dt$, and the heat production per unit magnetization change is $dQ_i/dI=\gamma dI/dt=\gamma\chi dH_a/dt$.

Moving from these well-known results, we now consider the case where F exhibits random fluctuations around the large-scale parabolic behavior, as a consequence of the presence of some quenched-in disorder in the system. We thus consider $F=I^2/2\chi+F_p(I)$, where $F_p(I)$ describes the random fine structure of the free energy. This leads to the formation of many metastable states. The precise functional dependence of $F_p(I)$ on I is different for different systems. We assume that $F_p(I)$ is continuous and has a continuous first derivative, so that the random pinning field $H_p(I)=\partial F_p/\partial I$ exists and is continuous, but otherwise random. The simplest stochastic process having such properties is an I-random-walk characterized by independent increments dH_p, with $\langle dH_p\rangle=0$ and $\langle|dH_p|^2\rangle=2A\,dI$. Some cutoff in this behavior is expected for sufficiently small or large I variations. These complications are not considered here and will be addressed in subsequent more refined treatments. By introducing the dimensionless variables $u=t/\gamma\chi$, $x=I/A\chi^2$, $v=dx/du$, $h_a=H_a/A\chi$, $h_p=H_p/A\chi$, we obtain

$$\begin{aligned} &v=h_a(u)-[x+h_p(x)],\\ &\langle dh_p\rangle=0,\quad \langle|dh_p|^2\rangle=2dx. \end{aligned} \tag{3}$$

The random nature of $h_p(x)$ is responsible for the corresponding stochastic evolution of v. As shown in the following sections, there is an intimate connection between the statistical properties of the v process and the hysteresis properties of the system.

 0021-8979/96/79(8)/5764/3/$10.00

III. ENERGY DISSIPATION

Let us consider the v process as a function of the dimensionless coordinate x.[3] By deriving Eq. (3) with respect to x in the case where the external field increases at the constant time rate $c=dh_a/du$, we obtain

$$\frac{dv}{dx}+\left(1-\frac{c}{v}\right)=-\frac{dh_p(x)}{dx}. \tag{4}$$

The associated Fokker–Planck equation for the v transition density $P(v,x|v_0)$ is

$$\frac{\partial P}{\partial x}-\frac{\partial}{\partial v}\left[\left(1-\frac{c}{v}\right)P\right]-\frac{\partial^2 P}{\partial v^2}=0. \tag{5}$$

From Eq. (5), the stationary distribution turns out to be

$$P_x(v)=\frac{1}{\Gamma(c+1)}\,v^c\exp(-v), \tag{6}$$

where the subscript x recalls the fact that P_x represents the distribution of v values picked up at random x positions. In the limit of quasistatic excitation ($c\ll 1$), the system evolves by a sequence of well-separated Barkhausen jumps, responsible for the quasistatic hysteretic behavior of the system.[4,5] The corresponding heat production $\langle dQ_i/dI\rangle_I=\gamma$ $\langle dI/dt\rangle_I=\chi A\langle v\rangle_x$ can be calculated from Eq. (6) as

$$\begin{aligned}\left\langle\frac{dQ_i}{dI}\right\rangle&=\chi A\langle v\rangle_x=\chi A\int_0^\infty vP_x(v)dv\\&=\frac{\chi A}{\Gamma(c+1)}\int_0^\infty v^{c+1}\exp(-v)dv\\&=\chi A\,\frac{\Gamma(c+2)}{\Gamma(c+1)}=\chi A(1+c)\\&=\chi A+\gamma\left\langle\frac{dI}{dt}\right\rangle.\end{aligned} \tag{7}$$

The heat production per unit average magnetization change has the dimensions of a field and represents the half-width of the corresponding hysteresis loop. The first term in the last expression of Eq. (7) represents the quasistatic dissipation associated with a hysteresis loop of half-width $H_0=A\chi$, while the second one is the dynamic dissipation expected when fluctuations can be neglected, so that $F=I^2/2\chi$, as calculated above. The fact that these two terms are simply summed up is what is commonly termed loss separation. Our result shows that this is a rigorous property of a certain class of dynamical systems, rather than, as is often assumed, a useful empirical assumption for the description of experimental results.

IV. EQUIVALENCE WITH THE PREISACH MODEL

As shown by Eq. (7), the model predicts the existence of rate-independent hysteresis in the limit of vanishing magnetization rates. We will show that these hysteresis effects can be described by the Preisach model. Mayergoyz proved that a system with hysteresis is equivalent to the Preisach model if it obeys the so-called "wiping out or return-point-memory" and "congruency" properties.[6] We will prove that the system described in the preceding sections obeys these properties.

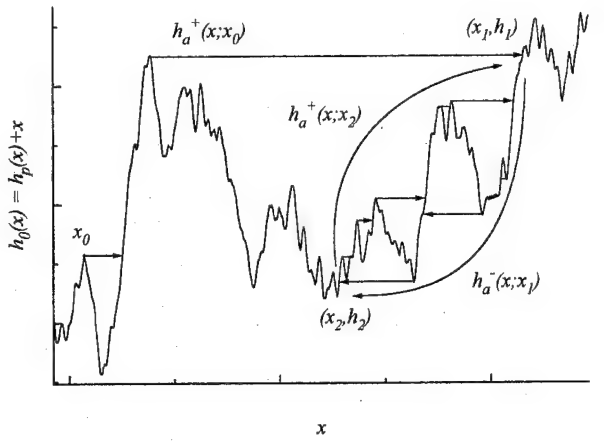

FIG. 1. Example of evolution of the system over $h_0(x)=h_p(x)+x$ with a field rate $dh_a/du=c\ll 1$. $h_a^+(x;x_0)$ is an ascending branch starting from the point x_0. The wiping out property assures the closure of the minor loop between the h_1 and h_2 fields.

Wiping out or return-point-memory property: If we consider a nonmonotone applied field with two subsequent reversal points h_1 and h_2, as the field goes back from h_2 to h_1 and reaches h_1 again, the system returns to exactly the same state it was at the first reversal point.

We prove this property in the limit of the low applied field rate $dh_a/du=c\ll 1$. In this limit, the behavior of the system depends only on the sign of dh_a/du. Irreversible jumps correspond to horizontal h_a segments starting from local maxima of $h_0(x)=h_p(x)+x$ (see Fig. 1). The evolution of the system is described by the $h_a(x)$ line. We indicate by $h_a^+(x;x_0)$ and $h_a^-(x;x_0)$ generic monotone branches originating from the point x_0, and associated with increasing (+) or decreasing (−) field. The system must be at rest at the point x_0, which means that $h_a^+(x_0;x_0)=h_0(x_0)$, $h_a^-(x_0;x_0)=h_0(x_0)$. Monotone branches satisfy the following laws:

(1) $h_a^+(x;x_0)\geq h_a^-(x;x_1)$ for any x_0 and x_1. This is the immediate consequence of the fact that, by definition, $h_a^+(x;x_0)\geq h_0(x)$ and $h_a^-(x;x_1)\leq h_0(x)$ for any x.

(2) $h_a^+(x;x_0)\geq h_a^+(x;x_1)$ for any $x_1\geq x_0$ and $h_a^-(x;x_0)\leq h_a^-(x;x_1)$ for any $x_1\leq x_0$. Let us consider the first inequality and suppose it is not obeyed. Then there exists a local maximum of $h_0(x)$ exceeding $h_a^+(x;x_0)$, with $x>x_0$. But this is not possible, because, as illustrated above, $h_a^+(x;x_0)\geq h_0(x)$ for any $x>x_0$.

The two inequalities (1) and (2) imply the wiping out property. In fact, let us consider a branch $h_a^+(x;x_0)$, up to the turning point $h_a^+(x_1;x_0)=h_0(x_1)$, $x_1>x_0$, and the subsequent decreasing branch $h_a^-(x;x_1)$ down to the second turning point $h_a^-(x_2;x_1)=h_0(x_2)$, $x_1>x_2>x_0$. Let us consider the branch $h_a^+(x;x_2)$. By inequality (1), $h_a^+(x;x_2)\geq h_a^-(x;x_1)$. On the other hand, since $x_2>x_0$, inequality (2) gives $h_a^+(x;x_0)\geq h_a^+(x;x_2)$. Thus $h_a^+(x;x_0)\geq h_a^+(x;x_2)\geq h_a^-(x;x_1)$. Since $h_a^+(x_1;x_0)=h_a^-(x_1;x_1)=h_0(x_1)$, also $h_a^+(x_1;x_2)=h_0(x_1)$. This proves the wiping out property.

Congruency property: All minor loops delimited by the same peak field values are geometrically congruent.

In order to prove this property, we have to properly define minor loops. Let us consider an applied field oscillating between the two reversal points h_1 and h_2. Because of the wiping-out property, cycling between h_2 and h_1 will eventually generate a closed minor loop in all cases. Individual minor loops between the same peak fields will have in general different shapes, so that congruency can hold only for the average loop obtained after statistical average over the subensemble of $h_0(x)$ portions selected by the applied field history. After the average, the minor loop shape can only depend on the difference $h=h_2-h_1$, and not on h_1 or h_2 separately. This occurs because the increments of $h_0(x)=x+h_p(x)$ for a given x increment Δx have a statistical distribution only dependent on Δx and otherwise completely independent of h_0 and x. Thus average minor loops associated with the same Δh difference are identical in shape. This proves the congruency property.

The fact that minor loops characterized by the same Δh, with different h_1 and h_2, are congruent implies that the Preisach distribution $p(\alpha,\beta)$ associated with the system is a function of $(\alpha-\beta)$ only. The analytic dependence on $(\alpha-\beta)$ can be determined by considering the rate of energy dissipation predicted by the model. According to the Preisach model, the energy dissipated during a given field change dH_a is

$$dQ_i=dH_a\int_{-\infty}^{H_a}d\beta(H_a-\beta)p(H_a-\beta)$$

$$=4dH_a\int_0^{\infty}dh_c h_c p(h_c), \tag{8}$$

where $h_c=(\alpha-\beta)/2$ represents the half-width of each elementary Preisach loop. Let us compare this expression with the term of Eq. (7) where the dissipation is expressed in terms of $P_x(v)$. The quantity h_c plays, in the Preisach model, the same role of $\gamma dI/dt$, i.e., of v, since it measures the rate of energy dissipation. Therefore, from Eqs. (7) and (8), by taking the limit $c\to 0$ and by exploiting the correspondence $h_c\leftrightarrow\gamma dI/dt=A\chi v$, $p(h_c)\leftrightarrow\exp(-v)=\exp(-h_c/A\chi)$ and the fact that $dI=\chi dH_a$, we obtain

$$p(\alpha-\beta)=\frac{1}{4A}\exp\left(-\frac{\alpha-\beta}{2A\chi}\right). \tag{9}$$

It is worth noticing that this distribution has no dependence on $h_u=(\alpha+\beta)/2$, as our model describes nonsaturating hysteresis. Furthermore, in the case of small applied fields the Rayleigh law $I=aH+bH^2$ holds with $a=0$ and $b=1/(2A)$.

V. CONCLUSIONS

The physical picture here proposed gives a convincing interpretation of several experimental observations. The model predicts Barkhausen jump properties which are in good agreement with recent experiments.[4,5] The Preisach description mentioned above predicts a hysteresis loop half-width proportional to $A\chi$. As shown in Sec. II, the parameter χ describes the curvature of the large-scale potential well in which a given domain wall is trapped. This curvature can be experimentally modified by various means, and the dependence of coercivity on χ has actually been observed and interpreted by methods similar to the ones discussed in Sec. III.[7] Finally, the Preisach density of Eq. (9) obeys the factorization $p(\alpha,\beta)=f(\alpha)f(-\beta)$, with $f(x)$ proportional to $\exp(-x)$. Recently, there has been some debate about the fact that such factorization might be the natural one when domain wall motion is the basic magnetization mechanism.[8,9] The present results make clear the context and the limits within which this assumption is acceptable.

Micromagnetics of polycrystalline two-dimensional platelets

K. M. Tako, M. A. Wongsam, and R. W. Chantrell
Physics Department, Keele University, Keele, Staffordshire ST5 5GB, United Kingdom

A numerical micromagnetic technique is used to simulate magnetization processes in two-dimensional thin metallic platelets. The platelets are modeled as an array of interacting polycrystalline grains. The technique assumes a triangular discretization at the subgrain level with the magnetization varying linearly over each triangle. The coupling between the grains has a profound effect on the magnetic structure of the platelets as does the grain size. For systems with strongly exchange coupled grains, approximately solenoidal magnetization structures exist. A single domain behavior exists for systems with weakly coupled grains. The magnetization pattern of the platelets has been characterized by the vorticity of the magnetization vector field. © *1996 American Institute of Physics.* [S0021-8979(96)20908-9]

I. INTRODUCTION

Since the theory of micromagnetics was formulated by Brown,[1,2] numerical techniques have become an everyday tool in solving micromagnetic problems. Then, only particles with the simplest of geometries were considered enabling analytical techniques to be employed. It is, however, apparent that for present day technological applications these particles generally have a wide distribution of complicated geometries. The demagnetizing field within the particles is generally nonuniform. This gives rise to nonuniform magnetization states. It is therefore not surprising that for particles with more complicated morphology, the idea of nonuniform magnetization within the particles cannot be ignored. The intergranular correlations in materials with nonuniform magnetization properties within grains is of great significance. Shape[3] and size[3,4] have been found to influence the magnetic behavior of these systems. Effort has been made by different authors to investigate the magnetization processes associated with such complicated shapes.

In this paper, we present a dynamic finite element method which is used to study magnetization processes in polycrystalline two-dimensional (2D) platelets with a realistic grain structure. The grains which are irregularly shaped, have been produced by the Voronoi construction[4] and have easy anisotropy axes oriented at random. The Landau–Lifschitz (LL) equation is used. We give a brief description of the model in Sec. II and we present some results in Sec. III.

II. MICROMAGNETIC MODEL

Since the bulk of the micromagnetic model has been described elsewhere,[4] we shall limit ourselves to a brief description. The 2D platelet is modeled as an array of irregularly shaped interacting polycrystalline grains produced using the Voronoi construction.[4] Each grain, assumed to be a single crystal, is assigned a random in-plane uniaxial anisotropy easy axis. The approach assumes a triangular discretization at the subgrain level with the magnetization allowed to vary linearly within each triangle. We have discretized each grain by joining its nodes to its seed point (center). The total magnetic field at each point within the platelet is made up of contributions from external, exchange, anisotropy, and magnetostatic sources. The formulation of all the field terms has been given in our previous work.[4]

The time evolution of the magnetization of the system is governed by the LL equation which can be written as

$$\frac{d\mathbf{m}}{d\tau}=\mathbf{m}\times\mathbf{h}-\alpha\mathbf{m}\times(\mathbf{m}\times\mathbf{h}), \tag{1}$$

where $\mathbf{h}=\mathbf{H}/H_k$ is the total reduced effective field from all sources, $\mathbf{m}=\mathbf{M}/M_s$ the reduced magnetization, α the reduced damping constant, and τ the reduced time. $H_k=2K/M_s$, K being the uniaxial anisotropy constant and M_s the saturation magnetization. A fourth-order predictor–corrector algorithm with error control capability and step size adjustment is used to solve the system of coupled differential equations (1). A suitable convergence criterion is adopted by limiting the angle between $\mathbf{m}$ and $\mathbf{h}$ to within 0.01 rad.

The magnetic structure is characterized by the vorticity (Γ) of the magnetization field vector. The vorticity defines the sense of rotation of the magnetization vector as well as the extent to which it is tilted in the vortex regions. It is defined as the line integral of the magnetization field vector along a chosen path in the film plane scaled with respect to the length of the path.[5,6] For convenience, we chose a circular path. Thus $\Gamma_i(r)=\oint\mathbf{m}\cdot d\boldsymbol{\lambda}/\oint\hat{p}\cdot d\boldsymbol{\lambda}$, defines the vorticity at points lying on the circumference of a circle of radius r centered on the seed point of grain i. $\hat{p}$ is a unit vector tangential to the path. Given that $\oint\mathbf{m}\cdot d\boldsymbol{\lambda}=\int_s(\nabla\times\mathbf{m})ds$ by Stoke's theorem, it is more convenient in practice to calculate the vorticity function via the curl of $\mathbf{m}$. Because of the presence of vortices with positive and negative sense, the most sensible system average is the absolute value of Γ. Thus we define the system vorticity as

$$\Gamma(r)=\frac{1}{N}\left|\sum_{j=1}^{N}\frac{\oint\mathbf{m}\cdot d\boldsymbol{\lambda}}{\int\hat{p}\cdot d\boldsymbol{\lambda}}\right|, \tag{2}$$

where N is the number of seed points considered. The vorticity function as defined is an extension of the previous definition[5,6] and is potentially sensitive to the magnetic microstructure of the films.

III. RESULTS AND DISCUSSION

We have simulated structures in Co platelets with different grain sizes and degree of intergranular exchange coupling. There are free boundary conditions. The predicted

 0021-8979/96/79(8)/5767/3/$10.00

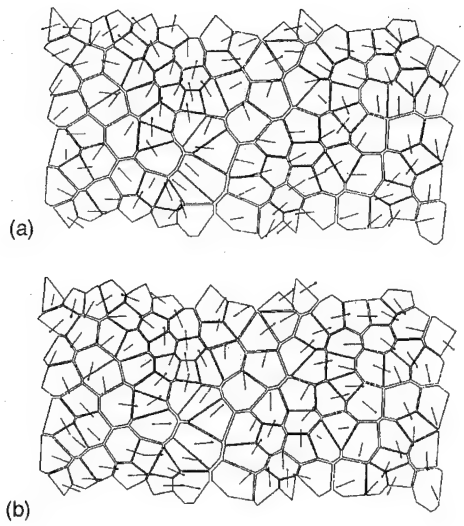

FIG. 1. (a) $C^*=0.0$, $h=0.23$, grain size=400 Å, thickness=1000 Å. (b) $C^*=0.4$, $h=0.15$, grain size=400 Å, thickness=1000 Å.

structures agree with the experiments of Wong *et al.*[7] The choice of material parameters is as follows: $\alpha=1.0$, $A=10^{-6}$ ergs/cm, C^* is in the range of 0.0–0.4, $K=4.2\times10^6$ ergs/cm^3, and $M_s=1.4\times10^3$ emu/cm^3. A is the exchange constant and C^* defines the strength of the intergranular exchange coupling. Films with an aspect ratio of 2:1 have been used with thicknesses of 125 Å for grains averaging 50 Å in diameter and 1000 Å for 400 Å grains. We have calculated hysteresis loops and obtained magnetization plots. The vorticity function has been used to characterize the magnetic structure and investigate the nature of magnetization reversal.

A. Magnetization structure

In Figs. 1(a) and 1(b), the arrows represent the vector average of the magnetization within the grains. The state of the system close to the coercive field for grains averaging approximately 400 Å in size are shown for $C^*=0.0$ and $C^*=0.4$. Clearly, the magnetic behavior of the systems differ. For low C^*, the magnetic structure is not well defined.

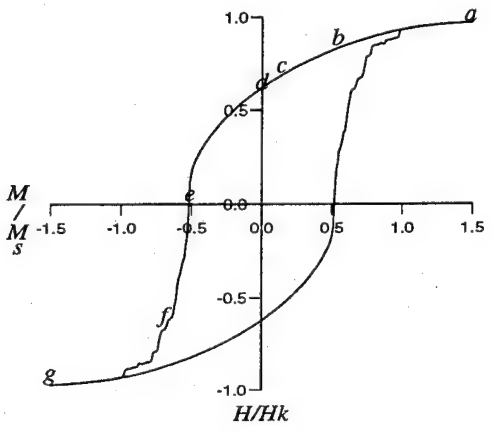

FIG. 2. $C^*=0.0$. No magnetostatic interactions.

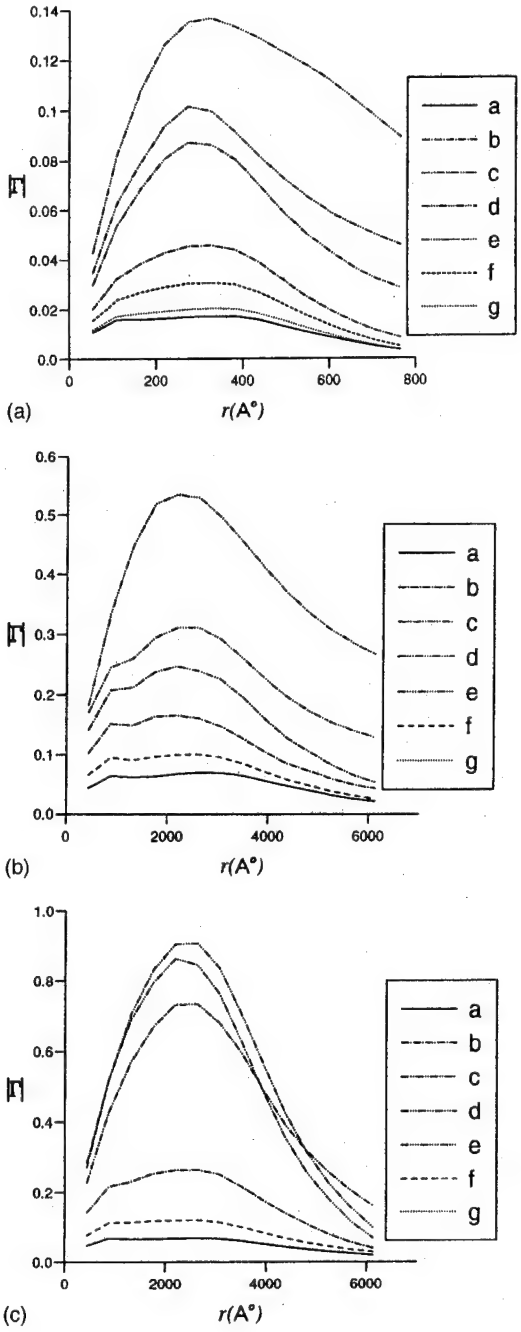

FIG. 3. (a) $|\Gamma|$ vs r, $C^*=0.4$, grain size=50 Å, thickness=125 Å. (b) $|\Gamma|$ vs r, $C^*=0.0$, grain size=400 Å, thickness=1000 Å. (c) $|\Gamma|$ vs r, $C^*=0.4$, grain size=400 Å, thickness=1000 Å.

There is considerable disorder in the flux pattern although a tendency to form a weak solenoidal structure can be discerned. This is due to the weak coupling between the grains. For high C^*, regions of flux closure exist. Local irregularities in the magnetization structure are minimal. The magnetization structure is approximately solenoidal. Similar to Ref. 8, similar behavior was observed for other grain sizes and is consistent with experimental data. The magnetic structure is not perfectly solenoidal probably due to the polycrystalline nature of the system.

B. Characterization of magnetization structures

The process of vortex formation and its subsequent expansion can be characterized by the vorticity of the magnetization distribution. $\Gamma(r)$ has a very characteristic behavior as can be seen by studying its variation with r at different points on the hysteresis loop, an example of which is given in Fig. 2. This loop (calculated for zero magnetostatic and exchange interactions) serves to define seven characteristic points at which the vorticity has been calculated for a number of simulations.

Figures 3(a)–3(c) show the absolute vorticity ($|\Gamma|$) versus the radii of the circular path. In Fig. 3(a), $C^*=0.4$ and the grain size is 50 Å. In Figs. 3(b) and 3(c), $C^*=0.0$ and 0.4, respectively, while the grain size is 400 Å.

The plots clearly demonstrate vortex formation in these systems and can be related to the magnetization structures and reversal mechanism as follows.

At saturation, the vorticity is quite close to zero in Figs. 3(a)–3(c). The fact that it is not exactly zero indicates the effects of the demagnetizing field at the ends which result in bending nonuniform magnetization structures. As the external field is reduced from saturation, a peak appears indicating the onset of vortex formation. The peak becomes more pronounced as the applied field is further reduced, indicating the subsequent expansion of the vortex as it moves inwards from the ends. The maximum vorticity reaches a peak close to the coercive field indicating that the vortices are fully expanded. For high values of C^*, the vorticity peaks sharply for systems with larger grain sizes [Fig. 3(c)] compared to Fig. 3(a) in which the average grain size is smaller and where the peak broadens. In addition, the peak value of the vorticity is significantly higher (≈ 1.0) in Fig. 3(c). Thus at the coercive force, peaks are pronounced in those systems where vortex formation occurs readily. For lower values of C^* as in Fig. 3(b), the peak is less pronounced and broadens, indicating that there is little sign of vortex formation. Further reduction in the applied field results in a gradual disappearance of the peak as the vortex moves through the particle and subsequently disappears at negative saturation. The maximum vorticity increases with increasing grain size. Thus Γ seems to be reflecting the form of the microstructure and magnetization reversal.

IV. CONCLUSION

A dynamic finite element method in micromagnetics has been described. The magnetic structures are profoundly influenced by the strength of the magnetic interactions and the shape and size of the grains. The structures have been characterized by the vorticity of the magnetization field vector. The magnitude and variation of the vorticity are strongly influenced by the grain size and the magnetic interactions. The solenoidal magnetization structures predicted by our theoretical model have been observed experimentally.

Three-dimensional analysis of the magnetization process of thin-film media

E. Miyashita, Y. Yoneda, and J. Numazawa
NHK Science and Technical Research Labs, 1-10-11 Kinuta, Setagaya-ku, Tokyo 157, Japan

A calculation model in which the medium is considered as a set of many fine magnetic particles is applied to thin-film media. The magnetic characteristics are calculated for a particle with an initial layer, a particle without an initial layer, and media composed of the particles of either type. The results show that the switching mode of both particles is a quasi-coherent rotation but the switching field dependence of the particle with an initial layer has curlinglike characteristics. The perpendicular medium with an initial layer is over corrected by $4\pi M_s$ demagnetization correction.
 [S0021-8979(96)21008-3]

I. INTRODUCTION

All kinds of recording media have intrinsic particle structures, sizes and shapes, and interactions between them. When analyzing media, we must consider the characteristics of fine magnetic particles of which they are constituted. In order to analyze a medium microscopically the authors have proposed a new medium model for calculating the magnetic characteristics of recording media.[1] Several calculation models have been proposed,[2,3] but they have assumed either that the magnetization in a particle is uniform or that the switching field characteristics of a particle are curling. In this model, no assumptions are made about either the magnetization in a particle or the reversal mode. The medium is considered as a many-body system of fine magnetic particles and the magnetic characteristics of the media are calculated from the magnetic properties of the isolated fine particles and interparticle interactions. The authors have previously calculated the characteristics of metal-particle and barium–ferrite-particle media and showed the effect of the interactive field on the magnetization process.[1]

We have now improved this model for application to thin-film media. In the improved model, the initial layer of a fine particle can be considered for calculation of the switching process. To calculate the medium magnetization process, the exchange and demagnetization fields are also considered. Using this model, we calculate the magnetization curves for perpendicular thin-film media. Perpendicular media have an initial layer which is semihard and has easy axis in the plane, because the surface roughness or adatoms of the substrate throw an initial crystal growth into disorder. In order to study the effect of initial layer on the magnetization process, we calculate the magnetization curves of perpendicular media both with and without an initial layer. The validity of a demagnetization correction for perpendicular media is also discussed.

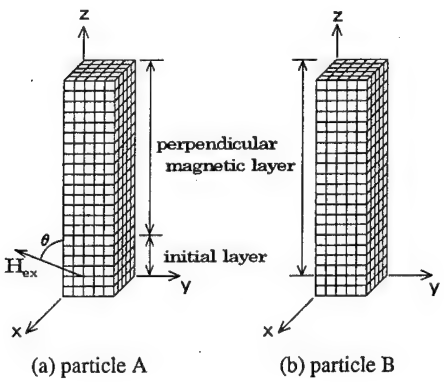

FIG. 1. Calculated particles.

II. CALCULATION MODEL

A. Calculation model for the switching process of an isolated fine particle

The switching process of an isolated fine particle was calculated numerically by use of the Landau–Lifshitz–Gilbert equation.[4] The fine particles are assumed to be hexahedral, as shown in Fig. 1. The particle is divided into $n_x \times n_y \times n_z$ cubic cells. The cell size is set sufficiently small for the magnetization in the cell to be considered uniform. The easy axis of each cell can be set independently for consideration of not only the perpendicular layer but also the initial layer. The forward differential method was used because the algorithms are simple and the free boundary condition was imposed. The calculation parameters are shown in Table I.

B. Calculation model for magnetization process of the medium

The medium model is shown in Fig. 2. The thin-film medium is composed of fine particles located on $N_x \times N_y$

TABLE I. Calculation parameters of particles.

	Particle A	Particle B
Division number $n_x \times n_y \times n_z$	5×5×26	5×5×26
Cell size [nm]	9	9

lattice points with each easy axis direction. The characteristics of the isolated particle have already been calculated in (a), and now the interactive field must be calculated. This includes considerations of the magnetostatic interactive field from other particles, the exchange field from the nearest neighboring particles, and the demagnetization field. For simplicity, the magnetostatic field was calculated on the assumption that the magnetization of the particles is uniform. The demagnetization field coefficient in the z-axis direction is equal to 1. The calculation range of the magnetostatic interactive field is to the sixth nearest neighboring particles. The periodic boundary condition was imposed. The calculation's parameters are shown in Table II. All distribution is assumed to be Gaussian.

III RESULTS AND DISCUSSION

A. Switching process of an isolated fine particle

Figure 3 shows the dependence of the switching field and coercive force on the angle of the external field with a crystalline anisotropic field strength of 8000 Oe. The switching mode of both particle **A** with an initial layer and particle **B** without an initial layer is a quasi-coherent rotation. The curve of particle **A**, however, is similar to a curling mode curve. Magnetization reversal of both particles starts at one end of the particle, with the reversal then gradually moving to the other end. This switching mode is taken because in the case of long and thin particles less total energy is used than in other switching modes. The switching field of particle **A** is much smaller than that of particle **B** in the small field angle. For particle **A**, the magnetization layer is in-plane by the easy axis in the plane in the initial layer and out of plane by the easy axis out of the plane in the perpendicular. The angle of magnetization in both layers is nearly 90°. Accordingly, a large torque acts on the initial layer in the low field angle.

TABLE II. Calculation parameters of media.

	Medium A	Medium B

(b) Medium B without initial layer

(c) Medium A without demagnetization field and demagnetization corrected curve

(d) Measured Co-Cr-Ta medium

FIG. 4. Calculated and measured magnetization curves.

B. Magnetization curves of the media

These magnetization curves were calculated for perpendicular medium **A** composed of particle **A** and medium **B** composed of particle **B**. Figure 4(a) and 4(b) show the magnetization curves of media **A** and **B** with the demagnetization field. Figure 4(c) shows magnetization curves of medium A both without the demagnetization field and after demagnetization correction of the curve in Fig. 4(a). (The curve of medium **A** is shown (c) without the demagnetization field and the corrected curve (a) is shown after demagnetization field correction.) Calculated magnetization curves (a) agree quite well with the measured curves. The coercive force of medium **A** is much smaller than that of **B**. The measured magnetization curves of the perpendicular Co–Cr–Ta film media are also shown in Fig. 4(d) for comparison with the calculated curves. The magnetization curve in the hard axis direction jumps near the zero field shown in Fig. 4(d) because the real perpendicular medium has an initial layer. The curve of the easy axis direction has a slope of nearly $4\pi M_s$ because of the demagnetization field. The dashed line in Fig. 4(d) is the corrected measured curve. Both corrected curves are over corrected after simple demagnetization correction. The switching field of the fine particle depends on not only the strength of the field but also on the angle between the magnetization and the field. The magnetostatic and exchange fields take various directions, so the switching field of each particle in the medium varies. The demagnetization field is uniform but the total field applied to particles exhibits various strengths and directions. The result is that the magnetization curve is not corrected precisely by simple demagnetization. The reason for over correction is that the magnetization process depends strongly on both the switching field characteristics and the magnetostatic interactive field.

IV. CONCLUSION

The improved fine particle model was applied to thin-film media and the magnetization curves were calculated. The following results were obtained:

(1) The switching field characteristics of the particle with the initial layer has curlinglike characteristics.
(2) The coercive force in the perpendicular direction of the medium is considerably reduced by the initial layer.
(3) The perpendicular medium with initial layer is over corrected by $4\pi M_s$ demagnetization.

Characterization of minor loops using Preisach-based models

Ferenc Vajda and Edward Della Torre
Institute for Magnetics Research, The George Washington University, Washington, DC 20052

This paper gives a theoretical analysis of recently reported experimental hysteresis data by O'Grady and Greaves [J. Magn. Magn. Mater. **138**, L233 (1994)] performed on a variety of thin film and particulate recording samples. Using recently developed hysteresis models, it is shown that the nonzero area of their measured minor loop is due to hysterons in the media that switch to the up state in negative field. Using the accommodation model, it is shown that, when cycling the applied field, the computed magnetization drifts up or down and approaches a stable minor loop. The direction of the drift depends on the accommodating magnetizing process. © *1996 American Institute of Physics.* [S0021-8979(96)21108-X]

I. INTRODUCTION

O'Grady and Greaves[1,2] recently reported experimental hysteresis data on a variety of thin film and particulate recording samples that they called anomalous effects in minor hysteresis loops. Using recently developed hysteresis models, this paper presents a theoretical explanation of the observed phenomena.

One of the experiments they performed was a magnetizing process that started from positive saturation, followed by the application of a negative field H_1 and then H_2 which in the experimental data they always set to zero. They observed that, for the samples considered, the magnetization of this first-order reversal curve increased as the negative filed H_1 was being removed. It was also observed that, when cycling between H_1 and H_2, the area enclosed by the stable minor loop was not zero. The experimental results also indicated that the minor branches closed only after the applied field had been cycled a sufficient number of times between H_1 and H_2 and that during this process, the magnetizations at the end points, denoted $M(H_1)$ and $M(H_2)$, decreased with each cycle until the stable cycle was reached. In our theoretical analysis, we will call these observations 1, 2, and 3, respectively.

In this paper we will show that observations 1 and 2 can be explained by the complete moving hysteresis (CMH) model.[3] The explanation of observation 3 requires the additional refinement of an accommodation model. The measured results can be explained by the accommodating complete hysteresis (MACH) model.[4] The parameters of the models are based on the statistical analysis of the interaction field and critical field in medium hard materials and accurately predict complex high-order reversal curves that include both locally reversible and irreversible processes.[3–5] It is emphasized that, since the reported experimental results are not sufficient to identify the parameters of the models, the goal of this paper is to show that the observed but unexplained phenomena are in agreement with our models.

II. STABLE MINOR LOOPS

In this section, we will show that it is necessary to use Preisach-based models[3,6] to explain observations 1 and 2 summarized above.[1,2] Since the measured minor loops are noncongruent, the classical Preisach model[7] cannot describe them. In order to characterize noncongruent minor loops, one has to use a magnetization-dependent model,[8] the simplest of which is the moving model. However, in order to compute minor loops with nonzero slope at the field reversal point, the locally reversible magnetization also has to be modeled. Since the observed data has a variable slope at the same applied field, the model must have a magnetization-dependent locally reversible magnetization, such as the DOK model[6] and the CMH models.[3]

A. The moving model

The moving model is a Preisach-based magnetization-dependent hysteresis model that computes the irreversible component of the magnetization and was developed based on the statistical analysis of the interaction field in longitudinal media. Using U and V to denote the "up" and "down" switching fields and α to denote the material-dependent moving constant, the operative Preisach plane, whose axes are the operative up and down switching fields $u=U+\alpha M$ and $v=V+\alpha M$, is illustrated in Fig. 1. The active region of the Preisach plane corresponding to the cycling between $H_1<0$ and $H_2=0$ for an initially up saturated sample is illustrated by the cross-hatched region in Fig. 1. The magnetization of all the other regions will remain unchanged after the first traversal of the minor loop. The active region is magne-

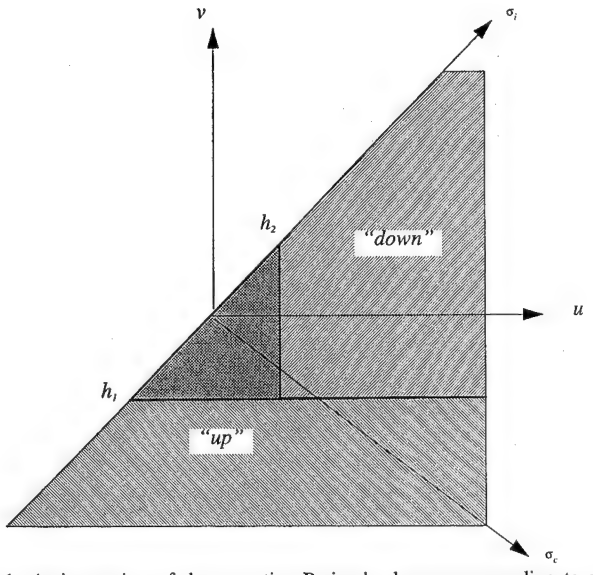

FIG. 1. Active region of the operative Preisach plane corresponding to a cyclical field between $H_1<0$, $H_2=0$. The initial magnetization state is up saturation.

 0021-8979/96/79(8)/5773/3/$10.00

tized down when $H=H_1$ and it is magnetized up when $H=H_2$. However, since the moving Preisach hysterons experience the operative field $h=H+\alpha M$, the active region in the moving model will be bounded by

$$h_1=H_1+\alpha M(H_1), \quad h_2=\alpha M(H_2), \tag{1}$$

where $M(H_1)$ and $M(H_2)$ are the magnetizations at H_1 and H_2, respectively.

The state of hysterons in the classical Preisach model is independent of the magnetization, that is, since H_2 is equal to 0, for any value of the applied field it is equal to H. This means that, as long as $H_1<0$ and $H_2=0$, the triangular actively switched region in Fig. 1 encompasses only quadrant III of the Preisach plane. Therefore, the classical Preisach function has to be nonzero in this quadrant to describe observations 1 and 2. In case of the moving model, the situation is more complex. During the experimental analysis of various longitudinal media we always observed, $\alpha>0$; therefore, if $M(H_2)>0$, as is the case in the experimental data presented,[1,2] then the vertical side of the actively switched triangular region lies in quadrant I of the Preisach plane. If $|\alpha M(H_1)|\neq hH_1$ then $h_1<0$ and the active region encompasses parts of quadrants III, IV, and I of the operative Preisach plane, as illustrated in Fig. 1. If $\alpha M(H_1)$ is sufficiently large so that $h_1>0$, then the active region may be entirely contained in quadrant I. In summary, the location of the actively switched triangular region computed by the moving model depends on the magnetization, as well. Therefore, it is not necessary for the operative Preisach function to be nonzero outside quadrant IV for the moving model to describe observations 1 and 2. Using the experimental data[2] one can only determine that $M(H_1)>0$ which is not sufficient to decide which case occurs for the specific samples. However, as discussed below, the moving model is generally applicable to characterize all possible cases. Thus

$$M(h_2)-M(h_1)=2\int_R\int p(u,v)dudv, \tag{2}$$

and the region of integration, R, is the cross-hatched triangular region illustrated in Fig. 1.

The above Preisach integrand is always non-negative; therefore, in agreement with observation 1, the computed magnetization increases as the applied negative field, H_1 is being removed. This is not surprising, since one expects the susceptibility to increase (decrease) as the applied field increases (decreases). This is true regardless of the sign of the applied field, since this susceptibility increases (decreases) depending on only the relative change in the applied field.

When the applied field is cycled between H_1 and H_2, the change in the irreversible magnetization is partially due to switching in quadrants I and III of the operative Preisach plane. Thus, the nature of the stable minor loop is dependent on how much the operative Preisach function extends into quadrants I and III. Therefore, the measured nonzere minor loop area,[2] also called the eye, is due to the relatively large interaction in these media.

Minor loops computed by the moving model for increasing values of σ_i corresponding to the magnetizing process $+H_{sat}$, $H_1<0$, $H_2=0$, $H_1<0$ are shown in Fig. 2. The aim of the computations, in which only σ_i was varied, was to show that the moving model can compute minor loops with a nonzero eye, and no attempt was made to fit the measured data presented in Ref. 2. Although the moving model computes the irreversible magnetization m_i only, it is seen that at $H_2=0$ the magnetization of the descending major irreversible branch decreases as σ_i increases. This is due to the increasing apparent reversible contribution of quadrants I and III of the operative Preisach plane for increasing values of σ_i. Although the apparent reversible contribution causes the magnetization to decrease (increase) when a positive (negative) operative field is being removed, it is different from locally reversible contributions in which no energy is dissipated during the process.[9] The computed magnetization at the reversal field, H_1, decreases as σ_i increases, which is due to the increasing apparent reversible contribution of the entire quadrant I of the Preisach plane. However, as seen in the inset in Fig. 2, the slope of all the computed minor loops is zero at the turning points, which is a property of all Preisach-type models.[6] Since the measured slopes at the reversal points are not zero, an accurate model of the observed phenomena must include the locally reversible magnetization, as well.

B. The DOK and CMH models

The DOK[6] and CMH[3] models are seven-parameter scalar hysteresis models developed for medium hard materials that add a state-dependent reversible magnetization to the moving model. Thus, these models compute both the irreversible and the state-dependent locally reversible magnetization. A parametric identification method of the models was developed and verified for a variety of recording materials in which the operative Preisach function is zero outside quadrant IV of the Preisach plane.[3] Such a Preisach function is commonly referred to as a IV quadrant Preisach function.

Minor loops computed by the CMH model for increasing values of σ_i corresponding to the magnetizing process $+H_{sat}$, $H_1<0$, $H_2=0$, $H_1<0$ are shown in Fig. 3. It is noted that, like the measured data,[2] the computed curves include both the irreversible and the locally reversible components of the magnetization. It is seen that, in agreement with experi-

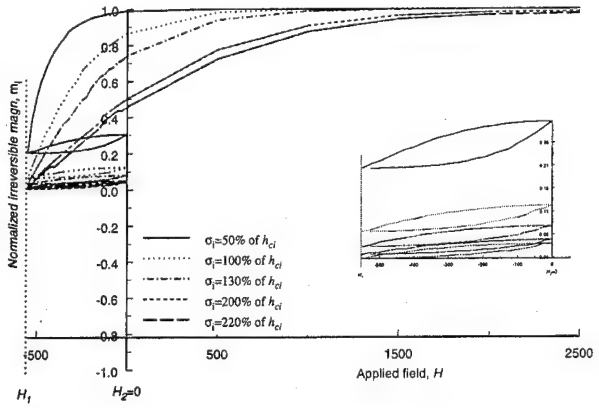

FIG. 2. Minor loops computed by the moving model for increasing values of σ_i corresponding to the magnetizing process $+H_{sat}$, $H_1<0$, $H_2=0$, $H_1<0$. The inset is an enlargement of the computed minor loops.

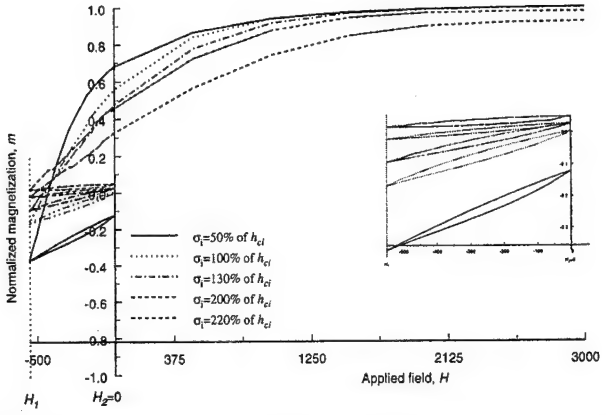

FIG. 3. Minor loops computed by the CMH model for increasing values of σ_i corresponding to the magnetizing process $+H_{sat}$, $H_1<0$, $H_2=0$, $H_1<0$ (a). The inset is an enlargement of the computed minor loops.

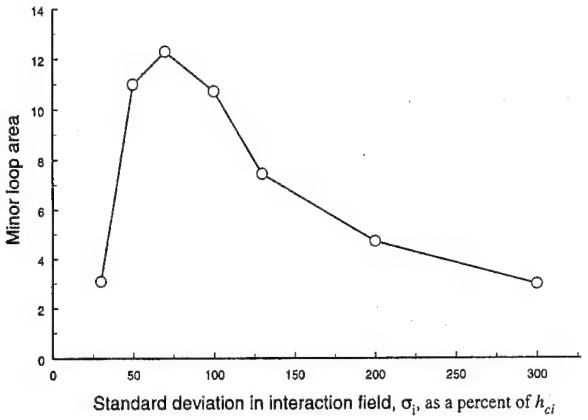

FIG. 4. The computed area of minor loops for increasing values of σ_i using the CMH model.

mental results, the minor loops have a nonzero slope at the reversal points. At smaller values of σ_i, a larger number of hysterons switch from the down state to the up state as the field H_1 is being removed. Therefore, since the slope of the individual hysteron loops is greater in the up state than in the down state, there will be a greater increase in the state-dependent reversible magnetization resulting in a larger relative increase in magnetization when removing the field, H_1. As σ_i is increased, a smaller portion of the hysterons switch to the up state while removing H_1; therefore, the relative change in magnetization decreases, as seen in the inset on Fig. 3.

The computed minor loop area for increasing values of σ_i is shown in Fig. 4. It is seen that, for small interactions, since the Preisach function is negligible in the active region illustrated in Fig. 1, there is a small change in the irreversible state during the magnetizing process. Thus, the area of the minor loop will also be small. As σ_i increases, the actively switched region will include an increasing portion of the Preisach function; therefore, the area will increase. At even greater values of σ_i, a considerable portion of the Preisach function will lie outside the actively switched region; therefore, after reaching a peak, the area of the minor loop will decrease. It is noted that the value of σ_i at which the peak area occurs is a function of all the other model parameters, as well as the reversal field, H_1.

III. ACCOMMODATION PHENOMENA

Observation 3 shows that, as the applied field is cycled between $H_1<0$ and $H_2=0$, the magnetization drifts down and the minor loop closes only after the field has been cycled a sufficient number of times,[2] a phenomenon known as the accommodation or reptation. As discussed in the MACH model,[4] accommodation is due to the interaction between the particles that comprise the medium. Using the MACH model it has been shown that, in agreement with measured results,[10] the measured accommodation is due to the change in the interaction field during the magnetizing process. In agreement with observation 3, the MACH model computes accommodating minor loops that approach a stable limiting cycle. The model also shows that, for the magnetizing process used to obtain observation 3, the magnetization drifts down at each cycle until the minor loop stabilizes. Using the MACH model, it can also be shown that, if the reversible magnetization is negligible then the accommodation in the minor loop is driven by the eye of the minor loop. Thus, for such materials, there would be no accommodation if the eye in the minor were zero. It has also between shown that the direction of the magnetization drift is dependent on the reversal field, H_1 and that the amount of accommodation can be maximized by selecting a magnetizing process that maximizes regions R_1 and R_4. This latter property of the model has been shown to be important when identifying the parameters of the MACH model.[10]

IV. CONCLUSIONS

This paper gave a theoretical explanation of recently reported experimental hysteresis data by O'Grady and Greaves[1,2] performed on a variety of thin film and particulate recording samples. Using recently developed hysteresis models,[3] it was shown that the nonzero area of the measured minor loop when cycling between a negative field, H_1 and zero field, H_2, is due to hysterons in the media that switch to the up state in negative field. It was also shown that, one does expect the measured magnetization to increase while the applied field is increased but is negative throughout the process, since a change in the magnetization is caused by a changing field regardless of its sign. Using the accommodation model,[4] it was shown that, in agreement with the measured data, when cycling the applied field, the computed magnetization drifts up or down and approaches a stable minor loop. The direction of the drift depends on the accommodating magnetizing process.

Radio frequency ion beam deposition of diamond-like carbon for sliders and heads

Lien-Chang Wang, Gary Halada, and Richard J. Gambino,
Department of Materials Science and Engineering, State University of New York, Stony Brook, New York 11794-2275

Alan Hayes and Sal DiStefano
Veeco Instruments, Plainview, New York 11803-2313

Diamond-like carbon prepared by direct ion beam deposition from a filamentless rf ion source has been found to have properties suitable for protective coatings on sliders and heads. One advantage of the rf inductively coupled plasma source used in this study is that it can be operated reliably for hundreds of hours with high concentrations of hydrocarbon gas. We have studied deposition from argon-CH_4 mixtures with 28% to 100% CH_4 and beam energies mainly in the 100 to 400 eV range. X-ray photoemission spectra analysis shows that films prepared with pure CH_4 have less sp^3 (diamond-like) bonding than films prepared from mixtures with argon. © *1996 American Institute of Physics.* [S0021-8979(96)15808-8]

I. INTRODUCTION

It has been estimated that the head/media separation may be as little as 20 nm in 10 Gbit/in.^{2} disk products[1] which are expected to be in production in the next five to ten years. This flying height puts extraordinary demands on the wear, tribological, and electric properties of the protective coating on the slider and head. Diamond-like carbon (DLC) films have been prepared by many different methods and the properties vary widely depending on the process and on specific process parameters. Direct ion beam deposition from low pressure hydrocarbon-rich atmospheres has been found to produce films with properties suitable for this application.[2] This article reports, for the first time, direct ion beam deposition of DLC films from a filamentless rf ion source. One advantage of the rf inductively coupled plasma source used for this study is that it can be operated reliably for hundreds of hours with high concentrations of hydrocarbon gas. In this paper we report on the effects of varying the fraction of argon in the hydrocarbon gas mixture used in the gun on the rate and film properties. We have also studied the influence of ion energy.

II. EXPERIMENTAL PROCEDURE

The vacuum chamber used for deposition of the DLC films is equipped with a Veeco RIM 210 rf inductively coupled plasma (ICP) ion source and a 1000 ℓ/s turbo pump. The base pressure of the system prior to deposition was less than 2×10^{-6} Torr. Substrates of Si and SiO_2 were cleaned prior to deposition by immersion in acetone, spray-rinsed with acetone, then with methanol, and blown dry. The substrates were mounted on a helium gas cooled wafer stage which was oriented during deposition so that the ion beam is normal to the substrate surface. A Kapton tape mask was put on each wafer to provide a step for thickness measurements. After the system reached base pressure the substrates were precleaned for 20 s with a 300 mA argon ion beam at 750 eV. The substrate holder was rotated during ion cleaning and deposition.

The deposition rate was determined by measuring the film thickness at a masked step using a Dektak, DT3 surface profiler. Film stress was determined from the curvature of the Si substrate after deposition, measured using the Dektak in a broad scan. Vickers microhardness measurements were made on selected films on Si. The films on Si were also used for x-ray photoemission spectra (XPS). The index of refraction (n) of the films on SiO_2 were measured on a Nanospec Microspectrophotometer. A Rudolph Research ellipsometer was used to get the index of films on Si. Optical absorption was also measured on a few films on SiO_2.

III. ION SOURCE

The RIM-210 ion source used in this study is briefly described as follows. A rf plasma is generated by a helical rf coil external to the quartz plasma chamber and is operated at 1.8 MHz. The 180-mm diameter ion beam is extracted from the plasma by a three grid set of ion optics fabricated from molybdenum. The inductively coupled plasma has been shown to provide a very uniform ion beam for etching.[3]

We have studied deposition from CH_4-argon mixtures with 28% to 100% CH_4 and beam energies of 100, 200, 300, and 400 eV. In these experiments, the gas flow rate was held constant at 20 sccm and the beam current was 250 mA. Under these conditions the pressure in the chamber was 3 to 4×10^{-4} Torr. A few experiments were carried out with beam energies of 50 and 100 eV and 150-mA beam current and flow rates of 6 to 10 sccm as noted below.

IV. RESULTS

Qualitatively hard, scratch resistant, transparent films typical of DLC were deposited by this process. The refrac-

 0021-8979/96/79(8)/5776/3/$10.00

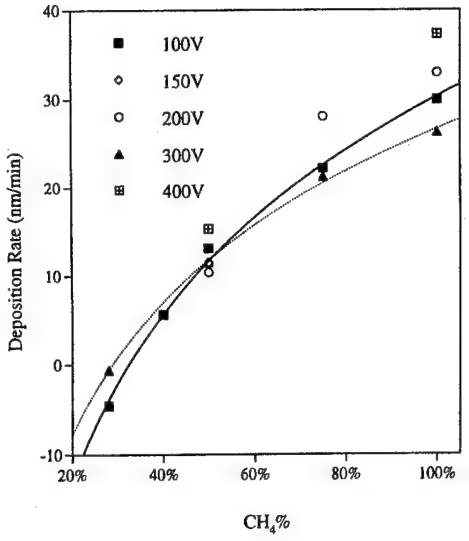

FIG. 1. Dependence of deposition rate on CH_4 percent with beam energies in the range 100 to 400 eV. The beam current was 250 mA and the gas flow rate was fixed at 20 sccm for these experiments.

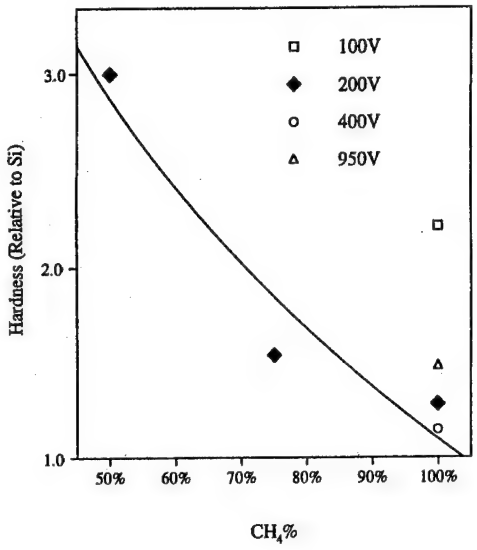

FIG. 3. Hardness vs CH_4 percent with various beam voltages. The trend line is for the 200-eV data.

tive index of the films is relatively high, typically about 1.8 to 2.0 as measured by both ellipsometry and Nanospec methods. Films about 100-nm thick show 90% transmission at a wavelength of 500 nm.

The dependence of the deposition rate on CH_4 percentage and beam energy are shown in Fig. 1. The rate decreases with decreasing CH_4 percent from about 30 nm/min at 100% CH_4 to about zero at 28%. These rates were measured on Si substrates but the rates on SiO_2 were the same within experimental error. The deposition rate is only weakly dependent on beam energy in this series of experiments with constant beam current. No clear trend with beam energy is seen in this data. The deposition rate of samples prepared with a beam current of 150 mA was in the 3 to 10 nm/min range.

Figure 2 shows stress and hardness as a function of beam energy up to 1000 eV. The lines are logarithmic fits to the data to show the trends. Figure 3 shows the hardness relative to the hardness of the Si substrate plotted against the CH_4 percent in the gas mixture for films prepared with various beam energies. The microhardness was measured with a 10-gram load, the lowest available load on our Vickers instrument. Measurements of the hardness of films are difficult in this thickness and hardness range.[4] The film was always extensively cracked and spalled in the region of the indent so the measured indent was actually in the silicon substrate. The penetration of the indenter was greater than the film thickness so the hardness was corrected for the fact that only part of the area of the indenter is pushing on the DLC film. The measured thickness of the film and the geometry of the indenter were used to calculate the area of the indenter in con-

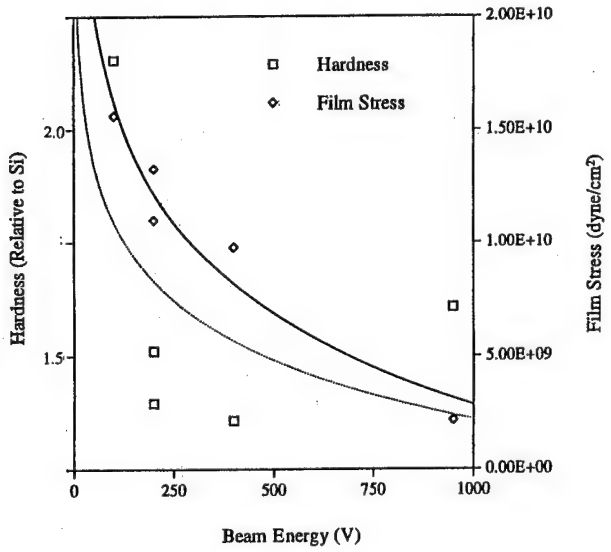

FIG. 2. Dependence of relative film hardness and stress on beam energy for samples prepared with pure CH_4.

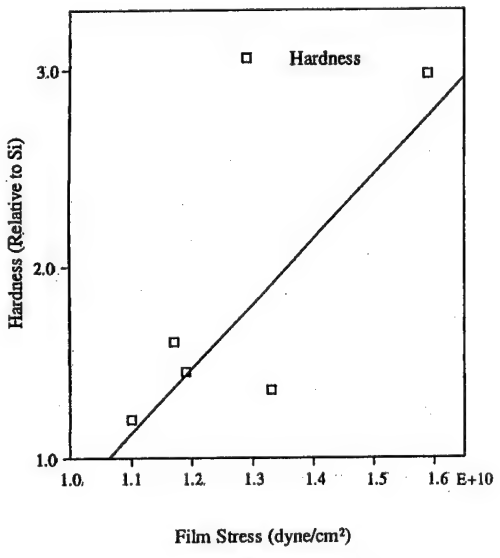

FIG. 4. The dependence of hardness on film stress for samples prepared at 200 eV, 250 mA, and 20 sccm with various argon-CH_4 mixtures.

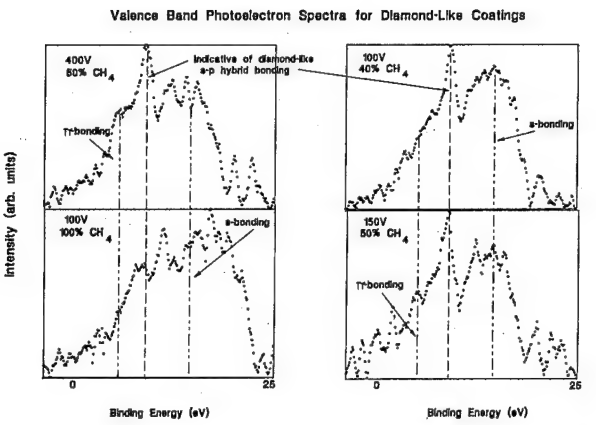

FIG. 5. The valence band photoelectron spectra of four DLC films prepared under different conditions. The spectra were taken using Mg $K\ \alpha$ radiation (1253.6 eV) with a hemispherical analyzer having a 20-eV pass energy.

tact with DLC and the corrected hardness. The measured hardness, therefore, is reported relative to the hardness measured on the Si substrate to show trends with processing conditions. The dependence of microhardness on film stress is shown in Fig. 4. Hardness and film stress appear to be strongly correlated.

Samples analyzed by XPS show less sp^3 (diamond-like) bonding when prepared from 100% CH_4 than from gas mixtures with argon. The XPS spectra of four DLC films prepared under different conditions are shown in Fig. 5. High levels of sp^3 bonding indicative of the diamond-like structure were observed in general. The sample prepared with pure CH_4 has significantly less sp^3 bonding than the samples prepared with argon-CH_4 mixtures. Among the samples prepared with argon-CH_4 mixtures, the 100-eV sample has slightly less sp^3 character than the 400- and 150-eV samples. On the other hand, the π bonding peak appears to be weaker in the 100- and 150-eV samples as indicated by the height of the low energy peak labeled π bonding. The sample prepared with an argon-CH_4 mixture at 150 eV shows both a strong sp^3 diamond-like peak and a weak sp^2 graphitic peak.

V. DISCUSSION AND CONCLUSIONS

This paper, for the first time, reports ion beam deposition of diamond-like carbon films from a rf ion source. The films have a high sp^3 fraction, refractive index of up to 2.0, and are highly transparent. Although we were not able to obtain accurate absolute hardness values with our equipment, we were able to show that the hardness is several times greater than that of the Si substrate. These properties show that DLC films prepared by rf ion beam deposition are suitable for coating heads and sliders.

DLC consists of an amorphous network of covalently bonded carbon with a mixture of sp^3 and sp^2 bonding.[4] The understanding of the relationship between processing conditions and the formation of sp^3 bonds has been advanced by recent models.[5,6] According to these models sp^3 bonds form when carbon atoms are forced into close proximity either by direct implantation of a carbon atom into the carbon network or by a knock-on process. This suggests a possible beneficial role of argon bombardment, that is the generation of additional knock-ons by argon ion impact. Another feature of the model is the effect of the "thermal spike" associated with the damage track along the ions implantation path. The interstitials and knock-ons form, for the most part, at the end of the implantation track. The track itself is treated as a region which has been thermally relaxed by the thermal spike. Since the sp^3 bonded regions are metastable at low pressures the thermal spike promotes the formation of the more stable sp^2 bonds. According to this model the optimum energy for high sp^3 bond fraction is between 100 and 200 eV. We do not observe a major difference in sp^3 bond fraction between 150 and 400 eV; however, more sp^2 bond character is seen at the high beam energy. This model and others also predict a correlation of high sp^3 bond fraction with high compressive stress[5] which we observe.

Nanoindentation study of the mechanical properties of metal evaporated magnetic tapes

Hong Deng and John A. Barnard
Department of Metallurgical and Materials Engineering and Center for Materials for Information Technology, The University of Alabama, Tuscaloosa, Alabama 35478-0202

Nanoindentation techniques have been used to examine hardness (H), Young's modulus (E), and strain rate sensitivity (m) in three types of commercial unaged and aged metal evaporated (ME) magnetic tapes. The aged tape samples were aged at 75 °C for 60 weeks at 5% and 90% humidity. The hardness of the ME layer can be determined at a depth of 30–50 nm, but for deeper penetrations the hardness value is increasingly affected by the soft polymer substrate. H and E are essentially the same for the unaged samples and the samples aged at 5% humidity but greatly decreased for the tapes aged at 90% humidity. The creep behavior (the time-dependent deformation) of these tapes was also characterized for the first time using the nanoindenter. Strain rate sensitivity increases with maximum applied load. On the other hand, a decrease in the strain rate sensitivity is observed for the tapes aged at 5% humidity. For the tapes aged at 90% humidity it is very difficult to obtain the strain rate sensitivity due to the excessive brittleness of the samples. Nanoindentation creep measurements appear to be quite sensitive to the degradation of ME tape caused by adverse environmental conditions. © *1996 American Institute of Physics.* [S0021-8979(96)11108-6]

I. INTRODUCTION

Metal evaporated (ME) magnetic tape is a most promising candidate for high-density audio/video recording, especially for small cassette digital video tape recorders (SCD-VTR).[1,2] With ever increasing magnetic recording densities the flying heights will be reduced to near zero. Therefore, wear and friction problems for both head and medium have to be minimized to meet durability requirements. The hardness (H), Young's modulus (E), and strain rate sensitivity (m) of magnetic tapes are important mechanical properties related to the wear and friction of the head/medium interface. Nanoindentation has been successfully used to determine the hardness and elastic modulus of thin films and coatings.[3,4] More recently, this technique has been employed to characterize the time dependent properties of thin films and to determine their strain rate sensitivity.[4,5] In this work, nanoindentation techniques are employed to characterize the mechanical properties of ME tapes. Preliminary results obtained using a newly developed approach[4,5] to the strain rate sensitivity of thin films are reported in this article.

II. EXPERIMENT

Three kinds of commercial ME tapes labeled as Tape 1, 2, and 3 obtained from the National Media Laboratory (NML) were studied. The tapes consist of a polymer substrate with a thickness of 10 μm and a magnetic metal layer which is about 150 nm without an overcoat. Because the effect of adverse environmental conditions on the durability of the ME tapes is always a major concern in practical applications, we also examined the aging effects of temperature and humidity on the mechanical properties of these ME tapes. For this purpose, several pieces of the tape samples were aged at 75 °C with 5% and 90% humidity for 60 weeks. Then, both unaged and aged samples were characterized using a Nano Indenter® II Mechanical Properties Microprobe (Nano Instruments, Inc. Oak Ridge, TN).

Nanoindentation experiments were carried out with two different methods. For H and E measurements, a constant displacement loading approach was used. The H and E were determined at six indenter penetration depths: 30, 40, 50, 60, 80, and 120 nm, with indenter descent rates from 3 to 10 nm/s depending upon the maximum depths. A 6×6 matrix indentation configuration with a 50 μm spacing was used for H and E evaluation. In the indentation creep test a constant load loading segment and a long time hold are employed for characterization of the strain rate sensitivity. In this experiment, the maximum loads used are 0.05, 0.1, 0.2, and 0.3 mN and the loading rate is 10 μN/s. A 600 s hold was used in this work. All the indentation tests were performed at room temperature.

The strain rate sensitivity was calculated using the data collected in the long time hold segment after loading. The elastic contribution has to be eliminated from the total displacement; only plastic deformation is considered in this work. 2500–3000 data points were collected in the hold segment. They were divided into about 40 groups. For each group the slope of a linear fitting line and an averaged depth were calculated. The stress for a given indentation plastic depth is defined as $\sigma=P/A$, in which P is the maximum load and A is the indenter projected area corresponding to the averaged plastic depth and can be calculated with the indenter tip area function determined by calibration experiments. The strain rate ($\dot{\epsilon}$) is defined as the plastic descent rate divided by the plastic indentation depth h, $\dot{\epsilon}=(1/h)(dh/dt)$. Thus, strain rate sensitivity (m) is obtained from the slope of a log-log plot for the creep equation, $\sigma=C(\dot{\epsilon})^m$.[5]

III. RESULTS AND DISCUSSION

The results of the nanoindentation hardness and Young's modulus measurements for the three ME tapes are shown in Fig. 1–3. The apparent hardness of the metal layer can be determined at a depth of 30–50 nm but for deeper penetrations the hardness value will be affected by the soft polymer

 0021-8979/96/79(8)/5779/3/$10.00

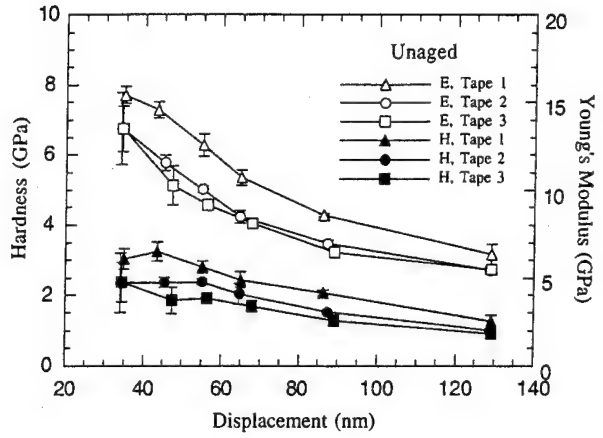

FIG. 1. Hardness and Young's modulus of the three unaged ME tapes.

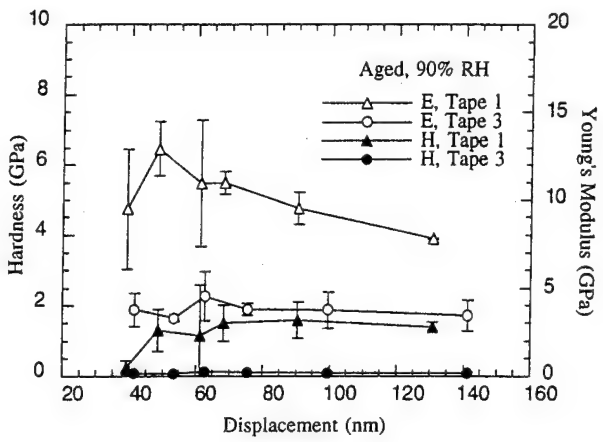

FIG. 3. Hardness and Young's modulus of the two ME tapes aged at 75 °C and 90% humidity.

substrate which has a hardness of 0.5 GPa and Young's modulus of 5 GPa. The hardnesses of the metal layers of the three unaged tapes are ~3.0, ~2.4, and ~2.0 GPa, and the Young's moduli are 15, 13.5, and 13.5 GPa. The hardnesses and Young's moduli are essentially the same for the unaged samples and the samples aged at 5% humidity but greatly decreased for the tapes aged at 90% humidity. The hardness values obtained in this test may not be the inherent hardness of the metallic layers of the tapes because the metal layer is very thin. The measurement of the inherent hardness of the magnetic layer on the polymer substrate is one of the subjects of our continuing research. In addition, the soft substrate effect on the elastic modulus is greater than on the hardness as we have reported before.[6]

A typical time dependent deformation experiment is shown in Fig. 4. This figure illustrates the indentation plastic depth as a function of time under two different maximum initial load. It can be seen that the deformation behavior depends on the maximum initial load. The effect of aging at 75 °C and 5% humidity on the deformation is also shown in the figure. It is obvious that aging at 75 °C and 5% humidity for 60 weeks makes these tapes much less deformable. This deformation capacity can be quantified by the strain rate sensitivity. An example of the log(strain rate) versus log(stress) plots from which the strain rate sensitivity is obtained by a linear fit is given in Fig. 5. The strain rate sensitivity of the unaged and aged ME tapes as a function of load are summarized in Fig. 6. The strain rate sensitivity of these ME tapes is strongly dependent on the initial loads. Increasing the maximum initial load increases the strain rate sensitivity. On the other hand, a decrease in the strain rate sensitivity is observed on aging. Aging generally shifts the load required for a given m to higher values. This is consistent with the polymer substrate becoming more brittle and less deformable on aging. Because the properties of the metal layer and the polymer substrate of a ME tape are very different the change in strain rate sensitivity with load probably indicates the different responses from the two different materials. The polyethylene terephthalate (PET) polymer substrate (H is 0.5 GPa and E is 5 GPa) is definitely superplastic. As can be seen in Fig. 7, even measured at a very low load such as 0.05 mN its

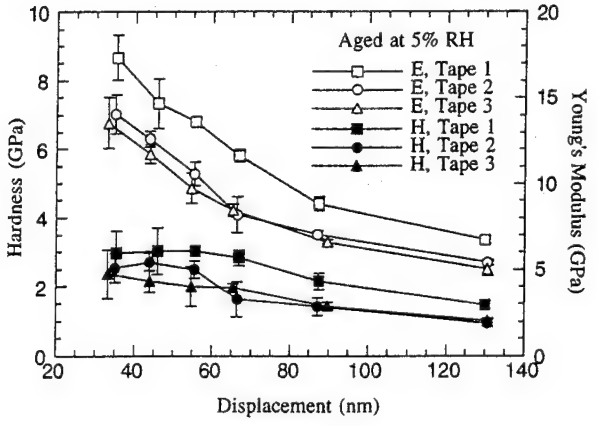

FIG. 2. Hardness and Young's modulus of the three ME tapes aged at 75 °C and 5% humidity.

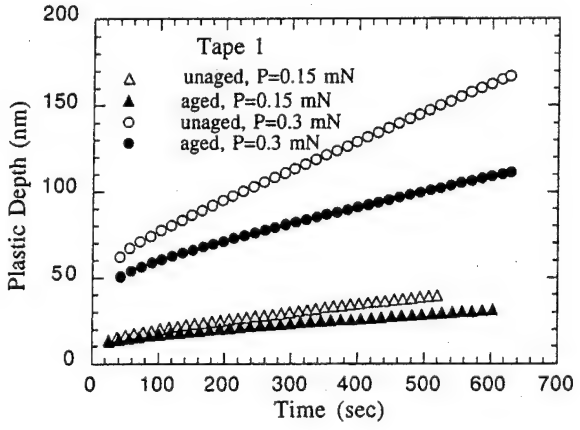

FIG. 4. The indentation plastic depth as a function of the holding time for tape 1 (aging conditions: 75 °C and 5% humidity).

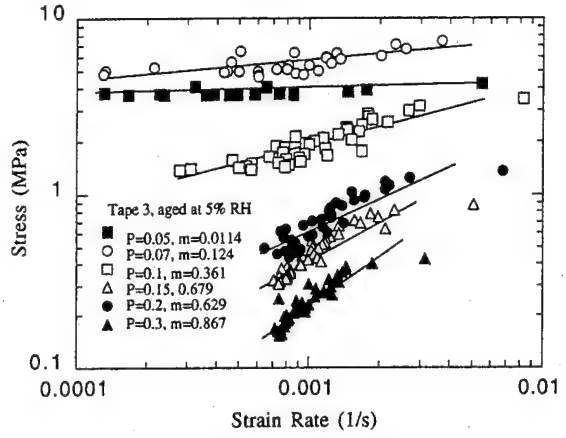

FIG. 5. Stress-strain rate for tape 3 aged at 5% humidity.

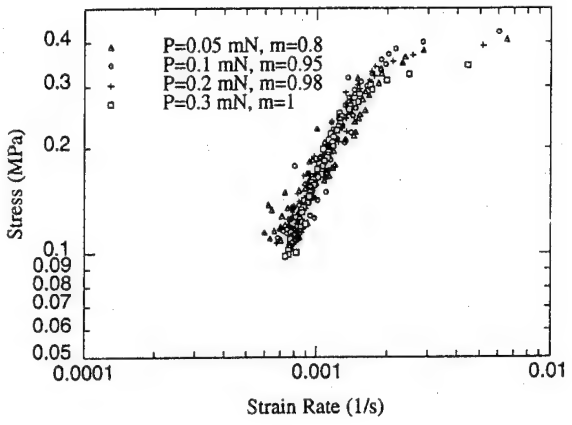

FIG. 7. Stress vs strain rate curves for the polymer substrate.

strain rate sensitivity is almost unity. According to the literature,[4] if the strain rate sensitivity of a given material is equal to or greater than 0.4, the material exhibits superplastic behavior and is capable of elongations of 100%–5000%. In this study, loads >0.1 mN result in $m>0.4$ for unaged samples. Therefore, it can be concluded that the time dependent deformation behavior of the metal layer of the ME tapes will be affected by the soft polymer substrate if the maximum initial load is above a certain load. In other words, the superplastic behavior above a certain load reflects the response from the polymer substrate rather than from the metal layers.

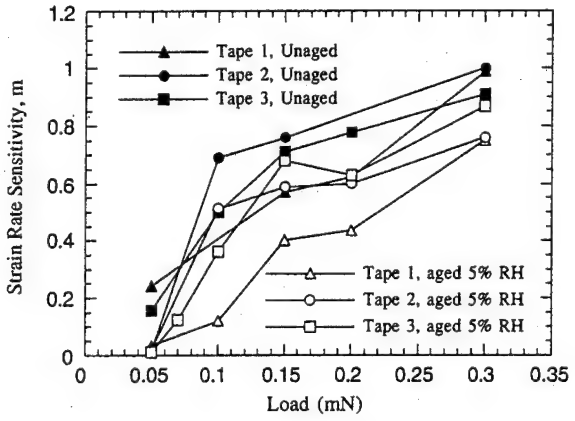

FIG. 6. Strain rate sensitivity as a function of load for ME tapes.

IV. CONCLUSIONS

The mechanical properties of three kinds of commercial ME tapes were characterized using nanoindentation techniques. The hardness of the metal layers can be measured at 30–50 nm penetration depths. Aging is expected to make the tapes more brittle even at 75 °C and 5% humidity. However, this property change is not sensitively detected by the hardness tests. Hardness and elastic modulus were found essentially the same for the unaged samples and the samples aged at 5% humidity. However, nanoindentation creep measurements appear to be quite sensitive to the degradation of ME tape caused by even mildly adverse environmental conditions. A clear decrease in the strain rate sensitivity is observed for the tapes aged at 75 °C and 5% humidity.

The wear performance of pure carbon and carbon nitrogen (C:N) coated thin film head sliders was evaluated by continuous drag testing (CDT). Comparison was made in light of protection of these two various carbon films. By studying the air bearing surfaces of the heads under atomic force microscopy (AFM) and secondary electron microscopy (SEM), it was found that during the CDT test, the head may fail before the disk fails and the area of Al_2O_3 is the most possible place where wear begins. There were small amounts of material transferred from head slider to disk, although no evidence of opposite transfer was found. © *1996 American Institute of Physics.*

I. INTRODUCTION

Increasing the amount of information that can be stored in a thin magnetic film is one of the key technological challenges facing the data storage industry. The areal recording density of stored information in today's state-of-the-art disk drive products is typically a few hundred megabits per square inch. Over the next decade, the data storage industry expects to increase this areal recording density by at least an order of magnitude, reaching several gigabits per square inch. To achieve this dramatic increase, the current flying height will need to be substantially decreased. Reducing the separation distance between the head slider and disk surfaces will place even more extreme tribological demands on the hard carbon overcoats. It has been demonstrated that a significant improvement in wear performance of the head–disk interface can be obtained by coating thin film head sliders with a carbon thin film.[1–3] However, the role of a carbon film remains unanswered. The purpose of this article is to present the results of atomic force microscopy (AFM) and secondary electron microscopy (SEM) mapping studies of the air bearing surface of head sliders uncoated and coated with pure carbon and carbon nitrogen after continuous drag testing. The possible mechanisms of the wear performance enhancements is explored.

II. EXPERIMENTAL PROCEDURES

The pure carbon and carbon nitrogen thin films were deposited on head sliders using a facing target sputtering (FTS) system which had a background pressure less than 5×10^{-7} Torr. The pure argon, or argon-nitrogen gas mixture (40%-N_2) was used as the sputtering gas. The resulting carbon nitrogen film has a 22 at. % nitrogen which was determined by Auger electron spectroscopy (AES). No adhesion layer was deposited under the carbon coatings. Continuous drag tests (CDT) were conducted with 50% Al_2O_3-TiC type thin film head sliders having a normal load of 4 gms dragged on 3.5″ unlubricated (H:C)-coated commercial disks. The radius at which to perform the CDT tests was chosen to be 1″ on the 3.5″ disks. The linear velocity was fixed at 26.60 cm/s. The average kinetic friction was measured every 500 revolutions at a speed of 0.1 rpm for one complete revolution. After the test was terminated, the head slider air bearing surfaces were carefully studied using AFM and SEM, and images of the most severe wear damage were taken for each sample.

III. RESULTS AND DISCUSSION

Figure 1 shows a comparison of the friction versus the number of revolutions for the cases of an uncoated slider and sliders coated with 90 Å of FTS sputtered pure carbon and carbon nitrogen. After a total of 23 000 revolutions in each CDT test, only that disk paired with an uncoated head exhibited any visible wear marks which indicate that the head–disk interface had failed at this point. The SEM micrograph of the disk surface around the wear track associated with wear testing with the uncoated head was shown in Fig. 2. For comparison purposes, we note that the coefficient of kinetic friction versus the number of revolutions increases rapidly

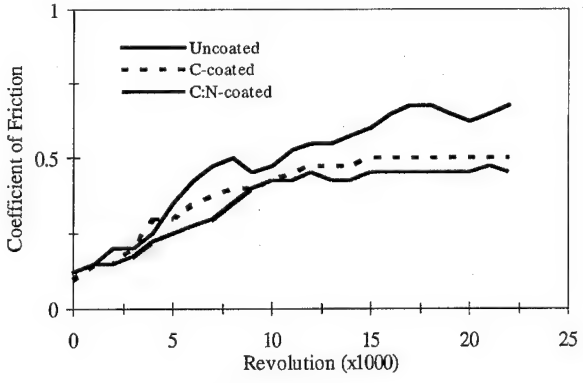

FIG. 1. The coefficient of friction vs number of revolutions with and without carbon coating on sliders.

 0021-8979/96/79(8)/5782/3/$10.00

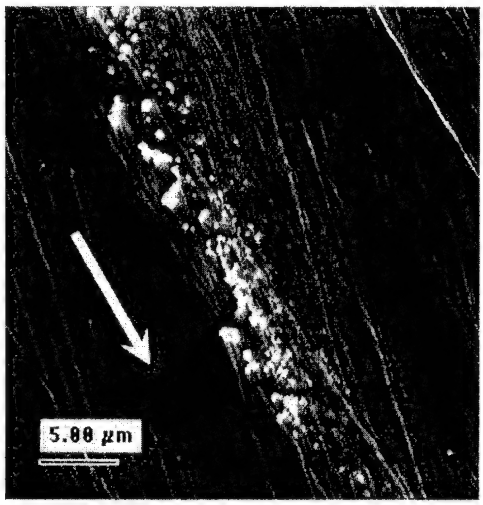

FIG. 2. The SEM image of disk wear track area associated with wear testing with the uncoated head.

from 0.12 initially to about 0.7 at 23 000 revolutions for the head slider which was uncoated. On the other hand, the kinetic friction coefficient of the head coated with 90 Å pure carbon increases from 0.1 initially to 0.5 at 15 000 revolutions and remained constant, whereas that for the head coated with 90 Å carbon nitrogen increases from 0.1 to a constant value of 0.45.

Upon completing the CDT tests, the head surfaces were observed using AFM and SEM and the resulting micrographs are shown in Figs. 3 and 4. In Fig. 3, all of the three testing heads exhibited some degree of wear damage where that of the uncoated head was the most severe and that of the carbon nitrogen coated head was the least. This is in agreement with the studies of Torng *et al.*[4] and Yeh *et al.*[5] which showed that carbon nitrogen has more sp^3 bonding and better wear performance than pure carbon. Figure 4 shows the SEM mapping results of the uncoated head surface, in which Al, Ti, and Cr were mapped. We see that there are a lot of wear particles on the air bearing surface [as shown in Fig. 4(a)], TiC was well separated from Al_2O_3 and no Cr was found.

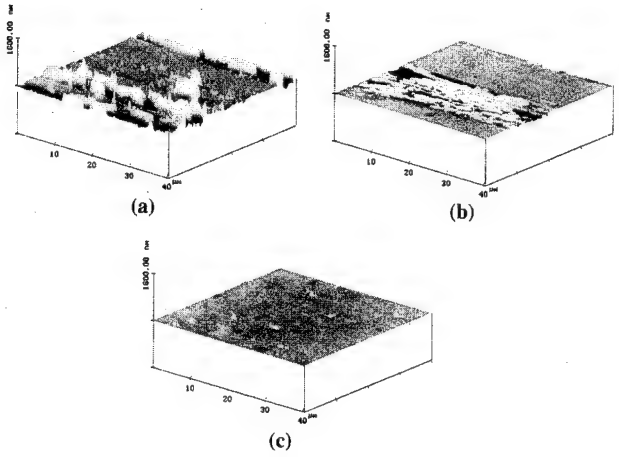

FIG. 3. The AFM images of the air bearing surfaces of (a) uncoated, (b) pure carbon, and (c) carbon nitrogen coated head sliders after 23 000 revolutions of CDT test runs.

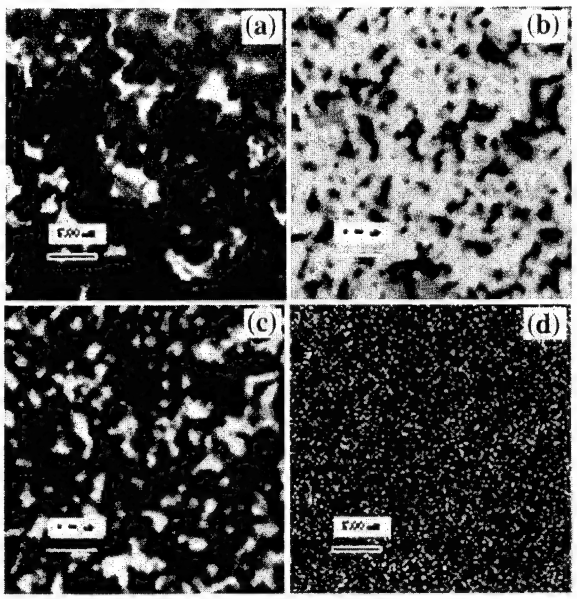

FIG. 4. The SEM mapping results of the uncoated head surface: (a) corresponding secondary electron image; (b) Al distribution; (c) Ti distribution; (d) Cr distribution. The scale bar is 5.00 μm.

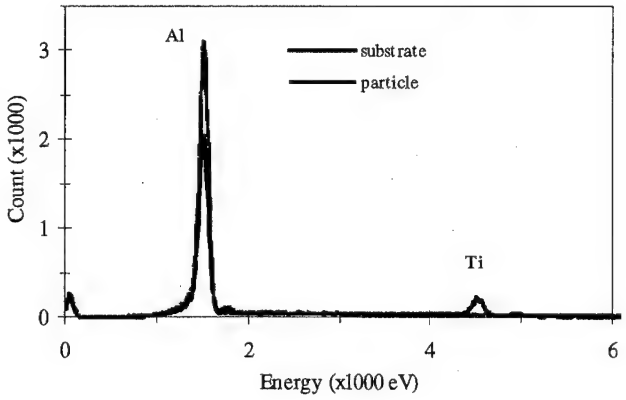

FIG. 5. The EDX spectrum of the uncoated head surface after CDT test.

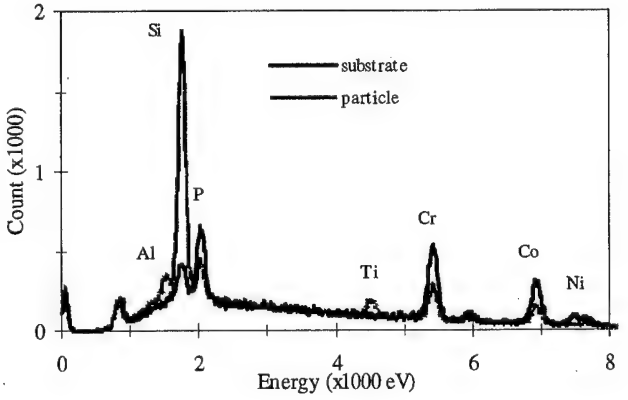

FIG. 6. The EDX spectrum of the disk surface around wear track after CDT test.

Figure 5 shows a typical energy-dispersive x-ray (EDX) spectrum of the testing head air bearing surfaces. Only Al had been detected from the wear particle which means that they were mainly composed of Al and came from the slider itself. In all cases being studied, there was no evidence that Cr was transferred to the sliders. On the other hand, Al and Ti (as shown in Fig. 6) particles were found on the surface around the wear track of the disk paired with the uncoated head slider.

Comparing Fig. 2 with Fig. 4(a), we note that the wear damage of the disk was less severe than that of the head. We also found that by dragging an uncoated head slider on a disk for 12 000 revolutions, although there was no visible wear marks on the disk surface, the head exhibited wear features under both AFM and SEM.

In summation, we can say that during the CDT test, the head may fail before the disk fails and the area of Al_2O_3 is the most possible place where wear begins. Since the Al_2O_3 is relatively softer than TiC, this conclusion is not unreasonable. Both the pure carbon and carbon nitrogen behave like a protective coating for the head slider where the carbon nitrogen is better than the pure carbon in light of the protection.

IV. CONCLUSION

Both FTS sputtered pure carbon and carbon nitrogen films can protect head slider from wear failure to some extent during CDT tests and carbon nitrogen is better than pure carbon. In CDT tests, the head may fail before the disk fails and the area of Al_2O_3 is the most possible place where wear begins.

Transient response of ultralow flying sliders over contaminated and textured surfaces

Paul R. Peck, Ki-Ook Park,[a] and Myung S. Jhon
Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213-3890

Soo-Choon Kang and Tom I.-P. Shih
Department of Mechanical Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213-3890

The transient flying dynamics of positive and negative pressure sliders over nonsmooth surfaces were investigated. Surface roughness was modeled by variously oriented sinusoidal waves, and contaminated surfaces were modeled as series of asperities and pits. A finite element algorithm was used which incorporates a generalized form of the Reynolds equation based upon the linearized Boltzmann equation. A new kinetic equation descriptive of ultralow flying was also discussed. Spectral analysis using fast Fourier transformation was adopted to explore the transient behavior of sliders in the frequency domain. © *1996 American Institute of Physics.* [S0021-8979(96)11308-9]

I. INTRODUCTION

In the magnetic storage industry, higher information storage densities are achieved by reducing the slider–disk separation. At ultralow flying heights, the effect of surface topography on transient slider dynamics becomes a critical issue in the dynamic stability due to the increase in the risk of detrimental slider–disk collisions.

Surface roughness effects have been previously studied either experimentally,[1] numerically,[2–4] or semianalytically.[5,6] Most of the previous investigations focused on IBM 3370 positive pressure sliders and utilized the first-order modified Reynolds equation. In this paper, we simulated positive and negative pressure "bow tie" shaped sliders[7] over various surface topographies and disk defects using a finite element algorithm. As a new methodology to analyze transient dynamic behavior of sliders, spectral analysis was introduced using fast Fourier transformation (FFT) into a time-dependent transient simulation code.

II. MATHEMATICAL MODELING OF THE HEAD–DISK INTERFACE (HDI)

Bow tie shaped positive and negative pressure sliders, shown in Fig. 1(a), were introduced to simulate ultralow flying slider dynamics over rough surfaces. These sliders are meant to serve as an illustrative example for nonrectangular shaped rail geometry, even though they may not be feasible for operational use. The negative pressure bow tie slider has the same configuration as the positive one with the addition of a cross rail between the side rails, which generates a suction force.

Sinusoidal roughness of several amplitudes oriented in various directions relative to the slider length (see Table I), was placed on either the slider or the disk to study the effects of moving and stationary roughness on flying characteristics. For a sinusoidal varying surface, the change in vertical displacement (z) was calculated using

$$z_{\text{rough}}=z_{\text{smooth}}-z_s^{\max}\sin\Phi_1(x)\sin\Phi_2(y). \tag{1}$$

The effects of contaminants on the disk were studied by introducing various configurations of ellipsoidal asperities and pits onto the simulated disk surfaces.

The equation governing the pressure distribution between the slider and disk surface is the modified Reynolds equation which incorporates kinetic theory based on the Bhatnagar–Gross–Krook's (BGK) approximation to the linearized Boltzmann equation (LBE).[8] A closed form[9] (no database lookup procedures) for this equation was used in the present simulations.

Under ultralow flying conditions, molecule–surface collisions occur more often than intermolecular collisions. The BGK theory is invalid under these conditions. A rigorous kinetic equation is currently being developed, which is structurally similar to the Fokker–Planck (FP) equation.[10]

The dynamics of a one particle distribution function in dimensionless velocity form, $f(\mathbf{r},\zeta,t)$, is described by the following kinetic equation:

$$\left(\frac{\partial}{\partial t}+v_0\zeta\frac{\partial}{\partial \mathbf{r}}\right)f(\mathbf{r},\zeta,t)=A(f\,). \tag{2}$$

$A(f\,)$ contains the collisional information of the gas molecules and depends on the kinetic model chosen.

TABLE I. Expression of surface roughness topology.[a]

Surface roughness	Stationary	Moving
Transverse	$\Phi_1=2\pi\omega x/U$ $\Phi_2=\pi/2$	$\Phi_1=2\pi\omega x/U-t$ $\Phi_2=\pi/2$
Longitudinal	$\Phi_1=\pi/2,\ \Phi_2=2\pi\omega y/U$	
Two dimensional	$\Phi_1=2\pi\omega x/U$ $\Phi_2=2\pi\omega yW/UL$	$\Phi_1=2\pi\omega x/U-t$ $\Phi_2=2\pi\omega yW/UL$

[a]ω is the wave number of the surface roughness, U is the disk velocity, W is the width of the slider, and L is the length of the slider.

Instead of comparing numerical results between several kinetic equations, the mathematical structures of the BGK approximation (LBE/BGK), an alternative kinetic equation (FP), and the collisionless kinetic equation (CL) are compared by expanding $A(f)$ in terms of the generalized orthogonal Hermite polynomial tensors $H^{(n)}_{i_1,i_2,\Lambda,i_n}(\zeta)$,[10]

$$A(f)=\int d^3\zeta' \Xi(\zeta,\zeta')f(\mathbf{r},\zeta';t), \tag{3}$$

with $\Xi(\zeta,\zeta')=\Sigma\lambda_n\varphi(\zeta)H^{(n)}_{i_1,\Lambda,i_n}(\zeta)H^{(n)}_{i_1,\Lambda,i_n}(\zeta')$.

The eigenvalues, λ_n, for the three models and the range of application of the equations are qualitatively summarized in Table II. Note that all of the models satisfy conservation laws, implying five zero eigenvalues.

III. NUMERICAL SIMULATION

Numerical simulations were performed for positive and negative pressure nano (50%) bow tie sliders. The length and width of the sliders are 2.0 and 1.5 mm, respectively. The recess depth of the negative pressure slider is 4.44 μm. In all simulations, the air inflow velocity is 10 m/s, the mass of the slider is 0.0125 g, the rotational speed is 5400 rpm, the skew angle is zero, the linear spring stiffness is 11 N/m, the torsional spring stiffness is 0.0006 N m/rad, and the moment of inertia is 9.2×10^{-11} kg m^2. The applied normal load is 5 g for the positive pressure slider and 1 g for the negative pressure slider.

○ Nonconserved	λ: mean free path

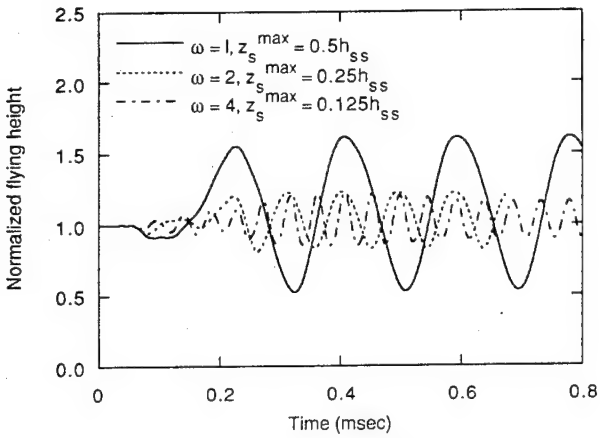

FIG. 2. Surface roughness wave number effects on the dynamic response over transverse sinusoidal surfaces.

A. Effects of sinusoidal surface roughness

The effects of roughness orientation and dimension on the slider flying characteristics were studied using sinusoidal surfaces. Simulations were performed with wave numbers, ω (inverse wavelength), equaling different multiples of the slider length. The ratio of the wavelength to the amplitude of the surface roughness was kept constant to be consistent with slider miniaturization. For a wave number of 1, the amplitude of the roughness is half of the smooth surface steady state flying height (h_{ss}).

Flying height variations normalized to h_{ss} are shown in Fig. 2 for transverse surface roughness. The slider follows the large wave form at the large wavelength, but as the size of the roughness is decreased, the flying height does not follow the surface roughness contour.

Transient dynamics of the bow tie negative pressure slider were simulated over the two-dimensional surface roughness shown in Fig. 1(b). The amplitude of the roughness is half of h_{ss}, and the wave number is 8 in the longitudinal direction and 6 in the transverse direction (to make the wave form square). The three-dimensional pressure distribution underneath the slider is shown in Fig. 3.

Dynamic responses show that the negative pressure slider does not follow the surface roughness as regularly as the positive pressure slider, however it does oscillate with smaller amplitude. This is attributed to the higher air bearing stiffness of the negative pressure slider.

B. Effects of multiple asperities

Contaminated particles which adhere to the moving disk surface can be modeled as multiple asperities randomly distributed over the disk surface. When a slider passes over a series of asperities, its behavior is affected by the time history. This non-Markovian behavior may cause sudden deviations from the designed flying characteristics.

To simulate possible scenarios of slider–contaminant interaction, two isolated ellipsoidal asperities and an asperity-

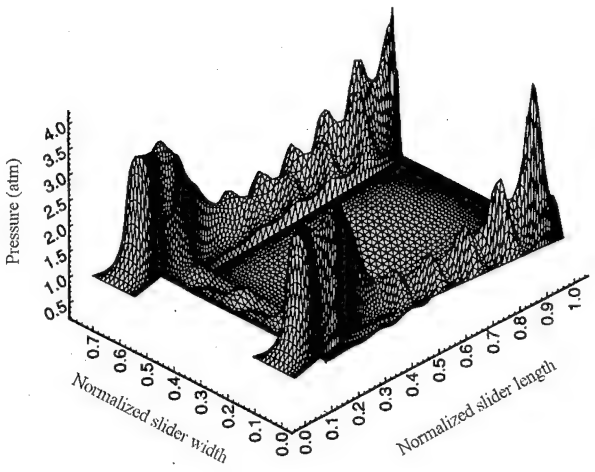

FIG. 3. Three-dimensional pressure distribution underneath a negative pressure slider flying over two-dimensional surface roughness.

pit combination were positioned beneath the center of the left rail (upstream to downstream) of a positive pressure slider. The amplitude of the asperity (or pit), h_a, was 20 nm and the radius of the asperity (or pit), r_a, was 100 μm. The separation distance between the centers of adjacent asperities (or the asperity and pit), L_a, was increased from 1 to 3 times the radius of the asperity. We refer to $L_a = r_a$ as a double asperity. Results for these simulations are shown in Fig. 4.

At smaller separations, a large amount of dynamic coupling occurs between the two asperities, while at larger separations ($L_a \geq 2r_a$), the coupling diminishes.

The effects of multiple asperities were examined in the frequency domain using FFT. A typical frequency spectra for the flying height mode is given in Fig. 5 for a double asperity, an asperity-pit, and two asperities with $L_a = 3r_a$. There are only a couple of dominant frequencies for each asperity

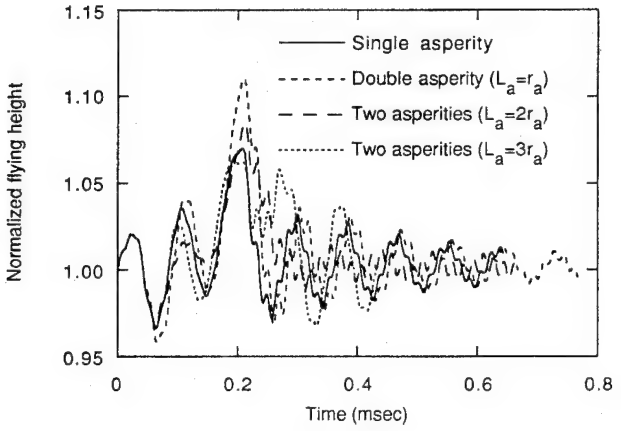

FIG. 4. Transient response of sliders flying over multiple asperities.

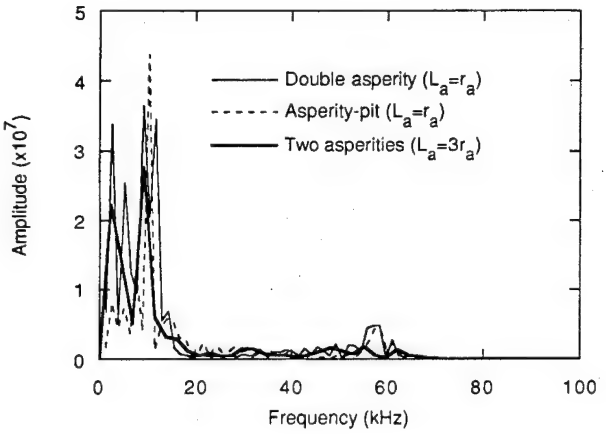

FIG. 5. Frequency spectra in the flying height mode.

set. The response for the double asperity shows a unique mode split phenomena at the dominant low frequency region.

IV. CONCLUSIONS

Transient dynamic responses of ultralow flying sliders were investigated over contaminated and textured surfaces using the LBE/BGK equation. A critique of this equation and the mathematical structure of the collision integral of an advanced kinetic equation descriptive of ultralow flying are given. Simulations were performed with positive and negative pressure nano bow tie sliders flying over various sinusoidal rough surfaces.

To simulate the effects of rough surfaces on the flying characteristics, multiple asperities and asperity-pit combinations were introduced. Non-Markovian memory effects of the slider response were prominent. As the asperity separation distance increased, coupling effects diminished. The asperity-pit combination showed the least disturbance to the dynamics of the slider.

Spectral analysis was introduced using FFT to characterize the dynamic response of sliders over various rough surfaces. This analysis showed the negative pressure slider to be more stable than the positive pressure slider in response to surface roughness.

The spreading characteristics of thin polymeric liquid films of perfluoropolyalkylethers (PFPEs) Fomblin Z15 and Fomblin Zdol (hydroxyl terminated PFPE) on silica surfaces have been measured by scanning microellipsometry (SME). We estimated the surface diffusion coefficients and propose a modified diffusion equation to interpret the spreading phenomenon from film thickness profiles measured with SME. We investigated the spreading of Z15 as a function of binary blend ratio of monodisperse Z15 fractions and found that the surface diffusion coefficients of the blends do not obey a simple linear mixing rule. A summary of thin PFPE film spreading characteristics as a function of molecular weight, film thickness, chain-end functionality, temperature, and humidity is presented. © *1996 American Institute of Physics.* [S0021-8979(96)11408-5]

I. INTRODUCTION

In magnetic hard disk drive systems, an ultrathin layer (~5–20 Å) of perfluoropolyalkylether (PFPE) is applied to the thin-film media surface to prevent wear of the media. In order to advance magnetic disk media technology, it is necessary to understand the interaction between the lubricants and the solid surface (retention), and the mobility of the lubricant molecules (replenishment). Only limited quantitative work has been reported on the mobility or diffusion of polymers in thin films on solid surfaces. Microscopic spreading characteristics of thin films[1–4] and small drops[5–7] of polymeric liquids on flat surfaces has gained considerable interest.

Surface diffusion of nearly monodisperse ($M_w/M_n<1.1$) PFPE films cast from solution onto the surface of silicon wafers was investigated as a function of molecular weight, film thickness, chain-end functionality, temperature, and humidity.[3,4] Scanning microellipsometry (SME) was used to measure the thickness profiles as the film spreads with time. The spreading of nonfunctional PFPE (Z15), a random copolymer of CF_2O and CF_2CF_2O moieties, and hydroxyl terminated PFPE (Zdol) exhibit distinctly different thickness profiles and mobilities. Spreading of Z15 occurs mainly by the diffusionlike movement of the fast moving front or foot of gradually decreasing thickness, and displays a greater mobility than Zdol. Zdol exhibits a characteristic shoulder by forming an apparent monomolecular "anchored" layer, which separates out from the initial film layer with a sharp boundary. The apparent surface diffusion coefficients of Z15 and Zdol increase with decreasing molecular weight and increasing film thickness (particularly for films <50 Å). Surface diffusion of 50 Å Z15 (M_w=13 800 g/mol) and Zdol (M_w=3400 g/mol) films were evaluated at temperatures ranging from 25 to 50 °C.[3] The activation energy for surface diffusion E_d of Zdol (50.6 kJ/mol) is higher than that of Z15 (20.6 kJ/mol), reflecting the stronger affinity of its hydroxyl end groups for the substrate. The bulk viscosity flow activation energies E_η were compared with E_d yielding $E_d \cong E_\eta$ for Z15 (neutral polymer–substrate interaction), and $E_d \cong 1.5E_\eta$ for Zdol (positive polymer–substrate interaction). Z15 is not significantly affected by humidity, whereas the PFPEs with functional chain-ends (i.e., Zdol, Ztetraol, and AM2001) exhibit a dramatic increase in mobility with increasing relative humidity.[4] In this paper, we introduce a full scale theoretical development of a modified diffusion equation to describe the spreading rate of the lubricant front. Using a finite difference scheme with the modified diffusion equation, the calculated positions of the moving front agree well with the measured data for a wide range of time. We focus on a binary blend system of Z15 monodisperse fractions to illustrate the essence of the experiments and theoretical development. This paper reports the first systematic study of lubricant thin film spreading behavior as a function of blend ratio, and the results presented may be useful in the development of advanced lubricant systems for hard disk drives.

II. EXPERIMENTATION

The commercially available Fomblin Z and its derivative Fomblin Zdol (products of Ausimont USA, Inc.) have the following random copolymer linear backbone chain structure:

$$X\text{–}CF_2\text{–}[(OCF_2\text{–}CF_2)_p\text{–}(OCF_2)_q]\text{–}OCF_2\text{–}X,$$

where X is F and $p/q \cong 2/3$ in Z15, and X is CH_2OH and $p/q \cong 1$ in Zdol.

Binary blends of monodisperse Z15 fractions were dip coated onto the surface of single-side polished silicon wafers. The silicon wafers were 25.4 mm in diameter and 0.2–0.3 mm thick having a native oxide SiO_2 (silica) layer of ~16 Å. Prior to coating, the wafer is cleaned by sequentially rinsing with isopropanol and perfluorohexane (FC-72, product of 3M). Half of the wafer is then immersed in a dilute solution of Z15 blend in FC-72 in order to form a film having a sharp step on one part of the substrate. The initial film thickness h_0 is controlled through solution concentration and

 0021-8979/96/79(8)/5788/3/$10.00

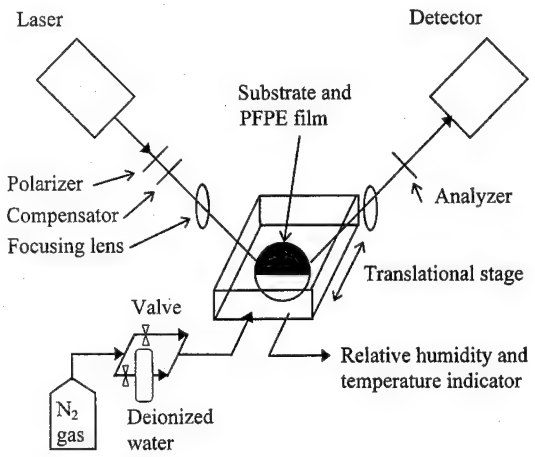

FIG. 1. Schematic of the SME setup.

the rate of drawing the wafer out of solution. The time-dependent thickness profiles of the films were measured using a SME (spot size 20×60 μm) having a translational stage with a temperature and humidity controlled environment as depicted in Fig. 1. The sample is oriented so that the steplike film boundary is parallel to the plane of incident light. All experiments were performed for h_0=50 Å films under a continuous stream of clean nitrogen gas at room temperature (≅26 °C) and 0% relative humidity.

III. RESULTS

A. Experiment

After dip coating, the PFPE film spreads with time along the surface of the silicon wafer and the thickness profiles are monitored using SME.[3,4] To determine the spreading rate of the lubricant, we focused on the leading edge of the advancing film front. The length that the front travels L is defined as the difference between the initial position of the lubricant front and each position in the subsequent profiles. Lengths L and corresponding travel times t are plotted as shown in Fig. 2 for Z15 M_w=13 800 g/mol. In the $L-t$ plot, the spreading

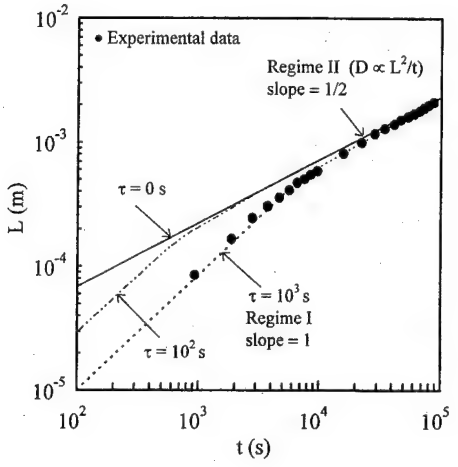

FIG. 2. $L-t$ plot of experimental data for Z15 over 24 h, and numerical $L-t$ curves obtained from Eq. (3) for different values of τ.

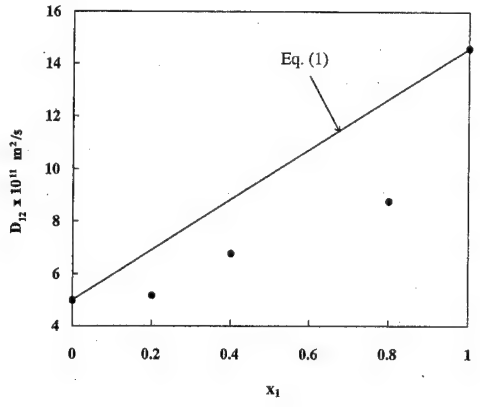

FIG. 3. Plot of D_{12} vs x_1 for binary blends of Z15.

phenomenon demonstrates $L \propto t$ for short times (Regime I) and after a gradual transition $L \propto t^{1/2}$ (Regime II; diffusion region). The surface diffusion coefficient D is estimated from the data in Regime II using[7] $D=L^2/t$. Film thickness profiles were monitored over 24 h for 0, 20, 40, 80, and 100 mol % ratios of Z15 monodisperse fractions M_w=5400 g/mol (component 1) and M_w=35 600 g/mol (component 2). As shown in Fig. 3, surface diffusion coefficients D_{12} were calculated for each of the binary Z15 blends of the low molecular weight fraction component 1 and high molecular weight fraction component 2. Applying a simple linear mixing rule for a binary mixture, the diffusion coefficient of an "ideal" mixture D_{12}^{id} may be expressed as

$$D_{12}^{\mathrm{id}}=(D_1-D_2)x_1+D_2, \tag{1}$$

where D_i and x_i denote surface diffusion coefficient and mole fraction of pure component $i(i=1,2)$, respectively. For Z15 blends, D_{12} does not obey the ideal mixing rule, i.e., $\Delta D=D_{12}-D_{12}^{\mathrm{id}}<0$ where ΔD is the excess quantity due to nonideality, as illustrated in Fig. 3.

Monodisperse fractions of Z15 M_w=5400 g/mol and Zdol M_w=4700 g/mol were blended in a 1:1 ratio by weight. From the characteristic shapes of the profiles shown in Fig. 4 and relative mobilities of Z15 and Zdol, the advancing front

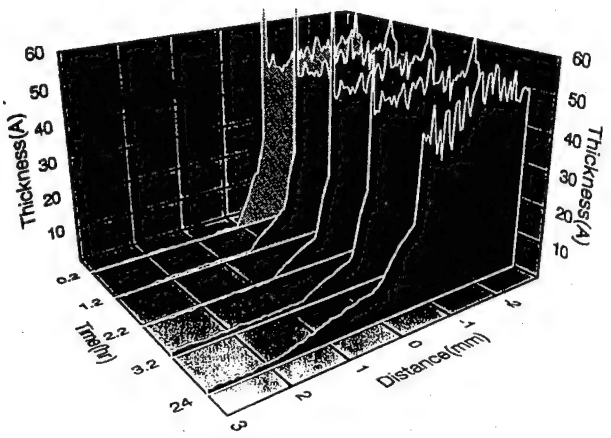

FIG. 4. Spreading profiles of a Z15/Zdol binary blend.

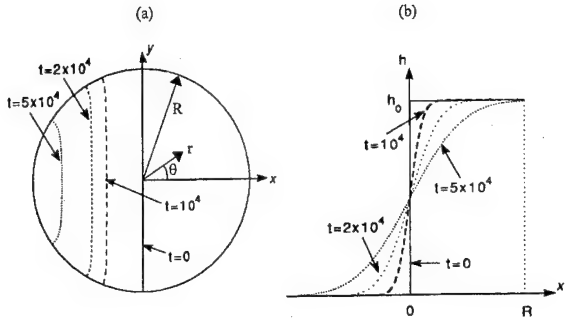

FIG. 5. Plots of $h(r,\theta,t)$: (a) contour of $h/h_0=0.01$ and (b) h at $y=0$ for $t=0$, 1×10^4, 2×10^4, and 5×10^4 s.

region of the film appears to be the relatively fast-moving Z15 and the remaining region, which exhibits a shoulder, should be the less mobile Zdol.

Two monodisperse fractions of Zdol ($M_w=1600$ g/mol and $M_w=4700$ g/mol) were blended in a 1:1 ratio by weight. Relative to its pure components, the Zdol blend shows a drastic increase in the dewetting exhibited on the film side of the profile which may be due to phase separation of its two components. The intermediate shoulder height of the blend is less distinct as compared to the shoulder heights of the anchored layers corresponding to the pure components.

B. Theory

To interpret experimental data shown in Fig. 2, the leading edge movement of the advancing film front was calculated with the conventional diffusion equation

$$\frac{\partial h(\mathbf{r},t)}{\partial t}=\nabla\cdot[D(h)\nabla h(\mathbf{r},t)], \tag{2}$$

where $h(\mathbf{r},t)$ is the thickness of the film (h=volume/area), and $D(h)$ is the thickness-dependent surface diffusion coefficient. Using a finite difference scheme, we solve for Eq. (2) in cylindrical form $h(r,\theta,t)$, for the system geometry in Fig. 5(a), assuming constant D, initial conditions $h(x>0,r\leqslant R;t=0)=h_0$, $h(x<0,r\leqslant R;t=0)=0$, and zero flux boundary conditions $\partial h/\partial r]_{r=R}=0$, $\partial h/\partial\theta]_{\theta=0,\pi}=0$. The numerical results shown in Fig. 5(a) of typical film thickness contours for the lubricant front assigned as $h/h_0=0.01$ at different times demonstrate $D\propto L^2/t$, and in Fig. 5(b) show the change in h with respect to time at $y=0$.

Although applicable in Regime II, the results obtained from Eq. (2) do not describe the $L\propto t$ behavior in Regime I. Therefore, we propose a modified diffusion equation given as

$$\tau\frac{\partial^2 h(\mathbf{r},t)}{\partial t^2}+\frac{\partial h(\mathbf{r},t)}{\partial t}=\nabla\cdot[D(h)\nabla h(\mathbf{r},t)], \tag{3}$$

where τ is a parameter related to the crossover time of the transition between Regimes I and II. Using a finite difference numerical scheme Eq. (3) can be used to describe the behavior of experimental data as shown in Fig. 2 for several different values of τ; note Eq. (3) reduces to Eq. (2) at $\tau=0$. The parameter τ can aid in characterizing microscopic spreading behavior of ultrathin polymeric films.

IV. DISCUSSION AND CONCLUSIONS

From Regime II of $L-t$ plots for films of binary Z15 blend ratios ranging from 0 to 100 mol %, surface diffusion coefficients were estimated using the relationship $D=L^2/t$. We found that surface diffusion of the Z15 blend deviates from an ideal mixture. Spreading of a 1:1 Z15/Zdol binary blend showed profiles in which the mobility of the individual PFPEs spread somewhat independently of each other. Thus, surface diffusion of a thin-film lubricant depends on its molecular weight distribution which should be one of the factors considered when selecting a lubricant. Since the conventional diffusion theory does not account for spreading in Regime I, a modified diffusion equation was proposed to more accurately describe and fit experimental data obtained from spreading profiles of PFPE films. The new term accounts for the early spreading where $L\propto t$. By analogy, the physical origin of τ can be understood in terms of the Deborah number commonly used in polymer rheology. Defining the "Deborah number of diffusion" as $\mathrm{De}_d\equiv\beta\tau/t$ (for Z15 $\beta\cong10$), then for $\mathrm{De}_d<1$ conventional diffusion ($L\propto t^{1/2}$) is applicable, and for $\mathrm{De}_d>1$ the new term in Eq. (3) becomes dominant ($L\propto t$) and describes the mobility of the lubricant front. Equation (3) was rigorously derived from Ficks law by introducing a delayed flux response, i.e., $j(\mathbf{r},t+\tau)=-D(h)\nabla h(\mathbf{r},t)$, for small τ. The details of this new theoretical investigation will be provided in a future publication.

Wear studies of contact recording interface with a microfabricated head

Bharat Bhushan and Youlin Li
Computer Microtribology and Contamination Laboratory, Department of Mechanical Engineering, The Ohio State University, Columbus, Ohio 43210-1107

In contact recording devices, a head is designed to remain in continuous contact with the disk surface. Friction/stiction and wear issues in continuous contact are critical to interface reliability. Objective of the present research is to study the wear mechanisms responsible for the wear of a microfabricated *a*-C:H contact pad sliding against a smooth disk surface. Wear rate of the contact pad was measured using a faceted technique. Disk wear track was measured using an atomic force microscope. After initial run-in, wear rate increased slightly with sliding distance. Wear rate at contact pressure when the pad is in complete contact with the disk is about 0.015 nm/h. Optical microscopy showed small accumulation of wear debris at the leading edge of the pad. The dominant wear mechanism initially is adhesive followed by some contribution by three-body abrasive wear caused by fine debris produced at the interface. Particulate contamination in the environment significantly increased the wear rate. Tests in various gaseous environments showed that wear rates in argon and in nitrogen are lower than that in ambient air, suggesting that tribochemical oxidation of carbon plays an important role in wear of carbon pad. © *1996 American Institute of Physics.* [S0021-8979(96)11508-1]

I. INTRODUCTION

In order to enable continued increase in storage density, one method is to minimize the head-disk separation (e.g., flying height) and ideally reduce it to zero. While a contact recording device (where the flying fight is zero) would be highly attractive from the perspective of magnetic performance, the tribological issues have to date discouraged their introduction into the commercial drives.[1] A number of contact recording devices are currently under development. In one of the most advanced designs, the contact pad consisting of Censtor MicroFlex head is substantially smaller (17 μm×36 μm) than the conventional heads.[2] During operation, the contact pad remains in contact with the disk at a typical applied normal load of 40 mg and at linear velocity of 3–8 m/s. A perpendicular-probe-type configuration can tolerate as much as 7 μm of vertical pole tip wear over the life of the drive (~5 y) without significant signal degradation.[3] Friction/stiction and wear problems associated with the continuous contact at head-disk interface become important. The objectives of the research are to study the wear mechanisms relevant to the pad/disk interface and the influence of the environments on the wear rate of the contact pad.

II. EXPERIMENT

The read-write heads used here were two-piece Censtor MicroFlex heads with gold contact on top of head body soldered to one end of a triangular stainless steel flexure beam. The laminated beam contains 25-μm-thick stainless steel with a polymeric layer topped with two parallel gold leads connecting the read-write element at the free end to bonding pads at the other end. The length and thickness of the flexure beam are 10 mm and 30 μm, respectively. The width ranges from 1.5 mm (head end) to 0.7 mm (free end). The flexure beam has an effective mass of about 600 μg with a spring constant of around 1.75 Nm^{-1}. The flexure is epoxy bonded to an alumina diving board which is then epoxy bonded to an anodized aluminum arm. A perpendicular-probe-type head, with a flux return pole and multilayered pancake coil, is fabricated using photolithographic techniques. The Co-Nb-Zr alloy pole and front yoke reside vertically along the center line of the head body with the coil placed orthogonally, and the gold contacts on the top. The head construction contains layers of SiC, Al_2O_3, and Si and the head is buried in a layer of plasma-enhanced chemical-vapor deposited (PECVD) *a*-C:H, which forms a contact pad with a cross section of 17 μm×36 μm with about 7 μm thickness.[4]

The magnetic disks used in this study were made of 0.635-mm-thick Al-Mg substrate with an outer diameter of 48 mm and an inner diameter of 12 mm. The disks were coated with 6-μm-thick electroplated Ni-Fe underlayer, 75-nm-thick sputtered Co-Cr-Ta magnetic layer, 10-nm-thick sputtered *a*-C:H overcoat and 1-nm-thick bonded perfluropolyether lubricant overlayer. The disks passed 38 nm glide height test. Roughness parameters of the disk surface measured using AFM are as follows: rms=0.55 nm, peak-mean distance=2.1 nm, P-V distance=4.2 nm, and β^* (correlation length)=0.3 μm.

Two tribotest apparatuses were used in this study to measure the wear rate of the contact pad. The wear tests in ambient air were conducted in a modified Seagate drive (ST-225), schematically shown in Fig. 1. The head-suspension assembly was mounted at an angle of about 8°–10°, on an actuator arm which is mounted on a vertical linear stage on a tower. The tower was actuated by a rotary actuator. The rotating speed of the disk was 3600 rpm and the applied normal force was 40 mg. Typical test duration was 120 h. The influence of various environments on the wear rate of the contact pad was studied using an ultra-high vacuum (UHV) environmental tribotester.[5,6] The experiments were performed in various environments of air (RH=65%), dry air (RH=10%), Ar, and N_2. The rotating speed of the disk, the applied load, and the test duration were 500 rpm, 40 mg, and 170 h, respectively. For experiments in environments other than in ambient air, the vacuum chamber was initially evacuated to a pressure of about 10^{-6} Torr and then backfilled with the desired gas.

 0021-8979/96/79(8)/5791/3/$10.00

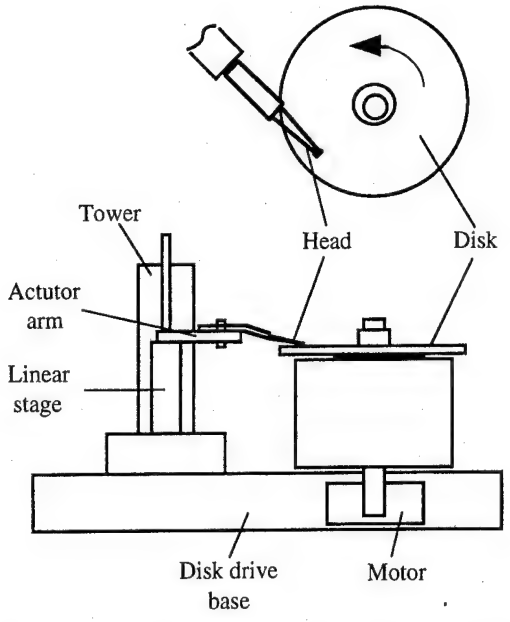

FIG. 1. Schematic of the disk drive for ambient wear test.

In these tests, the pad was brought in contact with the disk surface and was lowered by a known displacement to exert a desired normal load (normal spring stiffness is 1.75 Nm^{-1}). Displacement was measured by a noncontact fiber optic probe placed above the pad. Wear tests were conducted

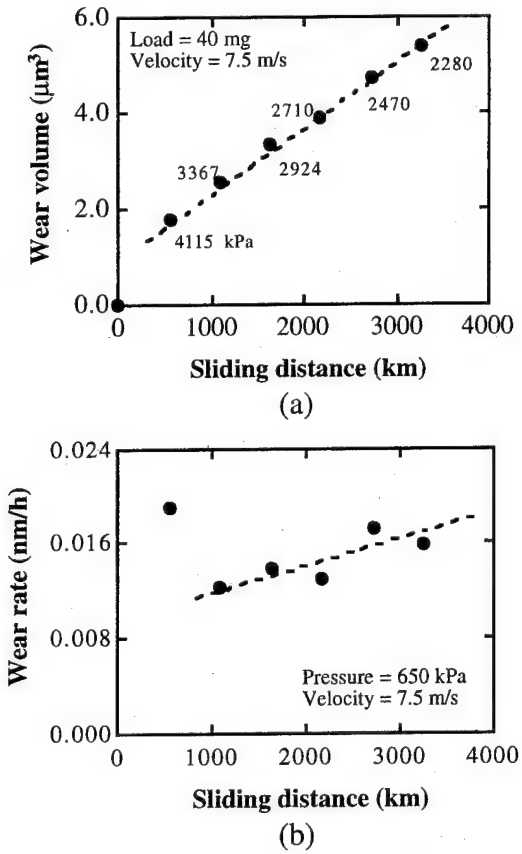

FIG. 2. Wear as a function of sliding distance (a) at pressures as shown in the figure, (b) at a normal pressure of 650 kPa.

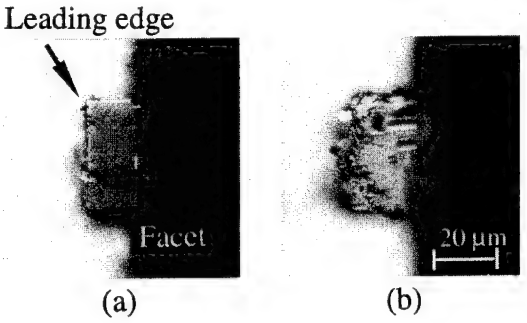

FIG. 3. Optical micrographs of the contact pads after 3250 km of test (a) in class 100 environment, (b) in class 10 000 environment.

by sliding the pad tilted with the disk surface to develop a facet on the pad surface. The wear rate of the contact pad was determined by measuring the growth in the size of the wear facet generated on the pad. The head was first loaded onto the coarse lapping disk (rms=235 nm) at a pre-test load (~58 mg) and ran for 10 s to create a single facet on the contact pad. It was then loaded onto the fine lapping disk (rms=1.4 nm) at the same load and ran for 120 min to remove the scratches on the pad surface. After that, the head was run on a test disk at the same load for 60 min and then repositioned to a new track, tilted about −0.75° (trailing edge in contact with disk surface) by decreasing the load to 40 mg and run for the test duration to create a new facet on the pad surface. Tilt angle was determined from the vertical displacement of the pad multiplied by the bending stiffness of the beam (7.4 degree/mm). The wear volume of the pad was calculated from the pad width, tilt angle and length of the new facet. The wear track on the disk surface was measured using AFM. All tests were conducted at ambient temperature of 22±1 °C. Humidity in the clean room environment was 50±5% RH.

III. RESULTS AND DISCUSSION

The wear volume of the contact pad as a function of sliding distance for the tests conducted at a normal load of 40 mg and tilt angle of −0.75° in class 100 environment is shown in Fig. 2(a). After the first 540 km of sliding at higher pressure, the wear volume increases at a nearly constant rate. Note that during the wear test, the facet gradually grew and

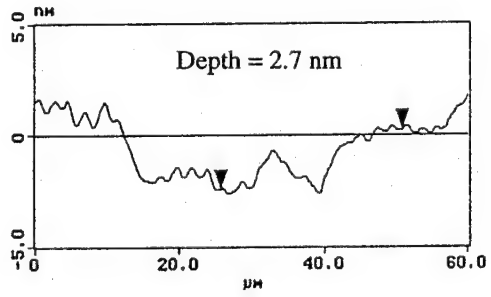

FIG. 4. AFM profile of the wear track in the disk surface after 3250 km of test.

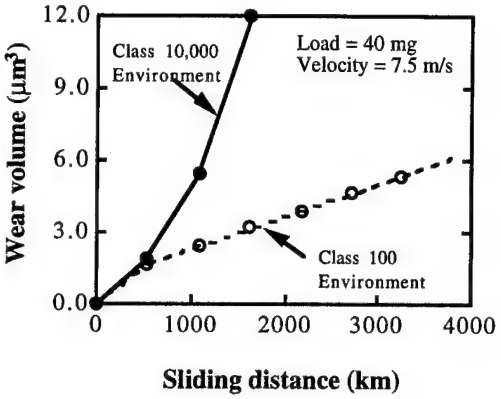

FIG. 5. Wear volume as a function of sliding distance in two environments.

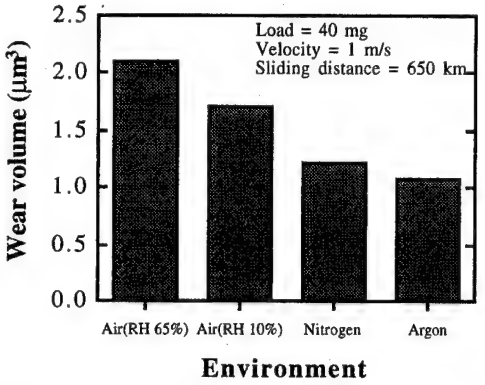

FIG. 6. Wear volume data in different environments after 650 km of sliding at 40 mg of load.

thus the contact pressure decreased with the test time. At the beginning of the test, the wear pad makes a line contact with the disk surface, and thus the contact pressure is very high. Optical microscopy of the head surface during initial sliding showed light burnishing of the pad, which suggests that wear was dominated by plastic deformation. Absence of any abrasion marks suggests that dominant wear mode was adhesive. Optical microscopy of the worn surfaces after considerable sliding (>2000 km) revealed very fine scratching of the pad surface and some debris accumulation at the leading edge of the contact pad, Fig. 3(a). EDX analysis of the debris revealed that the debris contains C, Si, and Al, which suggests that one source of the debris is the contact pad. Some of the debris accumulated at the leading edge of the pad, and some re-entered the contact region between the head and disk, causing the three-body abrasive wear.

Since the rate of wear volume was constant after initial run-in, Archard's wear law is applicable. From simple geometry, square root of wear volume is proportional to the contact pressure. Using this relationship, the equivalent wear rate at a contact pressure of 650 kPa as a function of sliding distance was obtained, as shown in Fig. 2(b). A pressure of 650 kPa corresponds to the pressure when the pad is in complete contact with the disk at 40 mg of load. The contact pressure at the beginning of the test was underestimated, which gives a high wear rate. The wear rate at 2700 km is about 0.017 nm/h. Assuming that the hardness of the carbon pad is 15 GPa, the wear coefficient for the contact pad at 2700 km of sliding is about 8×10^{-11}, which is extremely low for dry sliding conditions.[1] After the run-in period, an increase in the wear rate with sliding distance is consistent with the contribution by the three-body abrasive wear.

Figure 4 shows the AFM measurement of the disk after 125 h of sliding against the head at a normal load of 40 mg and disk rotating speed of 3600 rpm (7.5 m/s). The wear track depth ranges from 2.5 to 3.5 nm.

The effect of the particulate contamination in environment on the wear volume is shown in Fig. 5, under the test conditions of normal load of 40 mg and disk rotating speed of 3600 rpm (7.5 m/s). The wear volume increased with sliding distance more quickly in class 10 000 environment than in the class 100 environment. After 1620 km of sliding, the wear volume in class 10 000 is about 12.0 μm^3, as compared to 3.3 μm^3 in class 100 environment. Figures 3(a) and 3(b) show the typical optical images of the worn pads in class 100 and in class 10 000 environments. Severe scratches are clearly observed on the worn area in class 10 000 environment, which suggests that the particulate contamination in ambient environment caused severe abrasive wear and therefore increased the wear volume to a high value. The smaller scratches on the worn area in class 100 environment are caused by the contaminants and/or the fine debris generated during sliding wear.

Figure 6 shows the wear volumes in various gaseous environments under the test conditions of normal load of 40 mg, disk rotating speed of 500 rpm (1 m/s) and sliding distance of 650 km. These tests were conducted in the UHV tribotester. The wear volume in air with relative humidity of 65% is higher than in argon and in nitrogen. Tribochemical oxidation of carbon may be responsible for the higher wear rate in ambient environment, as compared to that in nitrogen or in argon environment.[5–7] The effect of environment on carbon pad sliding against carbon coated disk is not as significant as Al_2O_3-TiC slider sliding against carbon disk.[6,7] Catalytic effect of Al_2O_3-TiC slider is known to be responsible for very high wear rates in oxidizing environments. Further reduction in the interface wear will undoubtedly be desirable. Wear performance improvements may be accomplished by the use of alternative coatings, such as SiC_4 and cathodic arc carbon coatings[8] for the construction of contact pad and disk overcoat, and by the use of super smooth disks.

Non-Gaussian surface roughness distribution of magnetic media for minimum friction/stiction

Bharat Bhushan and Sameera Chilamakuri
Department of Mechanical Engineering, The Ohio State University, Columbus, Ohio 43210

Contact of two rough surfaces at an interface occurs at a small fraction of the nominal area. The real area of contact and interfacial adhesion primarily control the friction of an interface. With the presence of a thin film of liquid lubricant or adsorbed water layer at the interface, menisci form around the contacting and near-contacting asperities. The meniscus formation results in stiction problems in the head–medium interfaces. The objective of this research is to predict optimum surface roughness for minimum friction/stiction. For the first time, the effects of skewness and kurtosis of surfaces with non-Gaussian distribution on contact area and meniscus contribution have been studied. A numerical model that accounts for the effects of roughness distribution and liquid film was used for this study. Based on this study, a surface with non-Gaussian distribution with positive skewness between 0 and 0.2 and/or with high values of kurtosis ($K \geqslant 5$) should be used for low friction and stiction. © *1996 American Institute of Physics.* [S0021-8979(96)11608-8]

I. INTRODUCTION

High magnetic storage density in modern disk drives is achieved by the use of very smooth thin-film rigid disks that allow ultralow flying of read/write head sliders over the disk surface. However smooth surfaces result in high stiction during rest and high stiction/friction during the contact start/stop (CSS) operation, especially with the presence of a thin film of liquid lubricant or adsorbed water vapor at the head–disk interface.[1] Disk surfaces are textured to minimize stiction/friction. There is a critical h/σ (total liquid film thickness/standard deviation of surface heights) above which the stiction increases rapidly with an increase in the liquid film thickness.[1,2] Distribution of local roughness plays an important role in friction/stiction and wear. Thus optimization of roughness distribution on the disk surface is required. In the past few decades many analytical and numerical models have been developed for contact simulation of rough surfaces.[1,3] In most models surface height distribution is assumed to follow a Gaussian distribution. In the present model for the first time the effect of non-Gaussian distribution of roughness on real area of the contact and meniscus contribution have been systematically studied. Non-Gaussian surfaces were computer generated.

II. CONTACT MODEL

A Gaussian surface can be represented by two surface roughness parameters—σ (standard deviation of surface heights) or R_q (rms value) and β^* (correlation length).[1,3,4] A non-Gaussian surface may exhibit skewness (Sk) and kurtosis (K). Skewness is a parameter which defines the asymmetric spread and it is given by

$$\mathrm{Sk}=\frac{1}{\sigma^3}\int_{-\infty}^{\infty} z^3 p(z)\,dz, \tag{1}$$

where $p(z)$ is the probability density function of variable, z (the height distribution). A Gaussian surface has zero skewness. Kurtosis represents the peakedness of the distribution and it is given by

$$K=\frac{1}{\sigma^4}\int_{-\infty}^{\infty} z^4 p(z)\,dz. \tag{2}$$

A Gaussian surface has a kurtosis of 3. Figure 1 shows the probability density functions for surface heights with different skewness and kurtosis values. An algorithm suggested by Hu and Tonder[5] has been used for the generation of non-Gaussian surfaces with given skewness and kurtosis. By using a two-dimensional digital filter technique combined with fast Fourier transform, rough surfaces with any given σ, β^*, Sk, and K can be generated efficiently using a computer. A

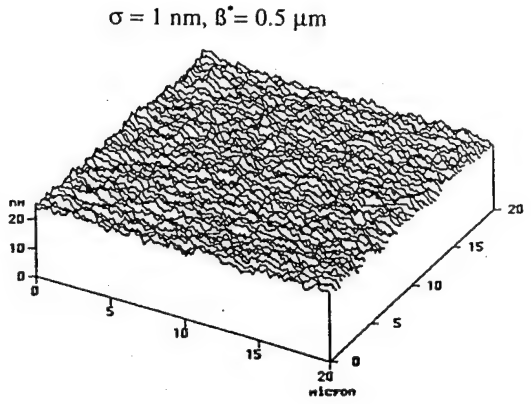

FIG. 2. Three-dimensional surface height profile of a computer generated Gaussian surface.

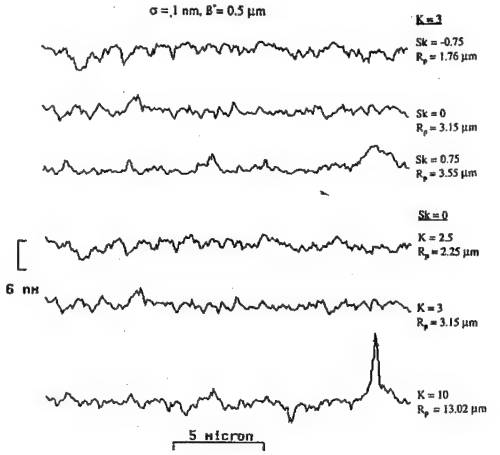

FIG. 3. Two-dimensional height profiles of surfaces with different skewness and kurtosis values.

computer generated three-dimensional Gaussian surface profile is shown in Fig. 2. The heights of the surface profiles consists of 256×256 data points. Figure 3 shows relative features of different non-Gaussian surfaces. A Gaussian surface with zero skewness and kurtosis of 3 has an equal number of peaks and valleys at a certain height. A surface with high negative skewness is almost flat with a relatively large number of peaks whereas a surface with high positive skewness consists of few high peaks. A surface with low kurtosis ($K<3$) has a relatively large number of peaks as compared to that of surface with high kurtosis.

A numerical model developed by Tian and Bhushan[6] has been used for the dry contact analysis of rough surfaces. The method is based on variational principle in which the real area of contact and contact pressure distribution are those which minimize the total complementary potential energy. The effect of meniscus force due to the presence of a thin liquid film is studied using the meniscus model developed by Tian and Bhushan.[7] Surfaces with different skewness and kurtosis were generated using a scan size of 20 μm×20 μm. Analyses were carried out using mechanical properties of Al–Mg/Ni–P disk with E (elastic modulus)=110 GPa, Poisson ratio=0.36, and H (hardness)=7 GPa against Al_2O_3–TiC slider with E=450 GPa and Poisson ratio=0.23 and perfluoropolyether lubricant with γ (surface tension)=25 dyn/cm and θ (contact angle)=10°. The composite modulus of elasticity of the interface was 101.6 GPa. Computer runs were made for a range of pressures. A pressure of 32.8 kPa corresponds to nominal pressure of a nanoslider (50%). Most computations were performed for h/σ=1 where h is the liquid film thickness.

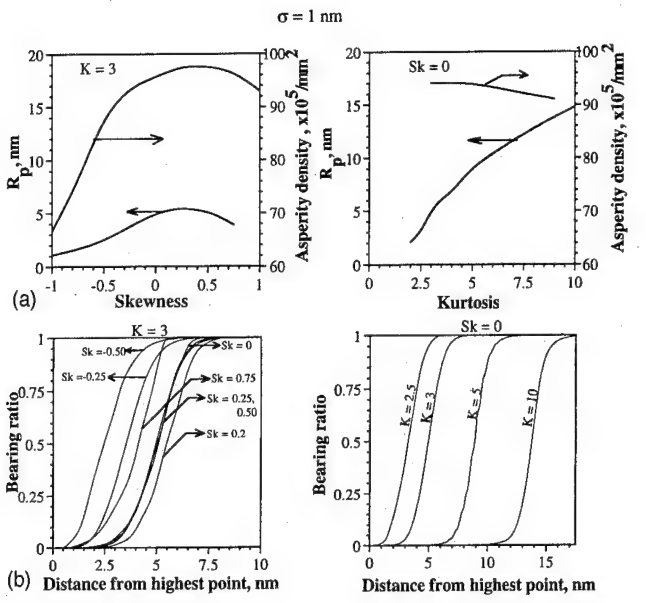

FIG. 5. (a) Peak-mean distance (R_p) and asperity density as a function of skewness and kurtosis. (b) Bearing ratio curves at different skewness and kurtosis values.

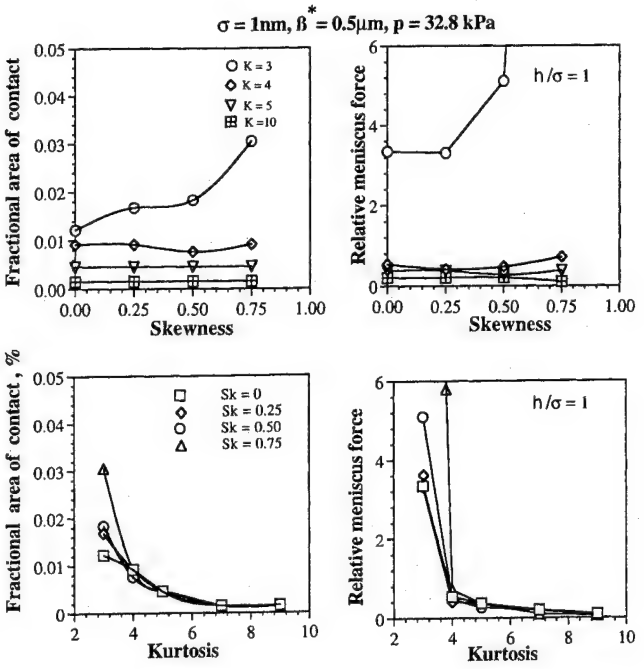

FIG. 7. Interplay of skewness and kurtosis on fractional area of contact and relative meniscus force.

III. RESULTS AND DISCUSSION

Figure 4 shows the variation of fractional real area of contact, contact density, and relative meniscus force with skewness and kurtosis. A positive skewness between 0 and 0.2 at low pressures and of 0.2 at high pressures, results in lowest real area of contact, contact density, and meniscus force. Fewer peaks in a surface with positive skewness as shown in Fig. 3 account for low real area of contact and meniscus force. Slightly positive skewness gives optimum number of peaks and the highest peak-mean value as shown in Fig. 5(a) which can support the applied load. Thus, it is clear that a positive skewness in the range of 0–0.2 is desirable with 0.2 being the optimum value. Figure 5(b) shows bearing ratio curves at different skewness values. Bearing ratio increases with an increase in negative skewness value, whereas it attains a minimum value at a positive skewness of 0.2 and increases again with further increase in skewness value. Figure 4 also shows that fractional area of contact, contact density, and relative meniscus force decrease with an increase in kurtosis of the surface. A higher kurtosis results in higher peak-mean value (R_p) and lower asperity density as shown in Fig. 5(a), which gives lower real area of contact and meniscus force. As shown in Fig. 5(b) bearing ratio increases with increase in kurtosis which again supports the trends observed in Fig. 4.

Figure 6 shows the variation of relative meniscus force with h/σ ratio at different values of skewness and kurtosis. We note that sensitivity of h/σ to meniscus force decreases at a range of positive skewness and kurtosis greater than 3.

Next we study the interplay of skewness and kurtosis to predict an optimum roughness distribution. Figure 7 shows the combined effect of skewness and kurtosis on real area of contact and meniscus force. For a zero or positive skewness, a kurtosis larger than 3 results in lower real area of contact and relative meniscus force. The plots of fractional area of contact and relative meniscus force are almost flat at kurtosis values greater than 5. So the effect of skewness (≥ 0) is negligible at kurtosis greater than 5. However at $K<5$, zero skewness is optimum. Based on this study, we conclude that a surface with a kurtosis of about 5 or larger with a skewness greater than or equal to zero (positive skewness has little effect) is optimum. However, if a surface with large kurtosis cannot be manufactured, then a skewness of 0–0.2 is desirable for surface with K equal to 3–5. Surfaces with negative skewness and kurtosis less than 3 must be avoided.

A micro-remote centered compliance suspension for contact recording head (abstract)

M. Nakao, S. Sugiyama, and Y. Hatamura
The University of Tokyo, Faculty of Engineering, Department of Engineering Synthesis, Tokyo, Japan

T. Hamaguchi and K. Watanabe
Mechanical Engineering Research Laboratory, Hitachi, Ltd., Japan

Nowadays contact recording has become one of the most important mechanisms for high-density recording of HDD. The contact recording head is always subject to friction when sliding. If the friction causes vibration on the sliding head, the swaying of the head is likely to lead to some undesirable bit shifts. The authors previously measured the head movement in sliding with a Watrous-type suspension where it was verified that the front edge of the head fell down to the disk surface because the rotational center of the pitching motion of the head was located above the sliding surface, inducing a heavy sticking. In order to prevent the sticking from occurring, we have already proposed RCC (remote centered compliance) suspension (15 mm in thickness) which consists of a pair of inclined plates.[1] With this suspension, the front edge of the head is raised up because of the enhanced location of the rotational center which is now below the sliding surface. In this article we present a newly designed micro-RCC suspension (125 μm in thickness) for an acutal small MR head ($1\times1\times0.5$ mm) of the contact recording. It has two pairs of the inclined plates structure for two-axis frictions which are caused by seeking and tracking motions of the head, respectively. This suspension is fabricated from a 125 μm thick sheet of polyimide using the ultraviolet laser beam. We evaluate its movement in sliding at low speed (50 μm/s) and at high speed (2 m/s) under a 10 mN load on a sputtered disk, respectively. The normal and frictional forces are measured by a micro two-axis force sensor (0.01 mN resolution) with parallel-plate structure and the pitching motion of the head is measured by an inclination sensor by means of laser reflection angle measurement (10 μrad resolution). From the experiment at low speed, we have clarified that the head yields a stable friction (0.15 ± 0.02 mN) and has the nose-up attitude (0 to + 100 μrad). In addition, from the evaluation at high speed, we have observed the stable read-back signal ($\pm7\%$ modulation) because of the stable motion without any sticking. As a reference suspension, we prepare a micro-Winchester-type suspension. From the similar evaluation, we have identified that the reference head shows unstable friction (0.25 ± 0.1 mN) with the nose-down attitude (0 to -500 μrad) and an unstable signal ($\pm50\%$ modulation). We have confirmed through these observations that the micro-RCC suspension will be an indispensable tool for contact recording in order to realize a stable recording against the friction. Micro/nanoscale studies of boundary layers of liquid lubricants for magnetic disks (abstract)

Vilas N. Koinkar and Bharat Bhushan
Computer Microtribology and Contamination Laboratory, 206 W. 18th Avenue, The Ohio State University, Columbus, Ohio 43210-1107

The atomic force/friction force microscope is used to study the micro/nanotribiological properties of perfluoropolyether lubricants. Single-crystal silicon wafers were lubricated with nonpolar (Fomblin Z-15) and polar (Fomblin Z-DOL and Demnum S-100) lubricants. The nanowear tests show that the nonpolar (Z-15) lubricant depleted from the wear track within few cycles whereas polar (Z-DOL) lubricant exhibits excellent nanowear resistance with no degradation. The polar lubricant results in a lower value of microfriction as compared to the nonpolar lubricant and unlubricated silicon sample. The effect of thickness of polar lubricant is studied for the thermally bonded Z-DOL lubricant before and after wash. Unwashed polar lubricant film with unbonded fraction exhibited better resistance to wear than that of washed lubricant film. Thicker films are also more durable. Wear experiments with magnetic disks show that lubricant film on a supersmooth disk is more effective in reduction of friction and wear than a smooth disk. Coefficients of friction on micro- and macroscales are compared. Variation in lubricant film thickness results in variation in the coefficient of friction. Thus, friction force microscopy can be used to measure lubricant uniformity with spatial resolution on the order of tens of nanometers. Finally, adhesive experiments show that bonded film behaves as a soft polymeric solid. © *1996 American Institute of Physics.*

Rough surface contact analysis and its relation to plastic deformation at the head–disk interface

Chin Y. Poon and Bharat Bhushan
Computer Microtribology and Contamination Laboratory, Department of Mechanical Engineering, The Ohio State University, Columbus, Ohio 43210-1107

Ni–P coated Al–Mg (Ni–P) and glass–ceramic (GC) substrates for magnetic recording are measured by an atomic force microscope (AFM) using different scan sizes and sampling resolution. AFM measurements of the Ni–P and GC surfaces at smaller sampling intervals reveal finer details. The GC surface contains more high frequency details than the Ni–P surface. The correlation length β^*, a spatial parameter, is used in addition to the rms roughness R_q to characterize the surfaces. Contact analysis using a three-dimensional elastic-plastic rough surface contact model shows that the asperity pressure of the GC surface increases more rapidly than the Ni–P surface as the sampling interval decreases. For both surfaces, asperity contact starts from plastic deformation, the scale of which depends on different surface topographical structures. The GC surface is shown to have higher asperity pressure because it has higher frequency structures. The high frequency structure will facilitate plastic deformation, and it can help explain previously published results why the disk with Ni–P substrate has better durability than the disk with GC substrate in different environments.
 [S0021-8979(96)11808-0]

I. INTRODUCTION

Contacts at head–disk interface on a microscale are generally elastic.[1] But real surfaces consist of a broad range of wavelengths and high magnification reveals more of the fine structures. Therefore when contacts are examined on a nanoscale, asperity contact size becomes smaller and asperity contact pressure becomes higher. Therefore, results of rough surface contact analysis depend on sampling resolution. In this article, a three-dimensional numerical rough surface contact model[2] is used to examine the contact of Ni–P and GC surfaces and study the effect of sampling resolution on contact pressure and contact area.

II. MEASUREMENT AND CHARACTERIZATION

Rough surfaces of Ni–P and GC substrates are measured by an atomic force microscope (AFM) using different square scan areas with scan length of L=64, 32, 16, 8, 4, 1, 0.5, 0.25, and 0.1 μm. Each scan area contains 256×256 data points. Therefore, the sampling interval τ decreases linearly with L. Figure 1 shows the AFM surface maps of both surfaces for L=1 and 16 μm. The GC surface appears to be smoother but contains higher frequency structures than the Ni–P surface.

Whitehouse and Archard[3] showed that the standard deviation of height distribution σ and the correlation length β^* can be used to characterize a rough surface. σ is equal to rms of height distribution R_q for zero mean. β^* gives information about spatial distribution of a surface. The knowledge of spatial variation of surface is essential, as it affects the distribution and density of asperity contacts. A surface with shorter wavelength structures has smaller β^*.

β^* is given by the autocorrelation function (ACF). For a two-dimensional profile $z(x)$, normalized ACF, $R(\tau)$, is defined as

$$R(\tau)=\frac{1}{\sigma^2 L}\int_L z(x)z(x+\tau)\,d\tau. \tag{1}$$

For many engineering surfaces, an exponential function ρ is found to fit the ACF. We have

$$R(\tau)=\rho(\tau)=\exp\left(\frac{-\tau}{\beta^*}\right), \tag{2}$$

where $1/\beta^*$ is the decay rate of the function. The correlation length can be defined as $\rho(\tau)$=0.1 (when τ=2.3β^*) or $\rho(\tau)$ =1/e (when τ=β^*). Both forms are considered to be a measure of the length at which single height readings become statistically independent of one another. In this article, β^* is given by $\rho(\tau)$=1/e.

The variation of R_q and β^* with scan size for the Ni–P and the GC surfaces is shown in Fig. 2. R_q of each surface initially increases with L and approaches a constant value when L reaches about 16 μm. This indicates that both sur-

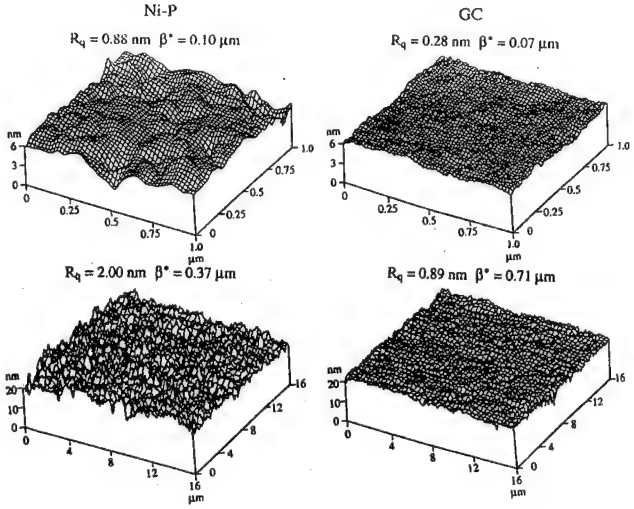

FIG. 1. AFM surface maps of Ni–P and GC surfaces for L=1 and 16 μm.

 0021-8979/96/79(8)/5799/3/$10.00

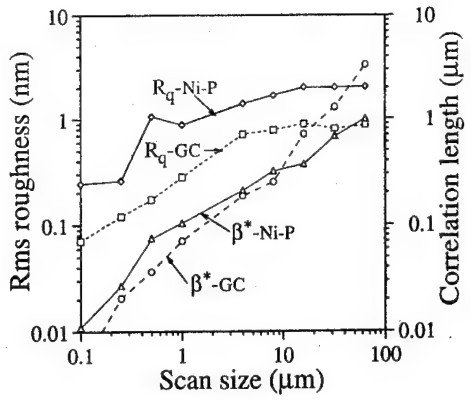

FIG. 2. Variation of rms roughness and correlation length with scan size.

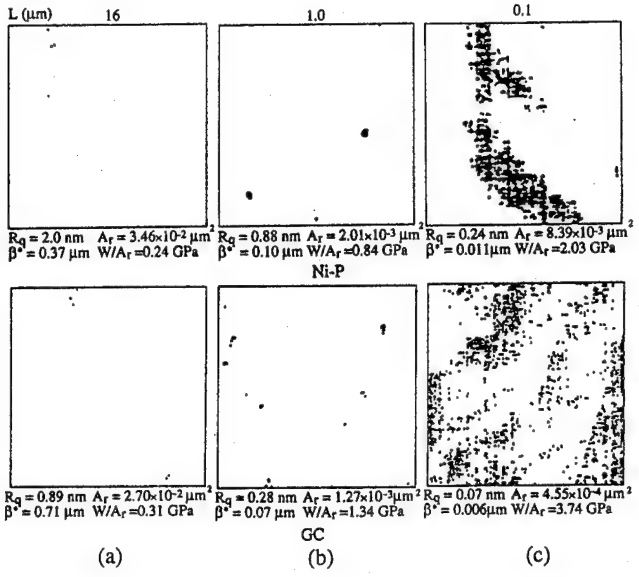

FIG. 3. Contact area of Ni–P and GC surfaces for $L=16$, 1, and 0.5 μm. $p_n=32.8$ kPa for $L\geq 16$ μm and $W=1.7$ μN for $L\leq 8$ μm.

faces contain a long-wavelength limit of 16 μm. Therefore, β^*, which represents the wavelength structure of a random surface, should approach a constant value as L reaches 16 μm for measurements made at constant τ. But in the AFM measurements, τ increases with an increase in L, which is responsible for an increase in β^* with L, observed in Fig. 2. As τ increases, the higher frequencies in the surface cannot be recorded[4] and error in sampling occurs. The surfaces being studied contain predominantly submicron details. Increasing τ will result in loss of high frequencies information. As τ increases, high frequency details of the original profile gradually disappear resulting in high β^*. R_q is a vertical parameter not sensitive to τ but is generally increasing with L. β^* is a spatial parameter affected by both τ and L.

III. CONTACT OF Ni–P AND GC SURFACES

A three-dimensional (3D) numerical rough surface contact model[2] is used to study the contact of a head slider on the Ni–P and the GC surfaces. This model analyzes elastic/plastic contact of two rough surfaces and predicts the contact statistics and contact pressure. Roughness data used in the model are the 3D roughness maps obtained at a given scan size and sampling interval. For the asperity undergoing plastic deformation, the asperity pressure is taken to be the hardness of the softer body, which is 8.0 GPa. The head slider is a 50% size slider made of Al_2O_3–TiC and is taken as perfectly smooth. The Young's modulus and Poisson's ratio for the slider, the Ni–P surface, and the GC surface are 450 GPa and 0.23, 130 GPa and 0.36, and 130 GPa and 0.25, respectively. The nominal load W_n is 3 g and the nominal area A_n is 0.915 mm^2, which gives the nominal pressure p_n of 32.8 kPa. In the contact analysis, the applied load is changed for different scan sizes according to different bandwidths involved in the nominal contact.

In Fig. 2, R_q of each surface approaches a constant value when $L\geq 16$ μm, which indicates that the surfaces contain a long-wavelength limit of 16 μm. Therefore, the applied load can be reasonably assumed to distribute evenly over the surface for $L\geq 16$ μm and is given by $W=p_n\times L^2$. p_n is equal to 32.8 kPa. For $L=64$, 32, and 16 μm, the load W are 134, 33.6, and 8.4 μN, respectively. The contact areas of the Ni–P and GC surfaces for $L=16$ μm are shown in Fig. 3(a). However, for $L<16$ μm, R_q increases with L because of different bandwidth structure for $L<16$ μm; therefore, the load cannot be calculated based on assumption of uniform distribution of load over the slider area.

From Fig. 3(a), the contact areas for the Ni–P and the GC surfaces are 0.035 and 0.027 μm^2, respectively. The number of contacts for both surfaces is five. Therefore, the average contact width for each asperity contact of both surfaces is about 0.08 μm and the average asperity contact load is 8.4/5 or 1.7 μN. Now, this particular asperity contact is examined in finer detail by reducing the scan size using the same number of discretized data points and assuming that each scan size contains asperity contacts. In this way, the scan size can go down to 0.08 μm using the same asperity contact load. For a range of scan sizes 16 μm$>L\geq 0.1$ μm, the load is taken as $W=1.7$ μN. The contact areas of Ni–P and GC surfaces for $L=8$, 4, 1, 0.5, 0.25, and 0.1 μm are calculated and the contact areas for $L=1.0$ and 0.1 μm are shown in Figs. 3(b) and 3(c). The contact areas of Ni–P and GC are significantly different; the contact area of the Ni–P surface is almost twice the GC surface, and the individual asperity contact of GC is much smaller.

Next, the effect of sampling interval on contact area and contact pressure is studied. The contact area calculated for different scan sizes is modified so that it can be compared based on a particular scan size. For surfaces with $L\geq 16$ μm, the contacts are taken as distributed evenly over the surface; therefore the contact area of the surfaces with $L=64$ and 32 μm can be divided by 16 and 4, respectively, to compare with the surface with $L=16$ μm. The number of contacts at $L=16$ μm is five, therefore at $L=8$ μm about one contact is expected. Therefore, the contact area for $L\leq 8$ μm is considered as the higher magnification of one of the five contact spots at $L=16$ μm and it should therefore be multiplied by

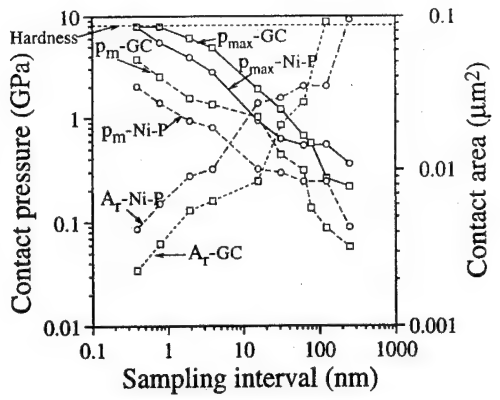

FIG. 4. Variation of mean contact pressure, maximum contact pressure and contact area with sampling interval for Ni–P and GC surfaces.

five to compare with the surface using $L=16$ μm. However, the mean contact pressure $p_m = W/A_r$, does not need to be modified with L because W and A_r will change by the same factor for different L. Using the preceding argument, the variation of contact area and contact pressure with sampling interval is shown in Fig. 4. For both surfaces, the contact area decreases and contact pressure increases as the sampling interval decreases. The contact pressure of the GC surface is always higher than that of the Ni–P surface. As the sampling interval becomes smaller, the maximum contact pressure p_{max} can reach the hardness. The subsurface stress is always higher than the surface stress and plastic deformation is expected to occur before surface stress reaches the hardness.

IV. DISCUSSION

Surface texture plays an important role in controlling friction and durability at the head–disk interface (HDI).[1] In general, friction and durability have been qualitatively related to vertical roughness parameters such as rms roughness R_q, center-line-average roughness R_a, peak-to-mean distance R_p, peak-to-valley distance P-V, and bearing ratio. On the other hand, spatial parameters have rarely been used. Since the complex nature of surface roughness covers a broad bandwidth of wavelengths, the measured surface profile depends on the scale of measurement and the surface measuring instruments.[5] In particular, spatial parameters are very sensitive to the sampling resolution.

Whitehouse and Archard[3] used a statistical approach for a gaussian surface and showed that the distribution of peak heights, curvatures, slopes, and peak density could be expressed in terms of R_q and β^*. Their expressions have shown a broad agreement with surface measurements of different surfaces used for magnetic recording.[6] Whitehouse and Archard further expressed the plasticity index in terms of R_q and β^*. Later, Onions and Archard[7] combined the approaches of Greenwood and Williamson[8] and Whitehouse and Archard.[3] They expressed the contact pressure in terms of R_q/β^*. Hirst and Hollander[9] provided experimental evidence that surface damage can be related to R_q and β^*. It appears that β^* can be used in addition to R_q to assess the disk's friction and durability at HDI.

From Fig. 2, R_q of the Ni–P surface is always higher than that of the GC surface. Based on R_q alone, it is expected that the contact pressure for the Ni–P surface is higher. On the contrary, Fig. 4 shows that contact pressure for the GC surface is always higher, except for larger L. But the results for larger L (higher τ) are not representative because much of the high frequency structures in the GC surface are excluded in the contact analysis. Figure 4 shows that for both surfaces, the contact pressure increases and the contact area decreases as τ decreases because finer asperities become involved in the contact. The GC surface contains more higher frequency structures than the Ni–P surface, which explains why the contact pressure for the GC surface is higher than the Ni–P surface. Results show that a spatial parameter such as β^* is also needed to characterize a rough surface.

From Fig. 4, the asperity contact pressure of both surfaces reaches the hardness of the softer material at low τ. This implies that the contact of real surfaces starts from plastic deformation on a nanoscale. The GC surface experiences a larger degree of plastic deformation than Ni–P surface because GC has higher frequency structures compared to the Ni–P surface. Bhushan *et al.*[10] have reported that the durability of Ni–P was generally better than the GC surface in different environments. In their paper, the R_p values of Ni–P and GC surfaces were comparable but the corresponding AFM surfaces showed that the GC surface contained much higher frequency details. The wear track on the GC surface showed a few very thin continuous scratches and the corresponding head slider contained a trail of wear particles after test. The wear particles may be generated from shearing of the asperities by plastic deformation which can get trapped at the interface resulting in the three-body abrasion.[1] Based on the contact analysis and the earlier tests on Ni–P and GC surfaces, the high frequency structure in the GC surface will facilitate the plastic deformation and form wear particles, which in turn take part in the three-body abrasion process. Therefore, the high frequency structure in the GC surface is not desired.

Environmental effects on the pause mode performance of metal-evaporated and metal-particle tapes

Steven T. Patton and Bharat Bhushan
Department of Mechanical Engineering, The Ohio State University, Columbus, Ohio 43210

A commercial *Hi*-8 VCR was instrumented to measure the friction force between the rotary heads and tape and rms head output. Pause mode experiments using metal-evaporated (ME) and metal-particle (MP) tapes were performed at design tension under equilibrium conditions inside of an environmental chamber at various temperatures and specific humidities (SH is the ratio of the weights of water vapor to dry air in the mixture). ME tape performed well only at high humidity [on the order of 80% relative humidity (RH)] in the operating temperature range of 15.6–32.2 °C. Under all conditions, lubricant was removed from the ME tape surface, which resulted in increased signal amplitude (due to decreased head medium spacing) and friction during individual experiments. For fixed temperature, increased SH reduced both the lubricant depletion rate and the number and magnitude of spacing loss signal dropouts. The thicker water film maintained on the interface components acted as an additional replenished lubricant, which reduced the displacement of the perfluropolyether lubricant from the tape surface and acted as a mediator for solid debris to traverse the contact region of the head and tape. For fixed SH, reduced temperature led to the same improvements due to increased lubricant viscosity at lower temperatures. Increased lubricant viscosity reduced the displacement of lubricant from the tape surface, and displaced lubricant remained on the tape contact region of the head surface and acted as a mediator for solid debris to traverse the contact region of the head and tape. Tests with MP tape showed a relative insensitivity to the environment. © *1996 American Institute of Physics.* [S0021-8979(96)11908-7]

Metal-evaporated (ME) and metal-particle (MP) tapes are leading candidates for high-density recording applications such as consumer digital audio, video, and data processing. The effects of temperature and specific humidity (SH is the ratio of the weights of water vapor to dry air in the mixture) on the performance of these tapes must be understood to ensure that the tapes can operate satisfactorily in the operating envelope for a given application. Previous studies showed that ME tape performance improved when operated above a threshold humidity for a given temperature (with a threshold value that increased with temperature), and that MP tape performance was relatively insensitive to the environment.[1,2] However, the effect of temperature on ME tape performance and the underlying mechanisms which improved performance above the threshold humidity are not known.

A commercial *Hi*-8 VCR (Sony EV-C100) with four heads was instrumented to measure the friction force between the rotary heads and tape and root mean square (rms) head output. The relative speed between a rotary head and tape is 3.8 m/s with an inlet tension of 0.1 N.[2] The average pressure at the contact region of the head and tape is about 100 kPa.[2] The two read/write metal in gap heads have a core material of single-crystal Mn–Zn ferrite with crystalline Sendust metal alloy (Fe–Si–Al) in the gap. Commercially available *Hi*-8 ME and MP tapes were used in this study.[3]

The data processing operating envelope is 15.6–32.2 °C

and 20%–80% relative humidity (RH) with a maximum wet bulb temperature of 25.6 °C. Pause mode experiments were conducted at design tension under equilibrium conditions inside of an environmental chamber in a broader envelope at temperatures ranging from 5 to 37.8 °C (±1 °C) and relative humidity ranging from 20%–80% RH (±1% RH). The VCR and tape samples were placed in the chamber 24 h prior to experimentation at a given condition which allowed the components to come to equilibrium. The friction force was measured by monitoring the voltage across the motor used for drum rotation, and the friction force was obtained using a previously developed calibration procedure.[3] The calibration constant was 54 mV/mN. The head output was measured in a rms voltage format using a rms signal converter. A sine wave was recorded on the tape at a wavelength of 0.6 μm using VCR electronics. The motor voltage and rms head output were sampled at a rate of 4 Hz over the duration of seven minute pause mode experiments using an analog to digital converter, and the data were stored in a personal computer. The head and tape samples were observed with an optical microscope after selected experiments.

Figure 1 shows the friction force and head output during testing with ME and MP tapes in the same environment. ME tape lacked the stability in friction and head output exhibited by MP tape. Head output for ME tape shows a rapid increase to about +1 dB, implying a decrease in the head–medium spacing of about 10 nm for a recorded wavelength of 0.6 μm based on the Wallace equation. Since the lubricant thickness is also 10 nm, this implies the removal of essentially all of the lubricant from the ME tape surface. After lubricant depletion, interaction of the rotary heads with the metallic layer prevented the rapid increase in head output observed during lubricant removal and generated solid tape debris, which, at this environmental condition, caused signal dropouts upon

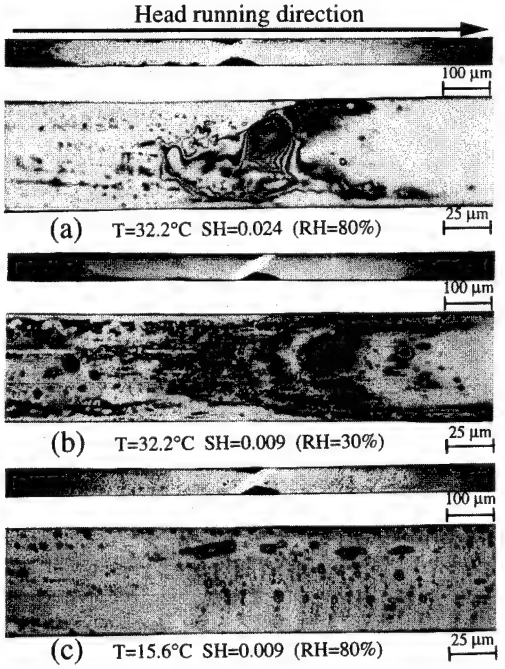

FIG. 4. Optical micrographs of the entire head surface (top) and magnified view of the trailing edge (bottom) after running to (a) point A in Fig. 3(a), (b) point B in Fig. 3(a) or point D in Fig. 3(b), and (c) point C in Fig. 3(b).

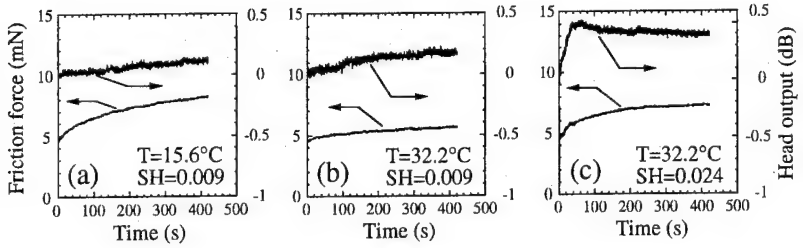

FIG. 5. Friction force and head output during testing with MP tape at various temperatures and specific humidities.

traversing the tape contact region of the head surface. The friction force increased as the lubricant was removed, and further increased and became unstable after lubricant depletion with friction spikes temporally correlated to signal dropouts.

Figure 2 shows durability results of pause mode experiments using ME tape at various temperatures and SHs. At constant temperature, increased SH improved tape performance. At constant SH, decreased temperature improved tape performance. At a given temperature more water vapor improved performance, and the amount of water vapor needed for improved performance decreased at lower temperatures. Experiments performed at various SH on the RH =80% line yielded good or excellent results in the operating temperature range of 15.6–32.2 °C. However, at temperatures lower than 15.6 °C, ME tape performed satisfactorily at lower humidity to RH=50%.

Figure 3(a) shows the friction force and head output at selected SH at constant temperature. At three different temperatures, increased SH improved the performance of ME tape. Increased SH reduced the lubricant removal rate, and improved signal stability after the lubricant depletion. The thicker water film maintained on the interface components acted as an additional replenished lubricant and a mediator for solid debris to smoothly traverse the contact region of the head and tape. Optical micrographs in Figs. 4(a) and 4(b) of the head surface after testing to points A and B in Fig. 3(a) show a relatively clean tape contact region for the head. Lubricant transferred to the leading edge from the tape, and collected on the trailing edge of the tape contact region. The amount of lubricant transferred to the head was greater after running at SH=0.009 than at SH=0.024, and thus the lubricant removal rate decreased at higher values of SH. The clean tape contact region of the head at points A and B suggests that the water film on the interface components must be the mediator which assisted solid debris in traversing the contact region of the head and tape.

Figure 3(b) shows friction force and head output at selected temperature at constant SH. At three different values of SH, decreased temperature reduced the lubricant removal rate and improved signal stability after lubricant depletion, due to increased lubricant viscosity at lower temperature. The average lubricant removal rate decreased from 10 to 4.3 nm/min, 10 to 5 nm/min, and 6.25 to 5 nm/min for SH equal to 0.009, 0.013, and 0.024, respectively, as the temperature was reduced in each case. In the cases of SH=0.009 and 0.013, the average lubricant removal rate was halved with a reduction in temperature of about 15 °C. Viscosity–temperature relations for perfluropolyether lubricants show that kinematic viscosity increases by about a factor of 2 with a 15 °C decrease in temperature within the range of temperatures used in these experiments.[4] For SH=0.024, the lubricant removal rate was reduced by about 20% for a smaller temperature reduction of about 5 °C. The data are consistent with the lubricant removal rate being inversely proportional to the viscosity. Figures 4(b) and 4(c) show optical micrographs of the head surface after testing to points D and C, respectively, in Fig. 3(b). The amount of lubricant transferred to the head was greater after running at 32.2 °C than at 15.6 °C, and lubricant remained on the tape contact region of the head after running at 15.6 °C. At lower temperatures, the lubricant removal rate decreased and lubricant persisted on the tape contact region of the head and acted as a mediator for solid debris to traverse the contact region of the head and tape.

Figure 5 shows friction force and head output in different environment using MP tape. Figures 5(a) and 5(b) show that MP tape performance was insensitive to changes in temperature at constant SH, and both friction and head output increased during each experiment due to mild burnishing of the tape surface. Figures 5(b) and 5(c) show that a thicker water film resided on the interface components with increased SH at constant temperature. The rapid increase in head output in Fig. 5(c) to 0.5 dB over the first 40 s of running suggests that about 2.5 nm of the water film on each interface component was removed by the friction force exerted on the components during this time. Subsequent head output decreased slightly as the water film partially reestablished on the head and tape surfaces.

Spin-dependent interface transmission and reflection in magnetic multilayers (invited)

M. D. Stiles
Electron Physics Group, National Institute of Standards and Technology, Gaithersburg, Maryland 20899

First-principles calculations of transmission and reflection from Ag/Fe, Au/Fe, Cu/Co, and Cu/Ni interfaces show very strong spin dependence that differs significantly from expectations based on free electron approximations. The results can be used to understand both the giant magnetoresistance and the oscillatory exchange coupling observed in magnetic multilayers of these materials. The spin dependence of the reflection probabilities is strong enough to give a large giant magnetoresistance even if there is no spin-dependent defect scattering. The calculated reflection amplitudes determine the strength of the oscillatory exchange coupling. [S0021-8979(96)79608-8]

I. INTRODUCTION

Magnetic multilayers, in which magnetic layers are separated by nonmagnetic spacer layers, exhibit two effects in which there has been significant recent interest: giant magnetoresistance (GMR)[1] and oscillatory exchange coupling.[2] The GMR is the change in resistance when the relative orientation of the magnetizations in neighboring layers is switched by applying a magnetic field. When the magnetizations are parallel, there is a "short circuit" effect; electrons of one spin have a lower average resistance. They carry more of the current, lowering the total resistance of the structure compared to the total resistance for antiparallel magnetizations. The spin dependence of the resistance can come from spin-dependent defect scattering or spin-dependent interface reflection. The oscillatory exchange coupling is the coupling between the magnetic layers that oscillates in sign as a function of the spacer layer thickness. In magnetic multilayers, multiple reflection from the interfaces produces quantum well states, which are spin polarized because the reflection amplitudes are spin dependent. The quantum well states increase or decrease in energy as the thickness of the spacer layer increases. When they cross the Fermi level, the energy gained or lost from filling them changes the relative energies of the configurations with parallel and antiparallel magnetizations.

Both GMR and oscillatory exchange coupling have been the subject of many model and first-principles calculations.[3] Model calculations, usually based on the free electron approximation, can be easy to interpret and give insight into the important mechanisms, but many important details, related to neglecting the appropriate band structure, are not included. First-principles calculations implicitly include many of these details, but extracting underlying mechanisms from the results can be difficult. It can be quite useful to combine the best of both approaches and carry out first-principles calculations of the band-structure-related details used in model calculations. Among such details, spin-dependent transmission and reflection probabilities, particularly those for Fermi surface electrons, play an important role in both the GMR and the oscillatory exchange coupling.

Here, I present first-principles calculations of the spin-dependent transmission and reflection probabilities for the (001) interfaces of Ag/Fe, and Au/Fe and the (001), (111), and (110) interfaces of Cu/Co and Cu/Ni. I discuss the implications of the results for the transport properties of these systems and compute the strengths of the oscillatory exchange coupling.

II. TRANSMISSION AND REFLECTION PROBABILITIES

In structures in which there is a single interface between two materials, an electron propagating toward the interface can either transmit or reflect. If the interface is coherent, that is, the two materials are well lattice matched, then the momentum parallel to the interface is conserved during transmission and reflection. Far enough from the interface, the time-independent scattering states for this process consist of linear combinations of bulk Bloch states. On one side of the interface, they each consist of one Bloch state propagating toward the interface plus one or more reflected Bloch states propagating away from the interface, and on the other side, they consist of zero or more transmitted Bloch states propagating away from the interface. Close to the interface, the scattering states consist of these Bloch states plus evanescent contributions that decay exponentially with distance from the interface. The transmission and reflection probabilities are just the flux in the transmitted and reflected Bloch states divided by the flux in the incident Bloch state. The two probabilities sum to one.

The calculation[4] of the time-independent scattering states starts by breaking space up into layers. The potential is computed for each layer from a bulk electronic structure calculation (a linearized-augmented-plane-wave implementation of the local spin-density approximation). Generalized Bloch states for a layer are computed from the potential in the layer. Generalized Bloch states are related to Bloch states by allowing the component of the wave vector normal to the interface to be complex. They form a complete set of states,

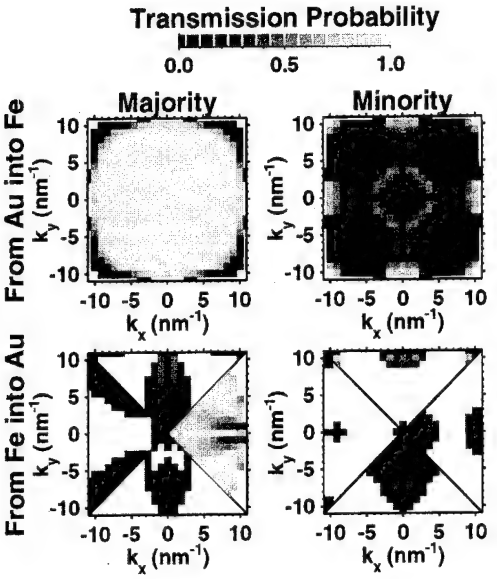

FIG. 1. Spin-dependent transmission probabilities for Au/Fe(001). The transmission probabilities are shown for various points on the Fermi surface projected onto the interface Brillouin zone. The gray scale for the transmission probability is at the top. The top (bottom) two panels show the transmission for electrons from the Au (Fe) into the Fe (Au). The two right (left) panels show the transmission probabilites for the minority (majority) electrons.

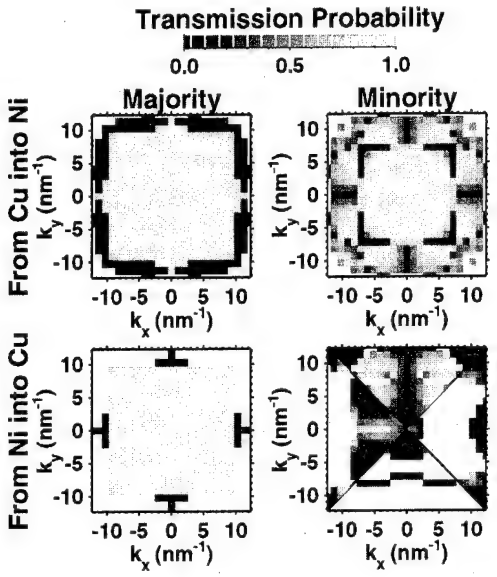

FIG. 3. Spin-dependent transmission probabilities for Cu/Ni(001). See Fig. 1.

which includes the usual Bloch states and all evanescent states, and consequently describe any time-independent solution of Schrödinger's equation for arbitrary boundary conditions. The generalized Bloch states for the two materials are matched together across the interface to construct the electron scattering states, giving the reflection and transmission amplitudes directly.

The calculations for Cu/Ni and Cu/Co, where the Co is face-centered cubic, use the bulk lattice constant of Cu for both materials. Face-centered cubic Ag and Au are quite well lattice matched with body-centered cubic Fe is the (001) planes are rotated 45° with respect to each other. The calculations for Au/Fe and Ag/Fe use the bulk lattice constant for Fe and a very slight tetragonal distortion, based on their bulk elastic constants, for Au and Ag.

Figures 1–4 show the transmission probabilities across interfaces between these pairs of materials calculated for states on the Fermi surfaces of both materials. The Fermi surfaces are shaded according to the transmission probability for each state, and then they are projected into the interface Brillouin zone. For simple Fermi surfaces and certain interface orientations, there is only one state moving toward the interface at each parallel wave vector. Grouped together, these states form a sheet of the Fermi surface. For the interfaces with only one sheet of states moving toward the interface, that sheet is shown in the whole interface Brillouin

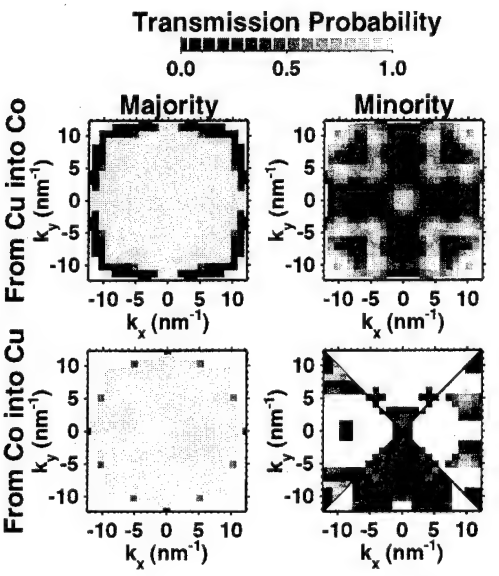

FIG. 2. Spin-dependent transmission probabilities for Cu/Co(001). See Fig. 1.

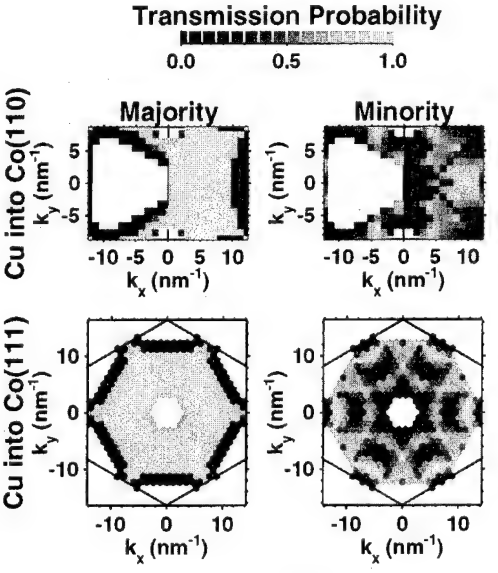

FIG. 4. Spin-dependent transmission probabilities for Cu/Co(110) and Cu/Co(111). See Fig. 1.

TABLE I. Transmission probabilities averaged over the Fermi surface.

	Into		From	
	minority	majority	minority	majority
Ag/Fe(001)	0.16	0.86	0.14	0.36
Au/Fe(001)	0.17	0.84	0.16	0.37
Cu/Co(001)	0.49	0.79	0.27	0.95
Cu/Co(111)	0.54	0.73	0.33	0.94
Cu/Co(110)	0.44	0.66	0.29	0.92
Cu/Ni(001)	0.72	0.73	0.33	0.93
Cu/Ni(111)	0.80	0.67	0.38	0.92
Cu/Ni(110)	0.62	0.63	0.31	0.60

zone. For other interface orientations, or for complicated Fermi surfaces, the Fermi surface has several sheets. That is, at some parallel wave vectors there is more than one state moving toward the interface. For Fe, minority Co and Ni, Cu(110), and majority Co(110), each sheet is shown in a fraction of the Brillouin zone. The behavior over the full Fermi surface is found by rotating each sheet into each fraction of the Brillouin zone and stacking the sheets on top of each other. Table I gives the average over the Fermi surface of the transmission probabilities.

Some general features of these results are straightforward to understand. For example, states reflect completely if there are no states in the other material with the same parallel momentum. In addition, the symmetry of the states is important. Fermi surface states have $s-p$ character for noble metals and majority states in Co and Ni, but they have mainly d character for minority states and Fe majority states. States with $s-p$ character tend to couple well to one another and to states with dz^2 character, but couple weakly to other d-like states. At high symmetry points, like the zone center, $\bar{\Gamma}$, these symmetry requirements become strict and some states, like the minority states in Au/Fe, reflect completely even though there are states with the same parallel wave vector.

Au/Fe (Fig. 1) and Ag/Fe (similar, but not shown) both show very good transmission into the majority states of Fe and poor transmission into the minority states. In the reverse direction the difference is much smaller, because there are many majority states that have very small transmission probabilities. These systems contain minority electrons that are largely confined to each separate material, majority electrons that transmit freely between them, and majority electrons confined to the ferromagnetic material.

The potentials in Cu are very similar to the potentials for the majority electrons in Co and Ni, but significantly different from those for the minority. This spin dependence leads to strongly spin-dependent scattering from substitutional impurities in these systems,[5,6] and strongly spin-dependent transmission across interfaces, Figs. 2–4. The majority Fermi surfaces in Co and Ni are similar to the Fermi surfaces in Cu, but are smaller. The similarities lead to almost complete transmission from the majority states in the ferromagnet into the nonmagnetic material, but the smaller sizes lead to complete reflection for the states in Cu with group velocities parallel to the interface. The transmission from Cu into minority states is not simply characterized. Some electrons transmit well, some completely reflect, but most exhibit intermediate behavior. The complicated behavior arises from the complicated nature of the minority Fermi surfaces of Co and Ni. Overall, the results do not vary much with interface orientation. It seems likely that transport calculations, which average in some way over all of the states, will have only a weak orientation dependence.

These transmission probabilities can be contrasted with those from free electron approximations. Projecting spherical free-electron Fermi surfaces on to the interface Brillouin zone gives circles of different radii. States with parallel wave vectors less than the Fermi wave vectors of the materials on either side of the interface transmit well. When the parallel wave vector becomes close to the smaller of the two Fermi wave vectors, the transmission goes to zero, and reflection is complete for states with a parallel wave vector greater than the smaller Fermi wave vector. This free electron behavior is a reasonable description of the behavior for the majority states in Cu/Co and Cu/Ni, but not for the minority states, or for Au/Fe(001) or Ag/Fe(001).

III. GIANT MAGNETORESISTANCE

Strongly spin-dependent interface reflection can lead to a GMR effect even if there is no spin dependence to the defect scattering. For the case of current perpendicular to the interfaces, a contribution to the GMR comes from the spin dependence of the resistance associated with each interface. For current flow parallel to the interface there is no resistance associated with reflection. However, if the defect scattering rates are different in the ferromagnetic layers and nonmagnetic layers, spin-dependent interface reflection will still contribute to the GMR as discussed below.

GMR is usually observed in samples in which the elastic mean free paths and the thicknesses of the layers are comparable and both lengths are much less than the spin diffusion length. The essential physics is most easily understood from semiclassical calculations, which are valid when the layer thicknesses are much greater than the mean free paths. Here, I discuss GMR from such a semiclassical perspective, and note some corrections that are a consequence of the mean free paths being comparable to the thicknesses. I also assume that the spin diffusion length is infinite. Throughout this discussion, GMR is caused by a short circuit effect. When the magnetizations are antiparallel, electrons of both spins have the same average resistance. When the magnetizations are parallel, electrons of one spin have a higher resistance and those of the other a lower resistance. The electrons with the lower resistance carry more of the current, lowering the resistance of both spins taken together. Thus the resistance of the structure is lower than the magnetizations are parallel.

Current flow perpendicular to interfaces that reflect electrons requires that there be a chemical potential difference across the interface, even if there is no defect scattering at the interface.[7] For interface separated by much more than the mean free path, the amount of current crossing the interface is proportional to the chemical potential difference across the interface. This proportionality means that there is a resistance associated with each interface even if the momentum randomization occurs elsewhere in the sample. This resis-

tance is independent of the separation of the interfaces and the bulk scattering rates, provided the interfaces are sufficiently far apart.

If the reflection probability is spin dependent, the resistance of the interface is also. Thus, if electrons of only one spin transmit freely through all the interfaces in the structure, those electrons will have a lower resistance when the magnetizations in the ferromagnetic layers are parallel. They cause the short circuit effect that gives the GMR. The interface resistance is dominated by electrons moving perpendicular to the interface; these tend to be close to the zone center. It is clear from Figs. 1 and 2 that this effect will give a large contribution to the GMR for Au/Fe(001), Ag/Fe(001), and Cu/Co(001), but from Fig. 3 it will be much smaller for Cu/Ni(001). For most of these systems, the spin dependence of the interface resistance is much greater than it would be in free electron models. In those models, the electrons close to the zone center reflect only weakly from both the majority and the minority states and do not contribute to the GMR.

When the separation between interfaces becomes comparable to the mean free path in the material between them, interference between electrons reflecting from different interfaces modifies the transport so that the interface resistance is no longer associated with a single interface. For periodic interfaces closer than a mean free path, the Bloch states of the superlattice become the appropriate basis for treating the scattering. In this regime, which has been used in all first-principles calculations to date,[5,6,8] the contribution to the resistance from the interfaces becomes obscured, but is still present.

The electronic structure of multilayers and superlattices can be constructed piecewise from the electronic structures of the bulk materials and the interface reflection amplitudes.[9] Such a construction allows the electronic structure of multilayers and superlattices to be understood in terms of these simpler parts. Where the reflection probability is small, the states tend to propagate readily through the whole structure, but when the reflection probabilities are large, the states tend to localize in one material. In superlattices, reflection from the interfaces produces gaps in the Fermi surface of the superlattice. When states are freely propagating through the superlattice, these gaps are small, but when the states are localized the gaps become large. The results shown in Fig. 2 explain the spin-dependent gaps found for Cu/Co(001) superlattices.[10] That calculation shows that even when there is no defect scattering, this spin dependence leads to a GMR effect in a point contact.[10]

For current parallel to the interface, "channeling" can make an important contribution to the GMR, as seen in studies based on free-electron models.[11] Channeling occurs for any multilayer in each layer in which electrons are strongly reflected from both its interfaces. If the scattering rate in that layer is lower than it is in neighboring layers, electrons in that layer which strongly reflect see a lower effective scattering rate than they would in the absence of reflection. In magnetic multilayers, channeling contributes to the GMR only for parallel wave vectors for which there is strong reflection for one spin, but not the other. In this case, channeling does not occur for electrons of either spin in antiferromagnetic alignment because both transmit through one or the other interface. On the other hand, for ferromagnetic alignment, electrons of one spin are confined to the layer, and if that layer has a lower scattering rate, these electrons cause a short circuit effect, giving a GMR.

In the Cu/Co and Cu/Ni systems, the electrons in Cu with the largest velocities parallel to the interfaces reflect completely from the majority states due to the mismatch in the Fermi surfaces. Since the same states transmit well into the minority states, channeling by these electrons will give a large contribution to the GMR if the scattering rate in Cu is much smaller than it is in Co. Closer to, but not at, the zone center, there are additional channeling contributions to the GMR from states that are strongly reflected from the Co minority states, but are readily transmitted into the Co majority states.

Free electron models will not correctly describe these channeling effects. In free electron models, the minority Fermi surface is smaller than the majority Fermi surface. Thus, the electrons in Cu with the largest velocities parallel to the interfaces will reflect completely from both the majority and the minority states and not contribute to the GMR. On the other hand, there will be a contribution, not found in the present results, from electrons with parallel wave vectors between the majority and minority Fermi wave vectors. Finally, free electron models will not include the contribution for electrons closer to the zone center found in the present results.

For the Au/Fe(001) and Ag/Fe(001), the difference in reflectivity is so large over the Fermi surface that channeling will be a very big effect, even though the electrons in the noble metal that are moving parallel to the interface reflect strongly from both majority and minority states and do not give a channeling contribution to the GMR.

There is an additional interface contribution to the GMR for parallel transport in supercell calculations.[8,10] Here, the group velocities of the states at the Fermi surface *of the supercell* are modified by the multiple reflection at the interfaces. This effect is related to the gaps in superlattice Fermi surfaces discussed above. The different group velocities at the spin-dependent Fermi surfaces in different configurations lead to a GMR.

The results presented there make it clear that free-electron models will not accurately predict the size of either the interface resistance or the channeling effect. Free electron descriptions are reasonable only for majority electrons in Cu/Co and Cu/Ni, but the contribution to the GMR depends on the difference in reflection between majority and minority systems.

IV. OSCILLATORY EXCHANGE COUPLING

The exchange coupling between ferromagnetic layers separated by nonmagnetic spacer layers is a product of geometrical properties of the Fermi surface of the spacer layer material and the reflection amplitudes from the interfaces.[12,13] There are oscillatory contributions to the coupling from parallel wave vectors where two sheets of the Fermi surface are parallel to each other and have opposite group velocities in the interface direction. For large spacer

TABLE II. Coupling strength due to various stationary points on the spacer layer Fermi surfaces, see Eq. (1).

Interface	k_x (nm^{-1})	k_y (nm^{-1})	Period (nm)	Period (layers)	$J^\alpha/(1.0\ nm)^2$ (mJ/m^2)

layer thicknesses, D, each of these critical spanning vectors, indexed by α, makes a contribution, J^α of the form

$$\frac{J^\alpha}{D^2}\sin(q_\perp^\alpha D+\phi^\alpha)=\frac{\hbar v_\perp^\alpha \kappa^\alpha}{4\pi^2 D^2}\,\mathrm{Im}[\Delta r_A^\alpha \Delta r_B^\alpha e^{iq_\perp^\alpha D}e^{i\chi^\alpha}], \tag{1}$$

where $v_\perp^\alpha$ is the component of the effective group velocity in the interface direction, κ^α is the radius of curvature of the Fermi surface, $\Delta r_{A(B)}^\alpha$ is the spin difference in the reflection amplitude for the left (right) interface, $q_\perp^\alpha$ is the critical spanning vector, which determines the period of the oscillation $L^\alpha=2\pi/q_\perp^\alpha$, χ^α is a phase from the type of critical point (maximum, minimum, saddle point), and ϕ^α is the resulting phase. (The reflection amplitudes are complex.)[14] Table II gives the coupling strengths for all of the critical points for these systems. These critical points are the same as those identified from experimental Fermi surfaces by Bruno and Chappert.[15]

For Ag/Fe and Au/Fe the critical point at $\bar{\Gamma}$ (the interface zone center) gives a long-period oscillation. Here the reflection probability for the minority spins is exactly one and for the majority spins it is close to zero. The other critical points, along the $\bar{\Delta}$ line close to the zone boundary, produce a short-period oscillation. At these points, the reflection probability is increasing rapidly as a function of parallel wave vector for the majority states and decreasing rapidly for the minority states. These rapid changes lead to a large uncertainty in the coupling strengths for these critical points. For Au/Fe, the ratio of the strengths for the two periods happens to be close to the experimentally determined ratio of 2.1,[16] but for Ag/Fe the ratio is very far from the experimental ratio of 1.0.[17] All the coupling strengths are roughly an order of magnitude larger than measured values.[18]

The Cu/Co systems have been extensively studied experimentally[19] and theoretically.[20–24] Previous theoretical results are similar to the results found here. For the (001) interface, the critical points along $\bar{\Delta}$ give a strong short-period oscillation and the critical point at $\bar{\Gamma}$ gives a long-period oscillation that is weak because both spins reflect weakly. For the (111) interface the critical points at the necks along the zone boundary give strong coupling. For the (110) interface, there are four critical spanning vectors, including one at the zone boundary which gives a strong long-period oscillation and one at $\bar{\Gamma}$ which gives an extremely strong short-period oscillation. The Cu/Ni systems have received much less attention. The differences in coupling strength compared to Cu/Co are due to the differences in reflection amplitudes.

As was the case for the Au/Fe and Ag/Fe systems, the calculated coupling strengths for Cu/Co are much stronger than those measured experimentally. In my opinion, the difference results from calculations being done for ideal interfaces while measurements are made on systems with interdiffusion and steps and other defects at the interfaces. Interface defects reduce reflection amplitudes by scattering electrons into all parallel wave vectors. Reduced reflection amplitudes lead to reduced coupling strengths. The experimental determination of the structural properties of the interfaces will allow a more detailed comparison between theory and experiment.

The major source of error in this work is the deviation of the Fermi surfaces calculated in the local spin-density approximation from the actual Fermi surfaces. Comparing predicted periods with those found from the measured Fermi surfaces[15] gives an estimate of this error. Differences range up to ±20%. Lee and Chang[23] compute coupling strengths for Cu/Co using empirical tight binding and Eq. (1). Since they fit their band structures for Cu to de Haas–van Alphen data, the contributions to the coupling from the geometrical factors are more accurate in their calculations. On the other hand, the reflection probabilities, which they calculate in a parametrized tight-binding approach, are less reliable. Their results disagree with the present calculations by up to a factor of 2. A less significant source of error in this work is the neglect of self-consistency in the interface potential. Experience[4] suggest that introducing a self-consistent potential leads to only small changes in the reflection and transmission amplitudes.

V. SUMMARY

First-principles calculations of transmission and reflection from Ag/Fe, Au/Fe, Cu/Co, and Cu/Ni interfaces show very strong spin dependence. The behavior of the spin-dependent transmission and reflection probabilities is significantly more complicated than expected from free electron models. The complications arise because many of the relevant Fermi surfaces are significantly more complicated than spheres. The spin-dependence of the reflection from interfaces is enough to give a large GMR even if there is no spin-dependent defect scattering. For perpendicular transport, it leads to a spin-dependent resistance associated with each interface. For parallel transport, it leads to channeling, which gives a GMR if the scattering rates are different in the two materials. The calculated reflection amplitudes predict strengths of the oscillatory exchange coupling which are

much greater than those observed experimentally. This disagreement is probably due to the assumed perfection of the interfaces.

How predictable is the current perpendicular to plane magnetoresistance? (invited)

W. P. Pratt, Jr., Q. Yang, L. L. Henry, P. Holody, W.-C. Chiang, P. A. Schroeder, and J. Bass

Prior measurements of the current perpendicular to the layer planes (CPP) resistances, taken on Co/Cu/Py/Cu (Py=$Ni_{84}Fe_{16}$) multilayers with a single pair of Co and Py thicknesses, are extended to three additional pairs of thicknesses. The same parameters, obtained from independent measurements on Co/Cu and Py/Cu multilayers that fit the original pair reasonably well, fit the three new pairs almost as well, from which we conclude that there is substantial predictability in the CPP magnetoresistance (MR). Because the predictability is not perfect, we examine the extent to which we can improve the fits to the Co/Cu/Py/Cu data by varying the Py/Cu and Co/Cu parameters within their uncertainties, without substantially weakening the fits to the original Co/Cu and Py/Cu data. We conclude by presenting the first CPP-MR measurements on Co/Ag/Py/Ag multilayers. The data are similar to those for Co/Cu/Py/Cu multilayers, but the Co/Ag/Py/Ag MRs are noticeably larger.

I. INTRODUCTION

For both scientific and technological reasons, the giant (G) magnetoresistance (MR) in magnetic multilayers consisting of alternating layers of ferromagnetic (F) and nonmagnetic (N) metals continues to be a topic of great interest.[1,2] Since tailoring of F/N systems for specific uses will likely require new combinations of F and N elements, one major goal of GMR studies is to be able to predict the behavior of samples involving these new combinations, using parameters derived from old ones. The fundamental parameters are those that characterize the magnitude and spin asymmetry of electron scattering in the bulk of the F metal and at the F/N interfaces.[2–5]

In the present paper, we extend a prior test,[6,7] of the predictability at 4.2 K of the current perpendicular to the layer planes (CPP)[8] specific resistances, AR_t (area A times total resistance R_t), of three-component Co/Cu/Py/Cu multilayers using parameters determined without adjustment from measurements of the two-component multilayers Co/Cu[9,10] and Py/Cu[10,11] (Py=$Ni_{84}Fe_{16}$).

Quantitative tests of predictability are easier in the CPP geometry than in the usual geometry with current in the layer planes (CIP),[2] because the analytical expressions are much simpler. We have shown that the CPP AR_ts at 4.2 K of Co/Ag,[3,12] Co/Cu,[9,10] and Py/Cu[10,11] multilayers can be described rather well by a phenomenological two-current, series-resistor model,[3,10–12] that has now been well validated theoretically[4,13,14] in the experimentally relevant limit where the electron spin-flip diffusion length is much larger than the F and N metal layer thicknesses, t_F and t_N. Electrons in the multilayer can then be divided into two classes that do not mix–spin up (+) and spin down (−) relative to the direction of the applied magnetic field H. $AR(\pm)$ for each spin direction is then the series sum over the multilayer of the ARs of all the interfaces and the resistivities times layer thicknesses of all the layers. AR_t is simply the parallel combination of $AR(+)$ and $AR(-)$.[3,4,13] The equivalent expressions for the CIP geometry are much more complex; in addition to parameters like those for the CPP ARs, they also contain exponential factors involving ratios of the electron mean-free paths in given layers to the layer thicknesses.[5]

The standard models of GMR[2,5] assume that the reduction in resistance as the magnetic field H increases is due to a field-induced reorientation of the magnetizations M_i of adjacent F layers, from an antiparallel (AP) alignment (total magnetization $M=0$) at small H to a parallel (P) alignment (maximum M) at large H. We thus want to measure AR_t(AP) and AR_t(P). However, most two-component F/N multilayer systems exhibit a complete AP state—if at all—only when the exchange coupling between adjacent F layers is strongly antiferromagnetic (af) in zero field; and, unfortunately, such strong af coupling occurs only at a single value of t_N for fixed t_F.[15] To extract the parameters of interest from our simple model, we need to use a range of t_F and t_N values, and we need for each t_F and t_N pair an AR_t that approximates well that for a true AP state. We have argued elsewhere[3,9,16] that the AR_t values for our virgin, as-sputtered samples (a state designated by H_0) approximate well those of the AP state, so long as t_N is large enough to magnetically decouple the F layers. This H_0 state was used to fix the Co/Cu and Py/Cu parameters for our analysis. For these decoupled F layers, the P state is attained when H exceeds H_s, the field at which the M_is of the F-layers saturate.

A positive feature of our three-component Co/Cu/Py/Cu multilayers is that there is a large difference in H_s between sputtered Co ($H_s^{Co} \approx 200$ Oe) and Py ($H_s^{Py} \leqslant 10$ Oe). This naturally leads to a closely AP alignment of the M_i for the Co and Py layers when H (applied parallel to the layers) is taken from above $+ H_s^{Co}$ to just below $- H_s^{Py}$.

We recently showed[6,7] that AR_t(AP) and AR_t(P) for a set of Co/Cu/Py/Cu multilayers with $t_{Co}=3$ nm, $t_{Py}=8$ nm, and $t_{Cu}=20$ nm (large enough to magnetically decouple the Co and Py layers) could be reasonably well described by parameters previously determined from independent measurements of the AR_ts at H_0 and H_s for Co/Cu and Py/Cu. These values of t_{Co} and t_{Py} were chosen to give nearly equal layer magnetizations (i.e., total magnetization $M \approx 0$ for AP Co and Py magnetization alignment) and to be comparable to those in the Co/Cu and Py/Cu multilayers from which the parameters

of interest were derived.[9–11] This agreement supported our argument that $AR_t(H_0)$ is close to AR_t(AP) for our Co/Cu and Py/Cu multilayers.

This agreement, however, was not perfect in that the difference $[AR_t(\mathrm{AP})-AR_t(\mathrm{P})]$ was about 20% larger than that predicted by the previously determined parameters. We argued that such a modest difference was reasonable, given that we had no adjustable parameters and also required all common parameters (ρ_{Cu} appears in all three sets, and most other parameters in two) to be the same for data sets taken years apart. In fact, those parameters that could be independently measured (ρ_{Cu}, ρ_{Co}, and ρ_{Py}) were found to be slightly different (compare columns 3 and 4 of Table I).

In the present paper we further test the CPP predictability.

First, we extend the measurements of the Co/Cu/Py/Cu AR_ts in two directions: (a) to a Co-Py pair where $M\approx 0$ in the AP state, but t_{Co} and t_{Py} are twice as large as in the prior fits, and (b) to two Co-Py pairs where t_{Co} and t_{Py} are closer to those used in the prior fits, but $M\neq 0$ in the AP state. The unadjusted parameters continue to predict AR_t(AP) and AR_t(P) for the new samples reasonably well, but also underestimate $[AR_t(\mathrm{AP})-AR_t(\mathrm{P})]$ now by 25–35%.

Second, we examine whether, by modifying the Co/Cu and Py/Cu parameters within their uncertainties, we can improve our fits to the Co/Cu/Py/Cu data, without excessively weakening those to the original Co/Cu and Py/Cu data.

Third, to test the sensitivity of the MRs of the three-component systems to the N-metal component, we measure, for the first time, the MRs of a set of Co/Ag/Py/Ag multilayers. We find MRs larger than those for Co/Cu/Py/Cu with the same nominal layer thicknesses.

II. SAMPLE PREPARATION

Our Co/Cu/Py/Cu multilayers were sputtered onto sapphire substrates in an ultrahigh-vacuum compatible, four-target system, using preparation conditions and procedures already described.[17] The base pressure before sputtering was $\leq 2\times 10^{-8}$ Torr; the sputtering pressure was held constant at $\approx$2.5 mTorr, and the sputtering rates were all $\approx$1 nm/s.[18] We used an *in situ* mask changing system[18] to fabricate the crossed-superconducting-strip geometry described elsewhere,[17] where the multilayer of interest is sandwiched between two $\approx$1.1-mm-wide, 300-nm-thick Nb strips, deposited at right angles to each other, that serve as both current and voltage leads. At the measuring temperature of 4.2 K, the Nb strips superconduct, becoming equipotential contacts, thereby ensuring that a uniform current passes through the overlap areas of the strips, $A\approx 1.25$ mm^2. To avoid proximity effects in the Cu layers, the first and last layers are Co at least 3 nm thick.[19] A sample thus consists of two Nb strips, the multilayer, and a "cap" Co layer just below the top Nb strip. In the CPP geometry, we measure the specific resistance AR_t, the overlap area A of the Nb strips times the voltage across the sample divided by the current through it. The measuring current was held constant at 50 mA, and the resistances of the reported samples were all current independent. The measuring system was the same as that already described.[17]

III. TWO-CURRENT MODEL

The two-current, series resistor model used here assumes that the electrons in the spin-up and spin-down channels are independent in that they do not flip their spins or mix. For $T=4.2$ K and N layers that are free of magnetic impurities and strong spin-orbit scatterers,[20] the assumed independence of the currents is a good approximation. For each spin channel the AR is a series sum of layer resistivities times layer thicknesses and the ARs for each interface. AR_t is then just the parallel combination of the ARs for each channel.[3] Using the notation of Valet and Fert[4] for a simple F/N multilayer, we denote the F-metal resistivities as $\rho^{\uparrow}_F(\rho^{\downarrow}_F)$ for electron

spin parallel (antiparallel) to the local F-layer M_i, and F/N interface resistance as $R^{\uparrow}_{F/N}(R^{\downarrow}_{F/N})$. The Nb/F interface resistances and the N-layer resistivities are assumed to be spin independent. That is, $R^{\uparrow}_{Nb/F}=R^{\downarrow}_{Nb/F}=2R_{Nb/F}$, and $\rho^{\uparrow}_N=\rho^{\downarrow}_N=2\rho_N$. We make these definitions: $\rho^{\uparrow(\downarrow)}_F=2\rho^*_F[1-(+)\beta]=2\rho_F/[1+(-)\beta]$ and $R^{\uparrow(\downarrow)}_{F/N}=2R^*_{F/N}[1-(+)\gamma]=2R_{F/N}/[1+(-)\gamma]$. For a thick F film, ρ_F would be its bulk resistivity. For the simple F/N multilayer, we obtain that the six fitting parameters of the two-current-model equations are the following: $2AR_{Nb/F}$, ρ_N, $\rho^*_F=\rho_F/(1-\beta^2)$, $AR^*_{F/N}=(AR_{F/N})/(1-\gamma^2)$, β, and γ. A constrained set of these parameters, derived from measurements on Co/Cu and Py/Cu samples, is presented in column 1 of Table I.[6]

For the more complex multilayer consisting of N[Co/Cu/Py/Cu] quadrilayers, the ARs for the up (+) and down (−) spin channels in the AP state are

$$AR^{AP(+)}=4AR_{Nb/Co}+4N\rho_{Cu}t_{Cu}+(N+1)\rho^{\uparrow}_{Co}t_{Co}+2NAR^{\uparrow}_{Co/Cu}+N\rho^{\downarrow}_{Py}t_{Py}+2NAR^{\downarrow}_{Py/Cu}, \quad (1)$$

$$AR^{AP(-)}=4AR_{Nb/Co}+4N\rho_{Cu}t_{Cu}+(N+1)\rho^{\downarrow}_{Co}t_{Co}+2NAR^{\downarrow}_{Co/Cu}+N\rho^{\uparrow}_{Py}t_{Py}+2NAR^{\uparrow}_{Py/Cu}. \quad (2)$$

AR^{AP}_t is then obtained by adding $AR^{AP(+)}$ and $AR^{AP(-)}$ in parallel, and the dependence of AR^{AP}_t on parameters ρ^*_{Co}, ρ^*_{Py}, β_{Co}, β_{Py}, $AR^*_{Co/Cu}$, $AR^*_{Py/Cu}$, $\gamma_{Co/Cu}$, and $\gamma_{Py/Cu}$ can be obtained by substituting in the above definitions. Here, unlike the simple F/N multilayer, we have $AR^{AP(+)}\neq AR^{AP(-)}$. For the P state, $AR^{P(+)}$ and $AR^{P(-)}$ will have only ↑ and ↓ terms, respectively, and then are combined in parallel to produce AR^P_t.

IV. DATA AND ANALYSIS

For most of the samples in this paper, the Cu layer thickness is held fixed at $t_{Cu}=20$ nm, a value that our previous data indicate[3,7–9,16] should be large enough to magnetically decouple the Co and Py layers. As mentioned earlier, because $H^{Co}_s \gg H^{Py}_s$, an AP alignment of M_i for the Co and Py layers should naturally occur when H is taken from above $+H^{Co}_s$ to slightly less than $-H^{Py}_s$. This formation of the AP state is illustrated in Fig. 1(a) for a Co/Cu/Py/Cu sample with t_{Co} and t_{Py} chosen so that $M\approx 0$ for the AP state. Indeed as H decreases toward −10 Oe, M rapidly decreases to zero as the M_i's of Py layers reverse. Thereafter M decreases more slowly, as the Co layers reorient over a larger field range. The behavior of M for this sample is very similar to that of the Co/Cu/Py/Cu sample shown in Fig. 2 of Ref. 6, where t_{Co} and t_{Py} were half those of the sample in Fig. 1. The main difference is that H^{Co}_s is somewhat smaller in the present sample due to its thicker Co layers. Figure 1(b) shows that AR_t rises rapidly over the same small field range (where M drops sharply), reaches a peak value, and then falls slowly along with M. For AP alignment, we choose AR_t(AP) at the peak of the curve in Fig. 1(b). For P alignment of the Co and Py magnetizations, AR_t(P) is measured at $H > H^{Co}_s$.

Figures 2 and 3 show AR_t(AP) and AR_t(P) versus quadrilayer number N for our published set[6,7] of Co/Cu/Py/Cu

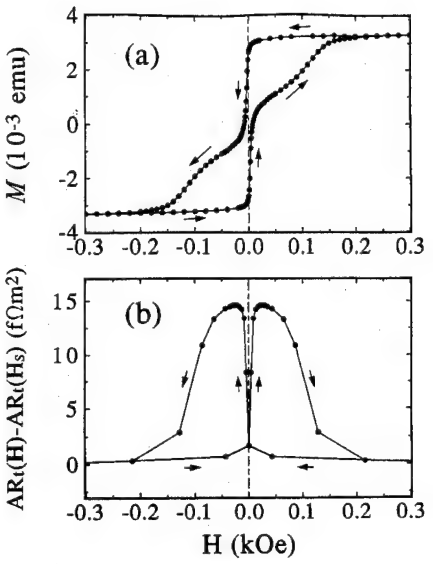

FIG. 1. (a) $M(H)$ vs H for a [Co(6 nm)/Cu(20 nm)/Py(16 nm)/Cu(20 nm)]$_8$ multilayer. (b) $[AR_t(H)-AR_t(H_s)]$ vs H for the same multilayer.

samples [Fig. 2(b)] and for three new sets of data [Figs. 2(a), 3(a), and 3(b)]. As shown in Fig. 2, changing t_N to 10 or 40 nm (+ and × symbols, respectively) does not significantly change the data. The no-free-parameter predictions, AR^{AP}_t and AR^P_t, from the independently derived parameters for Co/Cu and Py/Cu listed in column 1 of Table I, are shown as solid curves. The predictions fit all of the data reasonably well, but not perfectly. Figure 4 shows that for these column 1 parameters the quantity $[AR_t(AP)-AR_t(P)]/[AR^{AP}_t - AR^P_t]$, the ratio of the measured difference to the

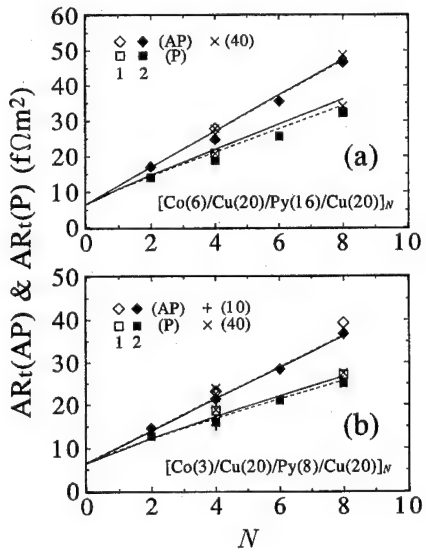

FIG. 2. AR_t(AP) and AR_t(P) vs quadrilayer number N for multilayers of (a) [Co(6 nm)/Cu(20 nm)/Py(16 nm)/Cu(20 nm)]$_N$ and (b) [Co(3 nm)/Cu(20 nm)/Py(8 nm)/Cu(20 nm)]$_N$ with nearly equal magnetizations in the Co and Py layers. Open and filled symbols refer to samples made in differing sputtering runs. The + and × symbols are for $t_{Cu}=10$ and 40 nm, respectively. The solid curves are predicted from the independently determined parameters listed in column 1 of Table I. The dashed curves are determined by the parameters in column 2 of Table I.

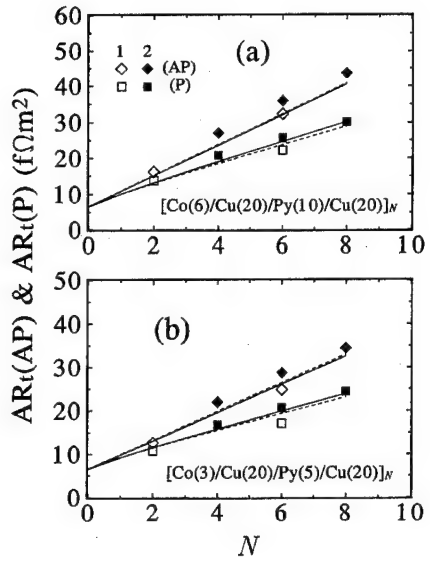

FIG. 3. AR_t(AP) and AR_t(P) vs quadrilayer number N for multilayers of (a) [Co(6 nm)/Cu(20 nm)/Py(10 nm)/Cu(20 nm)]$_N$ and (b) [Co(3 nm)/Cu(20 nm)/Py(5 nm)/Cu(20 nm)]$_N$ with different magnetizations in the Co and Py layers. Open and filled symbols refer to samples made in different sputtering runs. The solid curves are predicted from the independently determined parameters listed in column 1 of Table I. The dashed curves are determined by the parameters in column 2.

predicted one, averages about 1.3 (open symbols), with the ratios for the newer samples [Figs. 4(a)–4(c)] being a bit larger than for the old ones [Fig. 4(d)].

This systematic discrepancy between measurement and prediction led us to ask how much we could improve the fits in Figs. 2–4, within the uncertainties of the parameters in

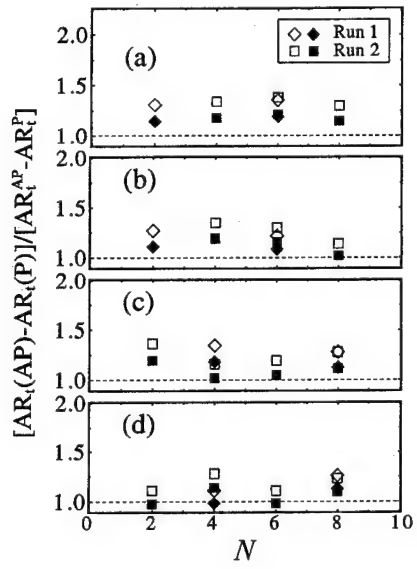

FIG. 4. $[AR_t(\mathrm{AP})-AR_t(\mathrm{P})]/[AR_t^{\mathrm{AP}}-AR_t^{\mathrm{P}}]$ vs N for all four data sets. Open symbols are for AR_t^{AP} and AR_t^{P} values determined from the parameters in column 1 of Table I. Filled symbols are determined from column 2 of Table I. (a) [Co(6 nm)/Cu(20 nm)/Py(10 nm)/Cu(20 nm)]$_N$, (b) [Co(3 nm)/Cu(20 nm)/Py(5 nm)/Cu(20 nm)]$_N$, (c) [Co(6 nm)/Cu(20 nm)/Py(16 nm)/Cu(20 nm)]$_N$, and (d) [Co(3 nm)/Cu(20 nm)/Py(8 nm)/Cu(20 nm)]$_N$.

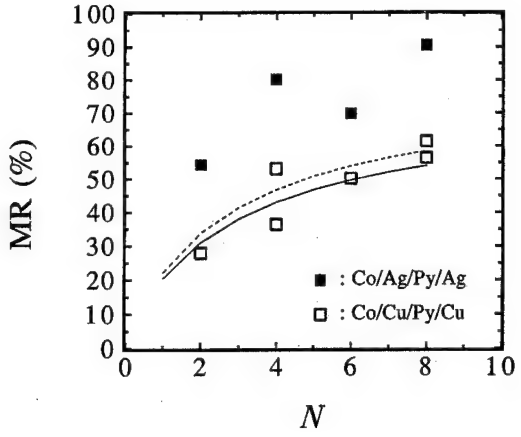

FIG. 5. Comparison of corrected MR vs N for [Co(3 nm)/Ag(20 nm)/Py(8 nm)/Ag(20 nm)]$_N$ and [Co(3 nm)/Cu(20 nm)/Py(8 nm)/Cu(20 nm)]$_N$ multilayers. Solid curve is determined from parameters in column 2 of Table I. The dashed curve is produced by replacing Co/Cu parameters in column 2 by Co/Ag ones.

column 1 of Table I. In previous papers,[6,7] we noted that the ratios in Fig. 4(d) could be reduced to about 1.1 by increasing ρ_{Py}^{*}, β_{Co}, and β_{Py}, well within their uncertainties, without excessively degrading the fits to the original Co/Cu and Py/Cu data. Those same parameters only reduced the average ratio for all of the samples in Fig. 4 to about 1.2. We thus searched for a set of parameters giving a better fit to all of our data, using the ratios in Fig. 4 (which emphasize the difference $[AR_t(\mathrm{AP})-AR_t(\mathrm{P})]$) as a guide for improving the fit to the Co/Cu/Py/Cu data. Such a set is given in column 2 of Table I. This new parameter set gives an average ratio for all four data sets that is now very close to 1.1 and is shown as filled symbols in Fig. 4. The fits of these column 2 parameters to the Co/Cu/Py/Cu AR_ts are shown as dashed curves in Fig. 2 and 3 and are better (smaller total χ^2) than those for the column 1 parameters. The parameters of column 2 lie within—usually well within—the uncertainties of the nonadjusted ones of columns 1, and only modestly degrade the fits to the original Co/Cu and Py/Cu data.[21]

Lastly, we recently started to examine the behavior of Co/Ag/Py/Ag multilayers with layer thicknesses similar to those for the Co/Cu/Py/Cu multilayers described above. We will show elsewhere that the M_s and AR_ts for these multilayers look very similar to those in Figs. 1 and 2.[21] Here, we focus upon the relative MRs of the two different systems. For this purpose, we compare the corrected multilayer MRs.

$$\mathrm{MR}\% = [AR_t(\mathrm{AP})-AR_t(\mathrm{P})]/[AR_t(\mathrm{P})-6.1\ \ \mathrm{f\Omega m^2}]. \tag{3}$$

In the denominator, the two Nb/Co interface resistances[22] $\sim$6.1 fΩm^2 have been subtracted from AR_t(P) to give the AR due to the multilayer alone (i.e., without the superconducting contact resistance). As shown in Fig. 5, the MRs for Co/Ag/Py/Ag are considerably larger than those for Co/Cu/Py/Cu, even though the nominal layer thicknesses are identical. The solid curve in Fig. 5 shows the computed MR for the adjusted parameters in column 2 of Table I. The dashed curve is generated by combining the column 2 parameters for

Py/Cu with the previously determined Co/Ag parameters.[3,18] The dashed curve still clearly falls below the Co/Ag/Py/Ag data. This disagreement implies that the Py/Ag parameters must be noticeably different from those for Py/Cu.

V. SUMMARY AND CONCLUSIONS

We have shown that the CPP specific resistance, AR_t, of Co/Cu/Py/Cu multilayers with four different pairs of Py and Co thicknesses can all be fit reasonably well with parameters obtained with no adjustment from independent measurements on Py/Cu and Co/Cu multilayers. Even the more challenging difference $[AR_t(\mathrm{AP})-AR_t(\mathrm{P})]$ is correctly given to within 20–35%. We have, thus, shown that the CPP-MR of a three-component system is fairly well predictable from parameters for the two-component multilayers of which it is composed. We have found also that the fit to the Co/Cu/Py/Cu data can be made better by modifying the Co/Cu and Py/Cu parameters well within their respective uncertainties, without substantially weakening the fits to the original Co/Cu and Py/Cu data. We conclude that the Co/Cu/Py/Cu, Co/Cu, and Py/Cu data are mutually consistent to within their uncertainties and reproducibilities. Lastly, we have shown that a set of Co/Ag/Py/Ag multilayers gives significantly larger MRs than those for Co/Cu/Py/Cu multilayers with identical nominal layer thicknesses, which leads us to predict that the as yet unknown CPP-MRs for uncoupled Py/Ag multilayers will be larger than those for Py/Cu.

The role of impurity scattering in Co/Cu (111) M.B.E. multilayers (abstract)

K. P. Wellock and B. J. Hickey
The Department of Physics, The University of Leeds, Leeds LS2 9JT, United Kingdom

The origin of spin-dependent scattering (sds) within magnetic/nonmagnetic systems is a controversial issue which has attracted much attention in recent years. There is now a consensus of opinion that sds is necessary for the giant magnetoresistance (GMR) and most work suggests that this scattering occurs at the interface, but the details have yet to be discovered. Numerous studies have been performed placing impurities within the multilayer and in nearly all cases a reduction in MR is observed. The only exceptions to this are the cases where magnetic impurities are used. We have observed the first enhancement of MR for the Co/Cu system using nonmagnetic impurities. In the case of a simple trilayer system up to an eightfold increase in MR is observed while for a multilayer system up to 40% increase is recorded. Impurities have been introduced during sample growth in a controlled manner using a shutter arrangement such that a direct comparison of impurity-doped and an undoped sample can be made. In previous impurity studies changes in coupling have given rise to confusing results. In order to avoid this we have used relatively thick Cu spacer layers and very small levels of impurities so that no magnetic coupling changes are induced by doping. All samples were characterized by x-ray diffraction and *in situ* RHEED where we found no evidence of structural changes induced by the Au impurities. We discuss these results in the light of current theories of spin-dependent scattering. [S0021-8979(96)60808-7]

Giant magnetoresistance multilayers of high thermal stability with thicker magnetic layers

S. A. Hossain, B. H. Pirkle, J. Yang, and M. R. Parker[a)]
The University of Alabama, MINT/MRSEC Center, P. O. Box 870209, Tuscaloosa, Alabama 35487

The problem of poor thermal stability in NiFeCo/Cu multilayers can be resolved by utilizing thicker magnetic layers than those giving optimum giant magnetoresistance (GMR), in the as-deposited state. This type of structure exhibits very little GMR in the as-deposited state, but upon appropriate post-deposition anneal, produces huge improvements in GMR magnitude and sensitivity. The described technique provides an improvement necessary for retaining the magnetic properties of the multilayers at temperatures that would be encountered in the fabrication and operation of GMR field sensors. © *1996 American Institute of Physics.* [S0021-8979(96)54608-8]

I. INTRODUCTION

A variety of multilayers with large giant magnetoresistance (GMR) values and low saturation fields have been made in these laboratories.[1,2] The poor thermal stability of these structures has, however, been a critical issue in our earlier work,[2] as well as in that of other groups.[3] High-temperature anneal causes serious degradation of the GMR magnitude and field sensitivity. GMR multilayers have been identified as long-term candidates for ultrahigh density heads in the data storage industry. Fabrication of any field-sensor microdevice would require thermal processing of materials at temperatures of 200 °C or thereabouts. No practical technique has been proposed until now to deal with this critical issue. Thermally induced reduction of GMR has been attributed to an enhanced interdiffusion at the interfaces of magnetic/nonmagnetic structures. Reasonable thermal stability has been identified in NiFeCo/Cu/Co/Cu structures[3] with, however, GMR properties worse than those of conventional NiFeCo/Cu structures. In the present study, a methodology is introduced for enhancement of the thermal characteristics of GMR multilayer films. The Cu spacer thickness is first optimized in the as-deposited state at approximately 23 Å. A corresponding optimization of magnetic layer thickness is then determined (~21 Å). Multilayers sputtered with ~21 Å magnetic layer thickness or less show good as-deposited GMR characteristics (GMR magnitude and field sensitivity), and multilayers with significantly thicker magnetic layers (>23 Å) show very poor (<2%) GMR characteristics, being dominated in the as-deposited state by positive exchange coupling. As expected, samples with NiFeCo layers of thickness <21 Å show a decrease in the GMR properties upon high-temperature anneal (>200 °C). By contrast, high temperature anneal of the samples with significantly thicker NiFeCo layers produces a marked improvement in GMR properties. This improvement appears to originate from a transformation to a minimum energy configuration in the antiferromagnetic (AFM) state at zero external field, which is induced by the high-temperature anneal. Subsequent annealing of these samples does not effect their GMR characteristics significantly. This technique, therefore, provides GMR multilayers with excellent thermal stability. The underlying mechanism(s) causing this thermal stability enhancement remain(s) unclear. It is obviously tempting to attribute the behavior described in the following sections to discontinuous multilayers of the sort normally associated with the NiFe/Ag system.[4] The experimental evidence discussing this issue is described below.

II. EXPERIMENT

Preparation conditions and experimental analysis of NiFeCo/Cu multilayers have been described in detail previously.[1,2] The GMR field sensitivity is defined as S=GMR%/FWHM of GMR field profile).

Six-bilayer (bl) structures with optimum Cu spacer thickness and various magnetic layer thicknesses (from 17 through 37 Å) have been investigated. In the as-deposited state, an optimum GMR effect occurs for a magnetic layer thickness around 21 Å. Multilayers with magnetic layers thinner than ~21 Å exhibit excellent GMR characteristics (~9% GMR, ~0.11%/Oe sensitivity for 10bl samples and ~8% GMR, ~0.22%/Oe sensitivity for 6bl) in the as-deposited state. An abrupt decrease in the as-deposited GMR magnitude and sensitivity is observed for magnetic layers thicker than this optimum. This observation is consistent with magnetization loop data, which indicates AFM and FM coupling in this sample and thicker magnetic layer samples,

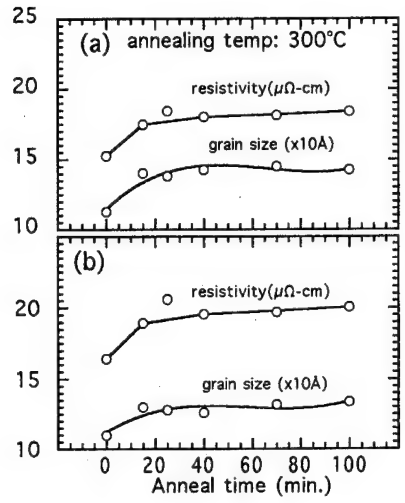

FIG. 2. The change in the grain size and resistivity as a function of annealing time for NiFeCo/Cu ML samples with (a) 17 Å and (b) 26-Å-thick magnetic layers.

respectively. High-temperature anneal (300 °C) rapidly degrades the above-mentioned GMR characteristics in samples with magnetic layer thicknesses of ~21 Å or less. By contrast, samples with magnetic layers of thicknesses >23 Å, with insignificant GMR characteristics in the as-deposited state [Fig. 1(a)], show a drastic improvement [Fig. 1(b)] upon annealing. Annealing at 300 °C also results in an increase in grain size and resistivity for all samples (Fig. 2). A linear extrapolation of the inverse of resistance versus the magnetic layer thickness is plotted in Fig. 3. The resistivity of the Cu spacer layers and the interfaces has been estimated from the intercepts at zero magnetic layer thickness. Our data indicates an approximately 26% increase in this resistivity after annealing. The low-angle x-ray diffraction (LXRD) data shows, following anneal, about a 5% reduction in effective bilayer thickness as well as a small change of the interface (see Fig. 4). This 5% thickness reduction does not equate directly to the 26% change in the resistivity. The additional increase in resistivity must therefore be attributed to other effects. Summary plots of GMR in the as-deposited and annealed states are given in Fig. 5 for a set of ten 6bl samples. Thin NiFeCo samples show increased AFM coupling with no significant uniaxial anisotropy in the annealed

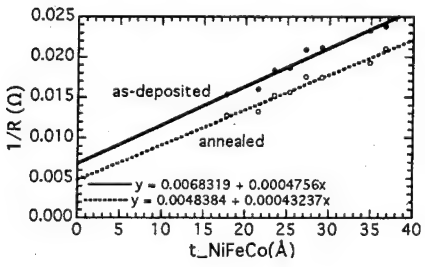

FIG. 3. Linear fit to the inverse of the resistance as a function of the magnetic layer thickness.

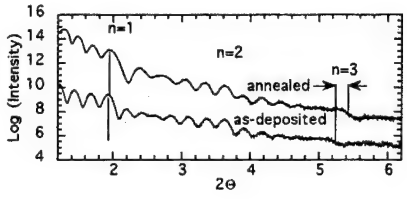

FIG. 4. As-deposited and annealed low-angle x-ray diffraction scans for a multilayer sample with 25-Å-thick NiFeCo layers.

state. Ferromagnetic resonance (FMR) data indicates a decrease in anisotropy upon annealing for the thick samples. An indication of a small decrease in magnetization is also observed, which is consistent with vibrating sample magnetometer (VSM) data.

III. ANALYSIS

One method for calculating the bilinear and biquadratic exchange fields H_1 and H_2 has been proposed earlier.[5] In our present study, we estimated the exchange fields, and hence the exchange constants J_1 and J_2 as a function of magnetic layer thickness (given in Table I) by a slightly different approach, as shown below.

From the experimentally determined full width half maxima (FWHM) of the GMR field profiles, the transverse (hard axis) and parallel (easy axis) fields can be related to H_1 and H_k conveniently. These fields are given[6] by the following equations:

$$H_{\perp 50}=\frac{1}{\sqrt{2}}(H_1+H_k) \tag{1a}$$

and

$$H_{\parallel 50}=\frac{1}{\sqrt{2}}(H_1-H_k), \tag{1b}$$

where

$$H_1=\frac{2(2N-1)}{N}\left(\frac{J_1}{M_s t}\right). \tag{2}$$

$H_{\perp 50}$ and $H_{\parallel 50}$ are, respectively, the FWHM field values in the hard and easy directions, $2N$ is the total number of magnetic layers, J_1 is the bilinear exchange constant, M_s is the saturation magnetization, and t is the magnetic layer thick-

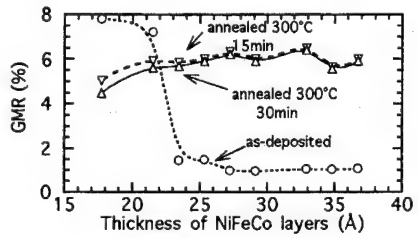

FIG. 5. GMR in as-deposited and annealed states as a function of the magnetic layer thickness.

TABLE I. Exchange constants J_1, J_2, and anisotropy field H_k.

NiFeCo thickness (Å)	H_1 (Oe)	H_2 (Oe)	H_k d(Oe)	J_1 (μJ/m^2)	J_2 (μJ/m^2)
18	109.6	11.4	10.6	5.73	0.60
21	77.8	8.1	7.1	4.74	0.49
23	55.9	7.5	6.4	3.73	0.50
25	56.2	8.3	7.4	4.08	0.60
27	58.0	8.0	5.7	4.55	0.62
33	40.3	5.5	7.8	3.86	0.53
35	38.2	5.3	5.7	3.88	0.54

ness. $H_k(=2K_u/M_s)$ is the field induced anisotropy field, where K_u is the uniaxial anisotropy constant. Clearly, it follows from Eqs. (1a), (1b), and (2) that $\sqrt{2}H_{\perp 50,\parallel 50}$ vs $1/t$ should be a linear curve of positive slope. From Eqs. (1a) and (1b) we can determine H_1 and H_k as follows:

$$H_1=\frac{1}{\sqrt{2}}(H_{\perp 50}+H_{\parallel 50}) \tag{3}$$

and

$$H_k=\frac{1}{\sqrt{2}}(H_{\perp 50}-H_{\parallel 50}). \tag{4}$$

Now, J_1 and H_k can be evaluated by inserting experimental data for $H_{\perp 50,\parallel 50}$ into Eq. (2), (3), and (4). Table I lists J_1 and H_k values after annealing for various magnetic layer thicknesses and J_2 is included for completeness. The data in Table I indicates that the J_1, J_2 values are effectively constant for magnetic layer thicknesses from 23 to 35 Å. The linear dependence of $H_{\parallel 50}$ and $H_{\perp 50}$ on the inverse of magnetic layer thickness (Fig. 6) also supports the conclusion that interlayer interactions remain constant as the thickness increases. A small reduction in the thickness of the bilayer stack was observed. $H_{\parallel 50}$ and $H_{\perp 50}$ decrease in accordance with the model of Ref. 5 accordingly for an increase in GMR sensitivity given that GMR magnitude is approximately constant. Calculation of J_1 as described in Eq. (2) is based on a continuous-layer model. This model predicts that $H_{\parallel 50}$ and $H_{\perp 50}$ should increase with the increase in inverse of the magnetic layer thickness. Our data in Fig. 6 show reasonable agreement with the model (using average values of J_1 and H_k from Table I for thicknesses in the range 23–35 Å) and, therefore, explains the decrease in saturation field with increasing magnetic layer thickness.

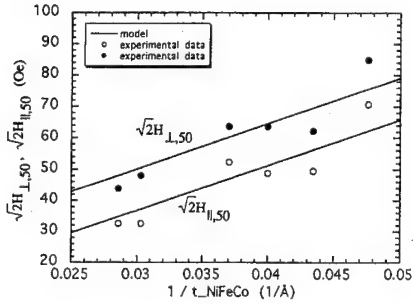

FIG. 6. $\sqrt{2}H_{\perp 50}$ and $\sqrt{2}H_{\parallel 50}$ as a function of the inverse of the magnetic layer thickness.

IV. RESULTS

We have developed a methodology to improve the thermal stability of magnetoresistive NiFeCo/Cu multilayers. Multilayers with "optimum" or thinner magnetic layers decrease in both GMR magnitude and field sensitivity upon high-temperature anneal. Samples with thicker magnetic layers (>23 Å) exhibit a huge improvement in GMR characteristics upon post-deposition anneal with enhanced thermal stability.

After much experimentation, the reasons for the dramatic post-anneal effects of Fig. 1 remain unclear. On one hand, the magnetization, as determined from FMR and from vibrating sample magnetometry, appears to decline following anneal, suggesting, possibly, fragmentation of the magnetic layers. Conversely, however, the low-angle x-ray patterns of these MLs before and after anneal (see Fig. 4) show little evidence of this. Additionally, the decrease of GMR saturation field (and, concomitantly, the magnitudes of $H_{\parallel 50}$, $H_{\perp 50}$) with increasing magnetic layer thickness seems consistent with theoretical expectations[5] for a continuous-layer GMR system. GMR enhancement, increase in resistivity, and grain growth all appear independent of the number of bilayers; similar enhancement is seen in 10- and 20-bilayer stacks. We conclude that the magnetic and spacer materials do not necessarily have to be immiscible to produce multilayers of high thermal stability.

Relaxation in NiFe/Ag giant magnetoresistive devices

R. W. Cross and A. B. Kos
Electromagnetic Technology Division, National Institute of Standards and Technology, Boulder, Colorado 80303

Giant magnetoresistance was measured as a function of time and device size for patterned NiFe/Ag multilayer films. The sputtered NiFe/Ag multilayers were postannealed at 340 °C for 5 min in order to produce a change in resistivity $\Delta\rho/\rho$ of 5% in a saturating field of 4 kA/m (50 Oe). The microstructure of these films is believed to be discontinuous due to Ag bridging through the NiFe grain boundaries after the anneal. The films were fabricated into rectangular stripes with Au current lead, and then exposed to a magnetic field pulse to measure the time response of the resistance, characterized by a time constant τ, from the relation $\Delta R(t)=\Delta R_0 e^{-t/\tau}$. An apparatus was developed to produce a magnetic field pulse up to 8 kA/m (100 Oe) with a turn-on/off time constant of 10 μs. The response of the NiFe/Ag devices saturated quickly with the turn-on step with a time constant nearly equal to that of the field pulse. The response to the turn-off step, however, had a time constant of nearly 300 μs. When the field is first applied, the torque on the magnetic moments quickly aligns the magnetization. When the field is shut off, however, the torque due to the field drops to 0, so interacting magnetostatic fields from the grains and thermal energy dominate the relaxation process. The average time constant depends on the device size and the applied current density. Relaxation may be detrimental for using this type of material for read heads where very high data rates are required. [S0021-8979(96)54708-4]

I. INTRODUCTION

Research in giant magnetoresistance (GMR) materials is moving toward device applications. Device-level characterization of different GMR systems is becoming more important with the goal of achieving the largest GMR with the smallest saturation field in micrometer size devices. The NiFe/Ag system is formed by sputtering bilayers of NiFe/Ag and then postannealing the films until the Ag diffuses into the NiFe grain boundaries and separates the grains to form a discontinuous structure. We have reported on the transport properties of micrometer-size discontinuous multilayer devices where noise, size, and self-field effects become important.[1,2] These effects may limit the usefulness of discontinuous GMR materials in applications like magnetic recording where very small devices are needed.

Relaxation in discontinuous films plays an important role in device performance as well. We report results of relaxation measurements on NiFe/Ag films fabricated into devices with micrometer dimensions. Relaxation rates are measured by exposing a device to a very fast turn-on/off field pulse while monitoring the response versus time. Long relaxation rates are observed in annealed NiFe/Ag devices due to the discontinuous structure compared to continuous films of NiFe. We find that the device response is very fast in large saturating fields, but long time constants are observed when the saturating field is removed. In addition, discrete structure and nonlogarithmic behavior are observed in the time response for submicrometer devices due to discrete switching of magnetic grains.

II. MATERIALS

The NiFe/Ag discontinuous system is interesting from a device point of view because of its low saturation field. Most GMR systems with large changes in resistivity $\Delta\rho/\rho$ of 50%–90%, like Fe/Cr or Co/Cu multilayers, have very large saturation fields, typically 800 kA/m (10 000 Oe).[3] This is not useful for recording applications, where the field from the bits is typically 0.8–8 kA/m (10–100 Oe) at the sensor. One requirement for GMR is antiparallel alignment of the magnetization between neighboring domains. A way of achieving this is to antiferromagnetically (AF) couple the layers using exchange interactions.[4] The layers can be engineered to obtain the strongest AF coupling, which in turn produces the largest GMR. However, to saturate the material, it is necessary to overcome this large exchange force, requiring very large saturation fields. The lesson is that the largest GMR is not necessarily the best for some applications like read heads, where high sensitivity is needed at low fields. High sensitivity at low field can be achieved by setting the AF coupling to a weaker level, or by using some other form of coupling to obtain antiparallel alignment. In the NiFe/Ag system, the coupling is magnetostatic, which is accomplished by annealing the multilayer into a discontinuous structure. This system has exhibited some of the highest sensitivities at low fields.[5]

The NiFe/Ag films were made following the original prescription outlined in Ref. 5. The films consisted of seven sputtered bilayers with a 4.4 nm layer of Ag and a 2 nm layer of $Ni_{82}Fe_{18}$. The films were annealed at 340 °C for 5 min to obtain a $\Delta R/R$ of 4.5%. The thickness of the Ag layer is such that the layers are not exchange-coupled. The microstructure of similar films has been studied in detail by Parker *et al.*[6] using scanning electron microscopy and cross-sectional transmission electron microscopy, and they determined that Ag bridges form during the anneal through the NiFe grain boundaries. This is important in the NiFe/Ag multilayers because magnetic poles can form along the edges of the grains and couple by magnetostatic fields to grains in adjacent layers, producing antiparallel alignment.[7] We have worked on simulating the response using a micromagnetic model of the magnetostatic interactions of a matrix of NiFe grains in Ag,

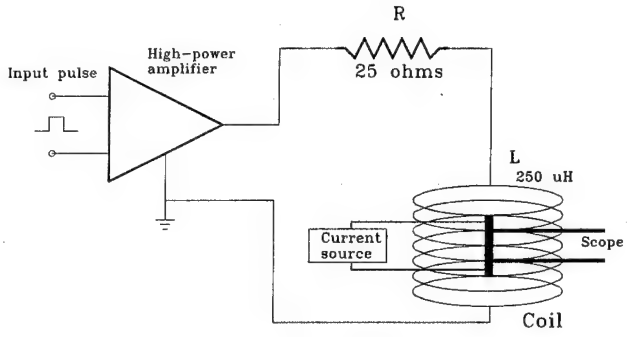

FIG. 1. Schematic diagram of field-pulse apparatus. The time constant of the field coil is determined by the inductance L and resistance R, and is 10 μs. The maximum field amplitude of the pulse is 8 kA/m (100 Oe).

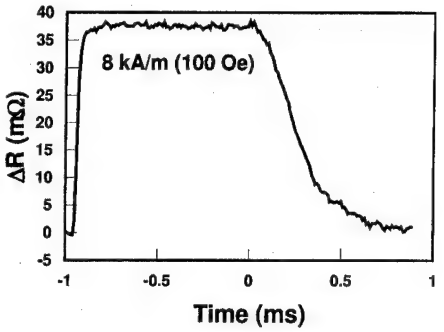

FIG. 2. Time response to the field pulse for a 4×4 μm (active area) NiFe/Ag device. The turn-on time constant of the device is nearly the same as that of the field pulse. However, the turn-off time constant is approximately 300 μs.

and found some agreement with experimental results.[8]

The films were fabricated into devices with Au current leads. Track widths, defined as the distance between the Au leads, varied from 1 to 16 μm. The total width of the stripe was typically much longer than the track width. The height of the stripes varied from 0.5 to 16 μm. The active area of the device is defined as the stripe height times the track width.

III. RELAXATION

The frequency response of NiFe read heads is generally limited by eddy currents, which reduce the permeability of the NiFe. The strength of the eddy currents depends on the size, thickness, and conductivity of the element as well as the strength and frequency of the external field. Presently, the permeability of NiFe read heads remains high up to 100 MHz, which is adequate for recording applications. The intrinsic limitation of NiFe devices is related to the relaxation time of the ferromagnetically coupled spin system and is on the order of 10^{-9} s, suggesting that these devices could be used up to 1 GHz. However, for the NiFe/Ag discontinuous GMR devices, the granular structure leads to other relaxation effects. In this case, the magnetostatic fields from the magnetic grains interact, causing the magnetization distribution to thermally relax into a metastable configuration. When one grain switches, it changes the field distribution and the relaxation conditions of the other grains, which in turn may switch, and the process continues until equilibrium is reached.

To measure the frequency response of the GMR devices, we constructed an apparatus that can supply a longitudinal field pulse up to 8 kA/m (100 Oe) with a turn-on/off time constant of 10 μs. The apparatus is shown in Fig. 1. The time constant of the field pulse is determined by L/R, making it necessary to use a small inductance L and a large resistance R. However, to get enough field from the coil, high voltage is needed to produce a large current. We use a low duty cycle for the pulse (one pulse per second) so that coil heating is kept small. A GMR device is placed at the center of the coil and exposed to the longitudinal field pulse while the output of the sensor is monitored using a high-frequency 16 bit digital oscilloscope. To remove any background signal due to the small inductance of the current leads and the sensor, two measurements are made, one with current applied to the device and the other without. There are typically 20 curves taken and averaged to improve the signal-to-noise level.

To test the system, we measured a continuous NiFe device and found that the output follows the applied field pulse with a time constant of 10 μs. The relaxation is described by a time constant τ in the relation $\Delta R(t)=\Delta R_0 e^{-t/\tau}$, where $\Delta R(t)$ is the change in resistance versus time and ΔR_0 is the characteristic GMR of the device.

The response of a 4×4 μm (active area) NiFe/Ag GMR device is shown in Fig. 2. The turn-on time of the response nearly coincides with that of the applied field pulse. The output remains flat until the turn-off step (see Fig. 2) at time $t=0$, where a decay time constant of 300 μs is observed. The fast turn-on time of the device is due to the large torque exerted on the magnetic moments of the grains from the applied longitudinal field, which is large enough to saturate the magnetization. For the turn-off step, however, the torque from the applied field suddenly goes to zero and all of the magnetic grains thermally relax to the zero-field condition. The interacting magnetostatic fields from the magnetic grains affect this process (this is not the case for continuous NiFe devices) because the field emanating from a given grain changes the relaxation conditions of neighboring grains. Long time constants may limit the usefulness of this type of material in applications like magnetic recording.

Device size also affects the GMR response to the field pulse, as shown in Fig. 3 for a 0.7×1 μm device. In Fig. 3(a), the response is shown for a slowly changing field cycle. The main things to note are the structure and hysteresis in the response, which are due to the discontinuous microstructure of the film. Discrete switching of magnetic grains or clusters produce jumps in the response.[1,2] The 0.7×1 μm device was then exposed to the field pulse and the output is shown in Fig. 3(b). The turn-off response is not an exponential decay as observed for the larger devices, but rather has steps or bends. The steps are not as sharp as they might be due to the curve averaging. Note that the output voltage does not return to the initial value in the time period shown in the figure (eventually it does relax back to $\Delta R=0$). Single-shot measurements would show more distinct switching events as

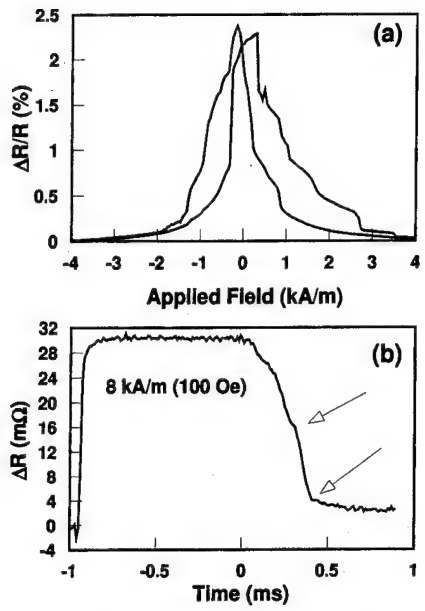

FIG. 3. (a) GMR response to a slowly changing applied field cycle for a 0.7×1 μm NiFe/Ag device, and (b) time response of the device to the field pulse. Note the structure in the relaxation curve.

jumps in the relaxation, but the noise was not low enough to observe this.

If a constant field is always applied to the device then the magnetic grains would partially align along the field direction, reducing the noise and relaxation rate. The magnetic field due to the applied current flowing through the device may be used to do this.[9] The current density produces a constant field transverse to the current flow that can be used to align the moments. The turn-off response of a 4×4 μm device to the field pulse is shown in Fig. 4 for low and high current densities for single-shot measurements. The curves were normalized so that the decay rates could be compared. (The values of $\Delta R/R$ are not the same because the high current density causes a 12% reduction in GMR response.) The time constant of the 5×10^5 A/cm^2 curve is greater than 300 μs and reduces to approximately 150 μs at 1×10^7 A/cm^2.

IV. CONCLUSIONS

We measured the time response of NiFe/Ag discontinuous GMR devices to a sharp field pulse and observed relaxation time constants greater than 300 μs when the applied field switches from saturation to zero. When the field is applied, the torque on the magnetic grains composing the discontinuous film causes the moments to respond quickly. However, when the field is turned off, interacting magnetostatic fields from the grains and thermal activation dominate the response, causing the long relaxation rates. We observed size effects in the response for devices approaching 1 μm in size. In addition, the relaxation rate depends on the magnetic field, whether due to an external field or self fields from the applied current. Application of a current density 1×10^7 A/cm^2 halved the time constant for a 4×4 μm active area device. The long time constants observed in the discontinuous NiFe/Ag system may limit their usefulness as read-head sensors where high bit rates are used.

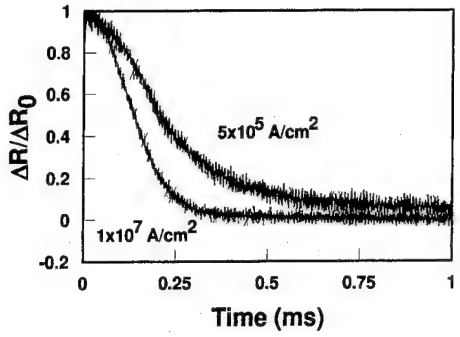

FIG. 4. The turn-off time response to the field pulse for a 4×4 μm (active area) NiFe/Ag device at low and high current densities. The self field due to the applied current density of 1×10^7 A/cm^2 halves the relaxation rate.

New methods to measure the current perpendicular to the plane magnetoresistance of multilayers

P. Dauguet, P. Gandit, and J. Chaussy
Centre de Recherches sur les Très Basses Températures, Centre National de la Recherche Scientifique, BP, 38042 Grenoble Cedex 09, France

The experimental devices presented here enable us to measure variations with magnetic field of electrical resistances in the range (0.1 nΩ, 1 μΩ), for applied magnetic fields up to 3 T, and for temperatures less than 9 K. The setups work with three measurement methods. Two provide direct access to $R(H)$, one in constant current, the other in alternating current. Their absolute sensitivity is about 1 pΩ, and their relative resolution $\Delta R/R$ is limited to 0.3%. The third method is a sinusoidal field modulation technique giving the field derivative of the resistance: dR/dH. It is sensitive to variations of the resistance as small as 1 pΩ independent of the absolute resistance of the sample, thus the resulting resolution $\Delta R/R$ is, for example, 10^{-6} for a 1 μΩ sample. With these devices, the magnetoresistance of multilayers can be studied with the current perpendicular to the plane. © *1996 American Institute of Physics.* [S0021-8979(96)54808-0]

I. INTRODUCTION

Since the discovery in 1988 of the giant magnetoresistance (GMR) of Fe/Cr multilayers,[1] many multilayer systems composed of ferromagnetic layers alternating with nonmagnetic layers have been found to exhibit the same effect, as for example Co/Cu, Co/Ag, NiFe/Ag. Their electrical transport properties have been extensively studied with the current flowing in the multilayer plane.[2] This geometry yields sample resistances in the range (1 mΩ–1 Ω) and the GMR effect can be investigated with standard measurement techniques. Whereas numerous theoretical models have been developed to describe the GMR effect with the current flowing perpendicular to the multilayer plane (CPP-MR),[3] few experimental results have been obtained,[4,5] the measurements being difficult. The square resistance of the samples is indeed about 10^{-8} Ω mm^2 in this geometry. For samples of surfaces 0.1–1 mm^2, the resistances to be measured range from 10^{-8} to 10^{-7} Ω. If biased with a 10 mA current, the voltage appearing across the sample is 10^{-10}–10^{-9} V and to study the magnetoresistance effects properly, the measurement method must have at least a 10^{-2} resolution. So the sensitivity of the measurement method has to be better than 10^{-12} V.

In this paper, we describe techniques which allow such measurements. The first two give a direct access to $R(H)$, the third one yields dR/dH. All are original in this investigation field and achieve high sensitivities not attainable with commercial instruments. We present the principles of the three methods, the experimental setups, their resulting performances, and the conditions required to get them. Then we show some CPP-MR measurements made on multilayer samples.

II. $R(H)$ MEASUREMENTS WITH CONSTANT CURRENT

The setup is designed to measure $R(H)$ from 50 mK to 9 K. A constant current is applied to the sample and a constant voltage appears across it. Because this voltage is very low (10^{-10} V), it is amplified at low temperature and as close to the sample as possible to avoid the appearance of parasitic thermoelectric voltages than can be far bigger than the signal. To do this, the constant voltage is first made alternating by means of a superconducting chopper[6] which consists of a superconducting bridge, two opposite branches of which are made normal alternatively with the aid of heating light-emitting diodes (LED) at a frequency of about 30 Hz (see Fig. 1). The alternating voltage is amplified with a transformer of amplification rate 25 000 working at 4.2 K, and then with a low-noise amplifier with a field-effect transistor (FET) working at 150 K. Finally, the signal is detected with a lock-in amplifier. This system is placed in a dilution refrigerator equipped with a superconducting magnet delivering fields up to 0.7 T. Its input noise voltage is 10^{-12} V/$\sqrt{\text{Hz}}$ in working conditions and in the maximum field. Averaging the signal over 100 s, the sensitivity of the method in thus 10^{-13} V. With a sample current of 0.1 A, the absolute sensitivity in terms of resistance is thus 10^{-12} Ω, the resolution of the method $\Delta R/R$ being to 0.3%.

III. $R(H)$ MEASUREMENTS WITH ALTERNATING CURRENT

It consists in detecting the ac voltage that appears across a sample supplied with a known ac current i of frequency f, and placed in a constant magnetic field H. The voltage to be measured V is amplified with a transformer of ratio 25 000 working at 4.2 K and then with a low-noise FET amplifier at room temperature, before being detected with a lock-in amplifier. This voltage V follows the equation:

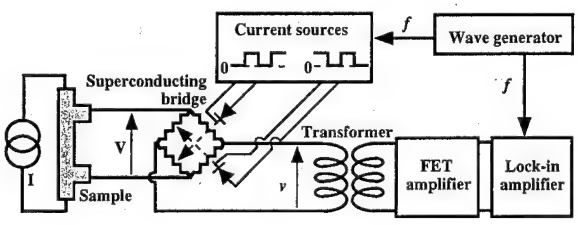

FIG. 1. Schematic diagram of the constant current $R(H)$ measurement method.

 0021-8979/96/79(8)/5823/3/$10.00

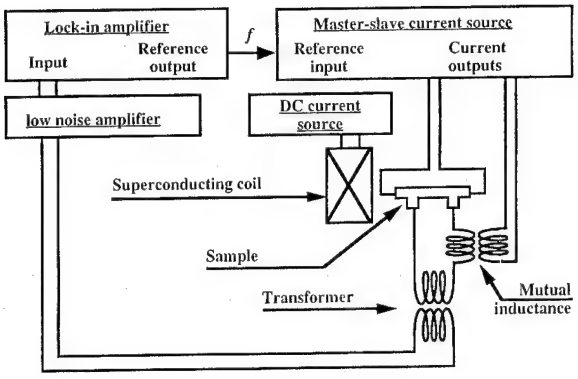

FIG. 2. Schematic diagram of the alternating current $R(H)$ measurement method.

$$V=R(H)i+M_p\frac{di}{dt}, \tag{1}$$

where M_p is the parasitic mutual inductance coupling the current injection circuit and the voltage measurement circuit at the sample level. M_p is about 10^{-10} H. As $(M_p\, di/dt)$ is proportional to f, we should work with a frequency as small as possible. But lowering f, the noise of the electronics grows (it is proportional to $1/f$ at low frequencies). So we work at the frequency where the white noise regime of our apparatus is reached, that is 9 Hz. At this frequency $(M_p\omega)$ is about 5×10^{-9} Ω, which is far bigger than the desired sensitivity in terms of resistance. Noticing that the perturbating voltage is in quadrature with the one of interest, it can be avoided using a lock-in amplifier phase locked to the sample current. The error it induces is thus reduced by a factor 10^3–5×10^{-12} Ω. Injecting in the circuit a signal in opposition to $(M_p\, di/dt)$ with the aid of a mutual inductance allows it to be reduced below the required level of 1 pΩ equivalent.

A schematic diagram of the measurement setup is presented in Fig. 2. It works at 4.2 K with fields up to 3 T. Its noise voltage measured in working conditions under a field of 1 T is 7×10^{-13} V/$\sqrt{\text{Hz}}$, which corresponds to an absolute sensitivity of 0.7 pΩ in terms of resistance, the resolution of the method $\Delta R/R$ being limited to 0.3%. This setup has been designed to permit the rotation of the sample in the field. It allows the study of the angular dependence of the CPP-MR of spin-value multilayers like, for example, Ag/NiFe/Ag/Co.

IV. (dR/dH) MEASUREMENTS

With the method we describe now, we get $dR/dH(H)$. The sample is subjected to a constant field H to which is superposed a small modulation dH at frequency f_1. The idea is to detect the response of the sample resistance to the field modulation. If the current biasing the sample is a constant current, the voltage appearing across the sample is the sum of a constant term:

$$V_{dc}=R(H)I, \tag{2}$$

and an alternating term at the frequency f_1:

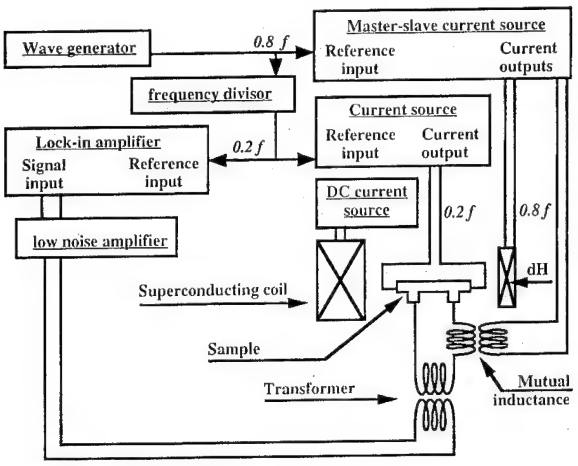

FIG. 3. Schematic diagram of the dR/dH measurement method. The numerical lock-in amplifier detects the signal at f (which is five times its reference frequency).

$$V_{f1}=\left(\frac{dR}{dH}\right)_H dH\, I+\frac{d\Phi}{dt}, \tag{3}$$

where $d\Phi/dt$ is the flux variation created by the field modulation and seen by the voltage measurement circuit. Working at 9 Hz with a field modulation of 10 Oe, this perturbating term is about 10^{-7} V which is 10^5 times the required sensitivity. To avoid $d\Phi/dt$, the first idea is to inject a voltage in opposition to it using a mutual inductance placed in the detection circuit. This way, it is reduced by a factor 10^3, which is still not sufficient to achieve the minimum required sensitivity of 10^{-12} V. So, the second idea is to supply the sample with a sinusoidal current i of frequency f_2. The voltage appearing across the sample is thus

$$V=R(H)i+\left(\frac{dR}{dH}\right)_H dH\, i+\frac{d\Phi}{dt}+M_p\frac{di}{dt}. \tag{4}$$

The perturbating terms are then at frequencies f_1 and f_2, and the term of interest is at (f_1+f_2) and (f_1-f_2). Amplifying V the same way as in the $R(H)$ method, and detecting its (f_1+f_2) component (V_{f1+f2}) with a lock-in amplifier, we get $dR/dH(H)$. In fact, the rejection of the lock-in amplifier between the signals at different frequencies is 10^4, and the component of V at f_1 $(d\Phi/dt)$ is more than 10^4 times the required sensitivity level, so the rejection of the lock-in amplifier is not sufficient. $d\Phi/dt$ has to be first opposed using a mutual inductance, and then V_{f1+f2} can be measured without any error induced by V_{f1} and V_{f2}.

For this measurement, the detection frequency f we use is 9 Hz. The way to avoid any perturbations produced by the small harmonic distortion of the $d\Phi/dt$ term induced by Foucault currents in the calorimeter, is to choose f_1+f_2 different from any higher harmonic of f_1. In what follows, the detection frequency f_1+f_2 is called f. Practically, we took f_1 equal to $0.8\,f$ and f_2 equal to $0.2\,f$.

A block diagram of the setup is presented in Fig. 3. It works at 4.2 K with fields up to 3 T. Its noise voltage measured in working conditions under a field of 1 T is

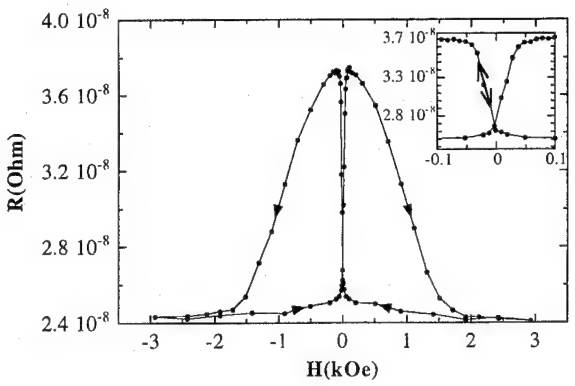

FIG. 4. CPP-MR of (Ag 40 Å/Co 4 Å/Ag 40 Å/NiFe 20 Å)$_{20}$ at 4.2 K obtained with both $R(H)$ methods. The double arrow in the inset indicates for comparison the dR/dH value measured at one point.

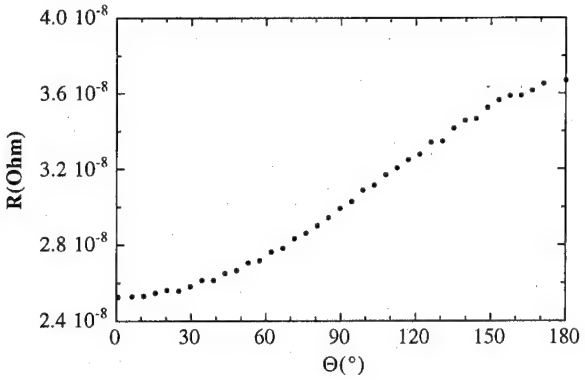

FIG. 5. Angular dependence of the CPP-MR of (Ag 40Å/Co 4Å/Ag 40Å/NiFe 20Å)$_{20}$ at 4.2 K.

7×10^{-13} V/ $\sqrt{\text{Hz}}$. It is sensitive to variations of the resistance as small as 0.7 pΩ independent of the absolute resistance of the sample, thus the resulting resolution $\Delta R/R$ is, for example, better than 10^{-6} for a 1 μΩ sample. This ultrahigh resolution has the advantage of allowing magnetoresistance studies of systems with very low magnetoresistances.

V. PRECAUTIONS

In order to achieve the sensitivities presented in Secs. II to IV, all sources of noise present in the circuits have been reduced.

To minimize the *thermal noise*, the transformer is placed in the helium bath. This reduces the Nyquist noise of its copper secondary, and enables the use of superconducting wires at primary. The total resistance of the measurement circuit seen from its input is about 10^{-6} Ω, which generates a total Nyquist noise of 2×10^{-14} V/$\sqrt{\text{Hz}}$.

The *electromagnetic perturbations* are minimized. Electrostatic shielding is ensured by the stainless-steel Dewar and a metallic shielding of the cables outside of it. The length and surface of each circuit are reduced to their minimum in order to reduce the effect of the electromagnetic perturbations coming from electronic devices, radio waves, and the Earth's magnetic field. Moreover, the transformers and mutual inductances are shielded from field variations by putting them in superconducting containers. These boxes at the same time shield out the constant field H, in which the transformers cannot work properly.

The last type of noise we had to deal with is *microphonic*. To reduce the vibration transmitted by the building, the Dewar is set on pneumatic shock absorbers. Some cables used are totally rigid, and the others are partially tied up. Despite this, the resulting noise level (see Secs. II to IV) is mainly due to the motion of the wires in the magnetic field. This noise voltage is proportional to the field and is about 10^{-12} V/$\sqrt{\text{Hz}}$ per T.

VI. MEASUREMENTS

To illustrate the high sensitivity of the setups presented above, we have measured the CPP-MR of Ag/Co/Ag/NiFe multilayers deposited between two superconducting leads by sputtering on Si(100) substrates. They were prepared and supplied by Schroeder and co-workers. A typical $R(H)$ curve at 4.2 K is given in Fig. 4, the two $R(H)$ methods gave the same result.

For the first time, the angular dependence of the giant magnetoresistance of multilayers has been measured with the current applied perpendicular to the multilayer plane. In the sample studied, the magnetization of the $Ni_{80}Fe_{20}$ layers can be rotated by rotating the sample in a small field, without affecting the remanent magnetization of the Co layers.[7] The sample is saturated in a field of 5000 Oe and then rotated in 150 Oe. The magnetization of the Co follows the sample rotation, whereas the magnetization of $Ni_{80}Fe_{20}$ remains parallel to the applied field. The angle between the magnetizations is called Θ. A $R(\Theta)$ curve is presented in Fig. 5. Analysis and physical interpretations of these measurements will be presented elsewhere.

We have tested the dR/dH method on these samples. A measure at one point is given by the double arrow in the inset of Fig. 4. We see that the results obtained with the dR/dH method are consistent with the $R(H)$ measurements.

Engineering coercivities by dual ion beam sputtering for synthesizing soft permalloy-based spin-valve multilayers (abstract)

C. J. Gutierrez, R. Dail, R. Selestino, L. Tristan, and M. Khater
Physics Department, Southwest Texas State University,

Steve Michel
Commonwealth Scientific Corporation

Thin permalloy ($Ni_{80}Fe_{20}$) single-layer films and multilayers were fabricated onto Ta-buffered oxidized silicon substrates using a prototype dual ion beam sputtering system (Commonwealth Scientific Corporation). The room temperature substrates were placed in a uniform in-plane magnetic field during growth (~150 Oe) yielding a uniaxial magnetic anisotropy in the permalloy films (typically ~6 Oe). An examination of single-layer permalloy films with thicknesses from 20–50 nm indicated that the presence of an ~100 eV ion-beam assist beam focused directly onto the substrate during film growth consistently modified the coercive and remnant characteristics of the films. Typically, the nonion beam assist modified NiFe films exhibited a coercivity ~1 Oe, while the ion beam assist modified films exhibit a slightly larger coercivity (~1.5 Oe). Based on this apparent influence of the assist ion beam treatment on the film coercivity, the fabrication of soft spin-valve multilayer structures exploiting differences in the ion beam treatment of chemically identical ferromagnetic layers seemed plausible. To test this idea ,two parallel series of multilayers composed of [2.5 nm permalloy]-[Cu (2.5 nm, 4 nm, or 5.5 nm)] or [0.3 nm Co-1.9 nm permalloy -0.3 nm Co]-[Cu (2.5 nm, 4 nm, or 5.5 nm)] were fabricated. In these 30 cycle multilayers, alternating ferromagnetic layers were subjected to a 150 eV assist ion beam treatment during growth (higher coercivity layer), or to NO assist ion beam treatment during growth (lower coercivity layer). VSM analysis revealed that the simplest uncoupled spin-valve multilayer configuration consisted of the [2.5 nm permalloy]-[4 nm Cu] multilayer with Hc1 ~0.8 Oe and Hc2 ~2.2 Oe, and the [0.3 nm Co - 1.9 nm permalloy - 0.3 nm Co] - [4 nm Cu] multilayer with Hc1 ~ 3 Oe and Hc2 ~ 15 Oe. Film analysis by low-angle x-ray diffraction and reflectivity, as well as the effect of the Co interface layer on GMR properties will also be reported. [S0021-8979(96)60908-0]

First principles determination of magnetocrystalline anisotropy for surfaces and interfaces using a torque method (abstract)

Xindog Wang and A. J. Freeman
Department of Physics and Astronomy, Northwestern University, Evanston, Illinois 60208-3112

R. Wu
Department of Physics, California State University, Northridge, California 91330-8268

D. S. Wang
Institute of Physics, Academia Sinica, Beijing 100080, People's Republic of China

Perpendicular magnetic alignment is vital for high density magneto-optical recording materials. Despite the tremendous theoretical/computional advances made during the last few decades, the determination of magnetocrystalline anistropy (MCA) from first principles still remains a great challenge for complex systems. We will describe our recently proposed torque method for the first principles determination of MCA. In the usual first principles methods, one calculates the band energies associated with two magnetization directions and substracts one from the other. Within this approach, one has the difficulty of getting rid of the random fluctuations arising from the two different Fermi surfaces due to different magnetization directions. We show that to accurately determine the spin-orbit induced uniaxial ansisotropy energy for surfaces/interfaces, calculation of the torque at a specific angle is sufficient and one avoids the complexities associated with two Fermi surfaces by employing the Feynman-Hellman theorem. In the k-space integrations, we used both linear and quadratic interpolation schemes and convergence is assured when these two schemes agree to the accuracy desired. Examples, including Fe and Co multilayer systems, will be presented to demonstrate the efficiency and precision of this method. Detailed comparisons with previously proposed state-tracing method by Wang *et al.*[1] are also made and discussed. [S0021-8979(96)43108-0]

Theoretical predictions of magnetic interface anisotropy in (Pd/Co/Pd)/X superlattices

J. M. MacLaren
Department of Physics, Tulane University, New Orleans, Louisiana 70118

We present first principles electronic structure calculations of the magnetic interface anisotropy for several (1Pd/1Co/1Pd)/nX superlattices with X=Pt, Pd, Ag, or Cu. The calculated anisotropies are compared to those found in Co/X and (1Pt/1Co/1Pt)/nX superlattices. The predicted anisotropies for monolayer spacers of Ag or Cu are similar in magnitude to those computed for Co/Pd or Co/Pt multilayers. In the case of (1Pd/1Co/1Pd)/1Pt, the anisotropy is enhanced when compared to either Co/Pt or Co/Pd superlattices, though to a lesser extent than that computed for (1Pt/1Co/1Pt)/1Pd. Surprisingly, increasing the number of spacer layers to three, results in a suppression of the perpendicular anisotropy in (1Pd/1Co/1Pd)/3X and (1Pt/1Co/1Pt)/3Cu superlattices. This result is inconsistent with a near-neighbor Neel model, which would predict little sensitivity to the number of X layers. The Neel model has been shown to work quite well on average for many fcc-based Co/Pt and Co/Pd multilayers. This suggests that the details of the superlattice electronic structure are important in these systems. © *1996 American Institute of Physics.* [S0021-8979(96)21208-6]

Magneto-optic data storage, using the polar Kerr effect to read stored data, requires a media with both perpendicular magnetic anisotropy and a satisfactory Kerr rotation. In order to achieve future aerial densities, the wavelength of the laser used to read data will need to be about 400 nm. Both Co/Pt and Co/Pd superlattices have been the focus of recent work since they exhibit large perpendicular anisotropies and significant Kerr rotations at wavelengths around 400 nm.[1] The magnitude of the magnetic anisotropy measured in a particular superlattice depends crucially upon sample preparation. Superlattices with sharper, more ideal interfaces, such as those made by molecular beam epitaxy, have the largest anisotropies, while those grown by sputtering have significantly smaller anisotropies because of diffuse interfaces. As an example of this, several 1 Co/5Pd superlattices have been prepared under different growth techniques. The observed magnetocrystalline anisotropies range from 5.9×10^7 ergs/cm^3 (Ref. 2) for a sample grown by molecular beam epitaxy, to 2.6×10^7 ergs/cm^3 (Ref. 3) for a sputtered sample. Theoretical values for a perfect 1Co/5Pd superlattice with ideal interfaces show even larger anisotropies, namely 6.6×10^7 ergs/cm^3 (Ref. 4) and 8.7×10^7 ergs/cm^3.[5] Within a nearest-neighbor Néel model of magnetocrystalline anisotropy,[6,7] we have previously shown that the magnitude of the interface anisotropy is always reduced by the presence of interfusion at the interfaces[7,8]—a result consistent with many experimental observations. In fact, Bertero and Sinclair[9] have stressed that, based upon their experiments for Co/Pt superlattices, the most important parameter controlling the magnitude of the anisotropy is the sharpness of the interfaces present. Thus, because of the inevitable loss of anisotropy associated with the presence of imperfect interfaces in the superlattice, it is clearly desirable to have a structure with a large intrinsic magnetocrystalline anisotropy.

In a recent experimental study, Bertero and Sinclair[10] observed improved coercivities and perpendicular anisotropies in sputtered (Pt/Co/Pt)/X superlattices, where X=Pd, Ag, or Cu, as compared to equivalent Co/X superlattices. The origin of the enhanced anisotropy was thought to result from either sharper interfaces, or an intrinsic property of (Pt/Co/Pt)/X superlattices. Bertero and Sinclair noted that in high resolution transmission electron microscopy images that the interfaces in the (Pt/Co/Pt)/Pd and Co/Pt superlattices appeared to be chemically sharp and of a similar quality, suggesting that the enhancement was an intrinsic property of the (Pt/Co/Pt)/Pd superlattice rather than through the production of better interfaces. However, this issue could not be unambiguously resolved, since reducing the number of Pt layers in the structure might be expected to improve the quality of the interface in Ar sputtered samples because of the reduction of backscattered Ar from the Pt target. First-principles electronic structure calculations predicted anisotropies of (1Pt/1Co/1Pt)/nPd that were several times larger than equivalent 1Co/nPt or 1Co/nPd superlattices.[11] The calculated enhancements were similar to those seen experimentally. Since the calculations all assumed perfect interfaces, it was concluded that this was an intrinsic effect.

In this paper, we use first-principles electronic structure calculations to study similar (Pd/Co/Pd)/X superlattices and compare the anisotropies to both Co/X and (Pt/Co/Pt)/X superlattices. In common with our previous first-principles studies of magnetic anisotropy we have used the layer Korringa–Kohn–Rostoker technique. This approach and its application to the calculation of magnetocrystalline anisotropy has been discussed in detail in several other publications.[4,7,12] In summary, the electronic structure for a perpendicular magnetization direction is solved self-consistently within the local spin density approximation, using the Janak, Moruzzi, and Williams parametrized functional to describe electronic exchange and correlation.[13] The muffin-tin approximation to the crystalline potential is assumed. The scalar relativistic Schrödinger equation including the spin–orbit term was solved within each muffin-tin sphere using the approach of Koelling and Harmon,[14] leading to a set of coupled differential equations. The longitudinal direction is then computed as a perturbation on the self-consistent perpendicular solution. The magnetic anisotropy is found from the force theorem by considering only the difference in

TABLE I. Superlattice anisotropy energies per Co atom.

System	Energy (Mergs/cm^3)	System	Energy (Mergs/cm^3)	System	Energy (Mergs/cm^3)
1Co/3Pt	110				
1Co/3Pd	90	1Co/3Ag	−33	1Co/3Cu	−2.6
1Pd/1Co/1Pd/1Pt	130	1Pd/1Co/1Pd/1Ag	107	1Pd/1Co/1Pd/1Cu	67
1Pt/1Co/1Pt/1Pd	320	1Pt/1Co/1Pt/1Ag	110	1Pt/1Co/1Pt/1Cu	76
1Pd/1Co/1Pd/3Pt	21	1Pd/1Co/1Pd/3Ag	8	1Pd/1Co/1Pd/3Cu	29
1Pt/1Co/1Pt/3Pd	240	1Pt/1Co/1Pt/3Ag	120	1Pt/1Co/1Pt/3Cu	23

the eigenvalue sum that is corrected for small changes in Fermi level associated with the change in magnetization direction.[15] This includes all first-order changes in the total energy. The approach yields essentially identical results compared to the difference in total energies of self-consistent calculations for perpendicular and longitudinal magnetization directions. Note that this is not quite the same as using the force theorem on calculations converged without the spin–orbit interaction. In the case of Co/Pt, we have found that this other approach introduces errors of about 10% in the anisotropy energy. As in previous work, care was taken to ensure convergence in all calculational parameters. The calculations[4] use 1620 special k points in the two-dimensional Brillouin zone, 48 energy points, and 13 plane waves. This Brillouin zone sampling corresponds roughly to 80 000 wave vectors in the three-dimensional Brillouin zone. The errors in the calculated anisotropies are estimated at about 7%. Convergence was demonstrated for Co/Pd superlattices by making comparisons to calculations which used larger basis sets.

All of the superlattices considered in this paper were assumed to be unstrained and to have a [111] orientation. The atomic positions are those of a fcc lattice whose lattice constant for each different structure was chosen to be a composition average of the elemental lattice constants. This choice of lattice constant is consistent with those lattice constants deduced from x-ray diffraction studies of [111] Co/Pt[16] and [111] Co/Pd systems.[17] In the results presented here, the demagnetization energy was not included. Since in a cubic system the demagnetization energy represents the dominant contribution to the volume anisotropy, the calculated anisotropies are, therefore, a measure of the interface anisotropies. In the superlattice geometry, the demagnetization energy always favors an in-plane anisotropy.

The calculated magnetic anisotropies of all the superlattices studied are shown in Table I. A positive (negative) number corresponds to perpendicular (in-plane) magnetocrystalline anisotropy. With the exception of 1Co/3Ag and 1Co/3Cu, all of the superlattices are computed to have perpendicular anisotropy, though in the case of 1Co/3Cu the anisotropy is smaller than the expected accuracy of the calculations. Superlattices with monolayers of the spacer all exhibit enhanced perpendicular anisotropy when compared to similar Co/X structures, and in the case where X is a noble metal the anisotropies are similar to those expected in Co/Pd or Co/Pt structures. The calculated anisotropy of (1Pd/1Co/1Pd)/1Pt is larger than that of either Co/Pt or Co/Pd, though it is significantly smaller than that seen in (1Pt/1Co/1Pt)/1Pd, a fact which probably reflects the smaller size of the spin–orbit interaction in Pd. The large enhancement calculated for (1Pt/1Co/1Pt)/nPd was first observed experimentally by Bertero and Sinclair;[10] these authors also found improved anisotropies and coercivities for (1Pt/1Co/1Pt)/Ag and (1Pt/1Co/1Pt)/Cu. Surprisingly, in (1Pd/1Co/1Pd)/3X superlattices, the anisotropy is sharply reduced. In contrast for (1Pt/1Co/1Pt)/3X superlattices, only the superlattice with a Cu spacer causes a similar reduction in anisotropy. In previous work,[4,7,8] we have used a near-neighbor Néel model to describe the magnetic anisotropy of fcc-based Co/Pd and Co/Pt superlattices. This model sums a pairwise interaction of the form $L(\mathbf{M}\cdot\mathbf{R})^2$ over all near-neighbor bonds ($\mathbf{M}$ and $\mathbf{R}$ are unit vectors representing the magnetization and interatomic separations). The interaction strength L depends only on the type of atoms under consideration. The Néel model reproduces the anisotropy of the Co/Pd and Co/Pt systems on average. Microscopic details of the electronic structure have been averaged into the interaction parameters which depend only on atomic type and not atomic environment. This model is applicable when the electronic structure of the superlattice is somewhat insensitive to the number and ordering of the constituent layers. Co/Pd and Co/Pt superlattices show this behavior, except for those structures containing a monolayer of Co. However, in (Pd/Co/Pd)/X and (Pd/Co/Pd)/X superlattices, the electronic structure is very sensitive to the number and ordering of the layers and thus a simple two-parameter Néel model is inadequate, not because the interaction is long ranged, but rather because the interaction parameters are not transferrable.

In Table II, we show the Co spin and orbital moments for all the superlattices studied. The Co layer contributes the dominant contribution to the anisotropy. Some insight into the calculated anisotropies can be obtained from Table II. The spin and orbital moments in all superlattices containing Cu are quite small. The size and anisotropy of the orbital moments and the magnetocrystalline anisotropy also depend upon the strength of spin–orbit coupling,[18] thus reduced orbital moments are concomitant with reduced anisotropy. In the other superlattices, where the Co l_z orbital moment is significant, it is found that the change in orbital moment between perpendicular and longitudinal magnetization directions correlates roughly with the size of the Co contribution to the magnetocrystalline anisotropy.

In conclusion, the anisotropy of (Pd/Co/Pd)/X and (Pt/Co/Pt)/X superlattices seem more sensitive to the environ-

ment than Co/X structures. Enhanced anisotropies are predicted for monolayers of X in both (Pd/Co/Pd)/X and (Pt/Co/Pt)/X systems. In the latter, there is experimental evidence of enhanced anisotropies and coercivities. The loss of anisotropy in the (Pd/Co/Pd)/3X superlattices is surprising and reflects the details of the electronic structure in these systems. Changes in Co orbital moment provide some insight into the subtle changes in electronic structure found in these sets of superlattices.

The full potential linearized augmented plane wave method and atomic force approach are employed for the theoretical determination of interface magnetocrystalline anisotropy (MCA) for superlattice systems of Co/Cu in (001), (110), and (111) orientations, and overlayer systems of the monolayer Co on Cu (111) substrate adsorbed by different further coverage of Cu. It is found in superlattices that the interface MCA is sensitive to the geometry arising from different orientations. In good agreement with experiment, the interface MCA with Cu overlayers is found to peak at 1 monolayer of Cu-coated Co/Cu(111) and then to decrease with further Cu deposition. In addition to the hybridization of electronic states at the Co/Cu interface, the interaction between the interface layers and the next-to-interface layers in superlattices and structure relaxation in overlayers may have a significant influence on the MCA of the Co layer.
[S0021-8979(96)21308-2]

A fundamental understanding of the magnetocrystalline anisotropy (MCA) arising from the interface between magnetic and nonmagnetic metal films is an important problem in magnetism that continues to receive a great deal of attention. Of particular interest are systems that display perpendicular magnetic orientations which are highly desirable for high density recording media. Examples of such systems include some Co/X (X=Cu,Ag,Pd,Pt) multilayers and short periodic superlattices, where for Co film thicknesses below a few atomic layers the magnetic easy axis is found to align perpendicular to the film plane.[1] The key to understanding interface MCA appears to be the clarification of structural and electronic influences. Experimentally, the study of the role of crystal orientation on the interface MCA of single-crystal Co/Pd superlattices grown along different crystal directions shows the interface contribution to MCA as independent of crystal structure.[2] On the other hand, an explicit demonstration of the orientational dependence was given by experiments on Co/Ni superlattices.[3] More interestingly, by an *in situ* polar Kerr effect measurement, it was found that the interface MCA shows anomalous changes in ultrathin molecular-beam-epitaxy-grown Co films with and without overlayers of various nonmagnetic metals (Ag,Cu,Pd). The perpendicular MCA is strongly peaked near 1 monolayer (ML) coverage, which is most pronounced for Cu, and the further Cu deposition causes a drastic decrease.[4]

Stimulated by these exciting experimental findings, we here present calculated MCA results for superlattice systems of Co/Cu with (001), (110), and (111) orientations, and overlayer systems of a Co ML on a Cu(111) substrate, and with ML and bilayer Cu depositions. The lattice constant is set equal to the ideal cubic Cu lattice ($a=4.83$ a.u.). For the superlattices, we use structures consisting of the repetition of magnetic Co MLs separated by n layers ($n\leqslant 5$) of nonmagnetic fcc (001), (110), and (111) Cu slabs. For the overlayers, the adatoms are put pseudomorphically over the fcc sites on the Cu(111) substrate and the vertical positions of all the atoms are optimized by calculating the atomic force acting on each atom based on the full potential linearized augmented plane wave (FLAPW) method. When self-consistency for the semirelativistic calculation is achieved, i.e., the average root mean square distance between the input and output charge densities and spin densities are less than 2×10^{-4} e/(a.u.)^3, the interface MCA is determined by calculating the torque at $\theta=45°$, where θ is the angle between the magnetization direction and the film plane.[5] As in the previous state-tracking approach (STA) treatment,[6] the occupancies of the perturbed states are determined by tracking the correct states from the unperturbed wave functions, owing to the adoption of self-consistent scalar relativistic charge/spin density. The convergence of the MCA energy with respect to the number of k points has been checked; we found that 120 k points in the irreducible Brillouin zone (Bz) is sufficient if an error bar of 0.025 meV/adatom for the MCA energy is allowed.

The calculated MCA can be simply related to the spin–orbit coupling (SOC) between the occupied and empty valence states. From a fundamental point of view, it is natural that the MCA should be sensitive to the geometry arising from different orientations. Owing to the spin–orbit interaction, the splitting and the shifting of electronic states depend on the magnetization direction. In the simple ML case, the lifting of twofold degeneracies is found to play an important role in determining the interface MCA of (001)- and (111)-oriented Co MLs.[7] It is therefore anticipated that a lower-symmetry interface, such as (110), which has no degeneracies, will exhibit a very different interface MCA. As shown in Table I, the calculated MCA shows an appreciable orientation dependence, and the most pronounced negative MCA

TABLE I. Orientation dependence of the interface (surface) MCA, ΔE^{sl} in meV (and in mJ/m^2 in parenthesis), and spin magnetic moment M (in μ_B) in isolated monolayer and superlattices.

Orientation	System	M	ΔE^{sl}	Exp. $(2K_s)$[a]
(001)	Co ML	2.06	−1.25(−3.07)	
	Co/Cu_1	1.67	0.02(0.05)

	Co/Cu_3	1.52	−0.12(−0.21)	−0.86
(111)	Co ML	1.83	−0.85(−2.41)	
	Co/Cu_2	1.51	0.06(0.17)	
	Co/Cu_5	1.58	0.10(0.28)	0.15

[a]From Ref. 1 in mJ/m^2 units.

is for (110), which gives almost twice as large a value as in the (001) case.

Upon contact with a nonmagnetic substrate at the interface, the energies and wave functions of the Co states, which are mainly out of plane d_{z^2} and $d_{xz,yz}$ states, will be changed by interfacial hybridization, which is expected to affect the strength of the SOC perturbation between these states, and thus the MCA energy. For the superlattices considered, the difference in geometry arising from different orientations will lead to different hybridization strength, and this is also confirmed by the calculated magnetic moments given in Table I. In fairly good agreement with experiment, the easy axes for (001)- and (111)-oriented Co/Cu superlattices are perpendicular, while the (110)-oriented Co/Cu gives an in-plane one.

More interestingly, for (001)-oriented Co/Cu superlattices, when the Cu spacer increases from 1 to 3 MLs, the interface MCA changes appreciably. The reason is that when the spacer Cu slab becomes thicker than 1 ML, the Cu d band is broadened due to the Cu–Cu interaction, and the top of the Cu d band is brought closer to the bonding Co d bands. These Cu bands strongly interact with the bonding Co bands, resulting in an upward shift of these Co bands. Now, the direct interaction between the Co layer and its next-nearest neighbor (nnn) layer is expected to be weak; however, this nnn layer strongly influences the interface Cu layer. It is this influence which leads, in turn, to the appreciable change of the Co bands and to the prominent change of the interface MCA.

For clean, ML and bilayer Cu-coated Co/Cu overlayers, the theoretical interface MCA is found to be highly sensitive to the presence of the Cu adsorbate and to structural relaxation. The clean Co/Cu(111) results show that the easy axis is in-plane, and switches to perpendicular when capped with 1 ML of Cu. Deposition of the second Cu layer leads to a decrease of the interface MCA. From the comparison with the calculated MCA for unrelaxed structures, it is found that the peaked feature is more pronounced owing to the interface relaxation, as can be seen from Table II.

In Fig. 1, we present the calculated density of states (DOS) for spin down d states of Co atoms. The different hybridization between Co and Cu due to structural changes

TABLE II. Calculated ΔE^{sl} (in meV) and spin magnetic moment M (in μ_B) of Co atoms in Co/Cu with different Cu coverage; the results for unrelaxed structures are shown in parenthesis.

Cu coverage	Clean	1 ML	2 ML
M	1.57(1.60)	1.26 (1.40)	1.37(1.41)
ΔE^{sl}	−0.30(−0.31)	0.23 (0.08)	−0.02(−0.05)

in the interface is clearly shown by the DOS peaks in the range of −1.0 to 1.0 eV with respect to E_F. Especially for the peak just below the E_F, there is an abrupt change versus Cu coverage, namely, when the Cu coverage varies, the location and the height of this peak is greatly enhanced and reaches a maximum with 1 ML coverage. This feature is consistent with the magnetic moment of Co in these systems. As shown in Table II, for the clean case, the magnetic Co is at the surface, and the hybridization between magnetic Co and nonmagnetic Cu atoms is expected to be weak. The presence of the interface Cu atom instead of vacuum is shown to reduce the magnetic moment of Co, through the strong interaction and hybridization.

Now it is clear that the effects of the nonmagnetic substrates on the Co MCA arise mainly from the hybridization with the Co-d_{z^2} and Co-$d_{xz,yz}$ states. Obviously, as revealed in an effective ligand interaction model (ELIM),[8] (i) the energy separation between the Co and substrate d bands and (ii) the strength of the interfacial hybridization plays a key role in determining the MCA energy. The stronger the hybridization, the more the perpendicular MCA prevails. This makes a connection between the interface MCA and the above DOS features, i.e., through hybridization. The presence of the Cu overlayer results in an upward shift of these bonding Co states, which mainly are out-of-plane Co-d_{z^2} and Co-$d_{xz,yz}$ states in the Bz, and a strongly positive MCA con-

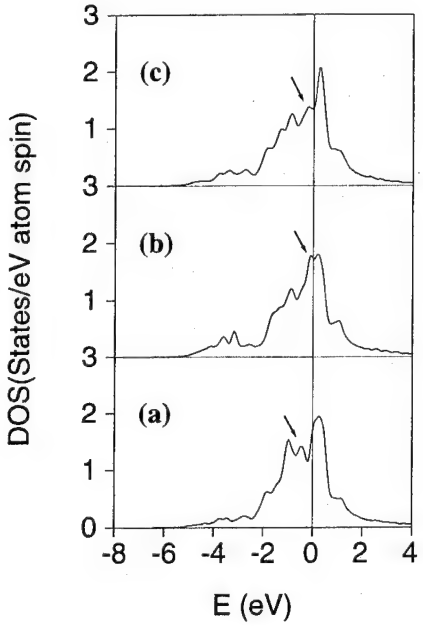

FIG. 1. Projected density of states for Co spin down d states for: (a) clean Co/Cu; (b) 1 ML Cu-coated Co/Cu; (c) 2 ML Cu-coated Co/Cu.

tribution exists through l_z coupling between occupied d_{xz} and empty d_{yz} bands. The presence of a Cu adsorption layer instead of vacuum is somewhat similar to the Co/Pd case,[9] where, due to hybridization, the large d—d bonding strength and high energy of the Pd d band cause a substantial component of the out-of-plane bonding Co states to be shifted upward, and thus lead to a strong perpendicular interface MCA.

A similar argument can be applied to explain why the second Cu layer deposition leads to a decrease in the interface MCA. Note that for bilayer Cu coverage, the interface Cu is located at subsurface, while in ML Cu coverage, the interface Cu is at the surface. Obviously, the energies of the d orbitals for surface Cu atoms are higher than those of subsurface Cu atoms, because the subsurface Cu atom is more bulklike. The strength of the Co–Cu hybridization will be stronger if the interface Cu atom is located at the surface, and thus a more positive MCA results.

When relaxation is introduced, the positive MCA is enhanced for the 1 ML Cu coverage (cf. Table II). This can be understood from the strength of the interfacial hybridization. Owing to the relaxation, the interatomic distance between Co and Cu in the ML Cu-coated case is the smallest, and then has the strongest hybridization. For bilayer Cu, the relaxation of Co and interface Cu atoms is released by the screening, the interatomic distance between Co and interface Cu is increased, and then weakens the interaction, and thus the positive contribution to interface MCA is expected to become smaller.

This is to be compared with the Co/Cu(001) overlayer and sandwich systems,[8] where the downward shift of out-of-plane states responsible for the interface MCA changes the result from a more negative MCA (−0.38 meV) in the overlayer to near zero (−0.01 meV) in sandwich. Here in the Co/Cu(111) overlayer with different Cu coverage, the MCA change is caused by two effects, the presence of the interface and relaxation. On the Co/Cu surface, due to the surface effect the energy of the coated Cu d band was brought closer to the bonding Co d bands and thus have strong interaction with the out-of-plane Co states; this results in an upward shift of these Co bands, and a strong positive MCA contribution exists through l_z coupling between occupied d_{xz} and empty d_{yz} bands. More Cu deposition is expected to decrease the surface effect on the Co/Cu interface and then weaken the interaction strength, and thus the interface MCA decreases drastically.

We present a study of the magnetic properties of compact Cr clusters deposited on Fe(001). A Cr monolayer deposited on Fe(001) is found to be $c(2\times2)$ ferrimagnetic (AP) and the moments of a single adatom and very small clusters are antiferromagnetically aligned with the Fe substrate moments (P). Therefore a transition from P to AP order is expected when the cluster size increases. An Ising model is used to model the magnetic energy of two geometric configurations, a square-shaped and a diamond-shaped cluster. Self-consistent tight-binding calculations allow us to determine the P to AP transition which is obtained for a 400 adatoms square-shaped cluster. The pair magnetic energies have been estimated to -105.7 meV for the first neighbors Fe–Cr interaction and to -111.3 meV for the second neighbors Cr–Cr interaction in the Ising model. © *1996 American Institute of Physics.* [S0021-8979(96)21408-9]

I. INTRODUCTION

The magnetic behavior of chromium deposited on a ferromagnetic iron substrate has been extensively studied during the last decade,[1–17] because of the interesting properties of Fe/Cr superlattices. First theoretical studies with tight-binding[1] and FLAPW band structure calculations[2] predicted that the monolayer (001) Cr is ferromagnetic and antiferromagnetically aligned with Fe(001), with large Cr moments nearly equal to 3 μ_B. Nevertheless, either the most recent experimental studies cannot estimate the moment[3] or are in discrepancy on its value.[4,8] Hence, Jungblut *et al.*[4] found an average Cr moment of 1 μ_B and Idzerda *et al.*[8] found 0.6 μ_B for low coverages, whereas several authors[5–6,9] supposed a giant moment or observed Cr magnetic "dead layer".[10] Following Blügel,[11] who displayed within FLAPW an antiferromagnetic $c(2\times2)$ configuration as the most stable solution for the free-standing Cr monolayer and a $c(2\times2)$ ferrimagnetic solution for Cr on Pd and Ag, tight-binding studies[12,15] predicted a $c(2\times2)$ ferrimagnetic solution as the most stable state for the Cr monolayer on Fe(001). The energy difference per adatom with the usual $p(1\times1)$ ferromagnetic solution is found to be small ($\simeq$20 meV) and of the order of the room temperature excitation energy. Following Vega *et al.*,[12] both solutions can coexist at room temperature and the experimental determinations of both the chromium magnetic structure and magnetic moment may become harder. In this paper, we investigate the magnetic transition from the ferromagnetic small clusters toward the $c(2\times2)$ ferrimagnetic monolayer of Cr deposited on Fe(001), increasing the size of the clusters for two different shapes (square, diamond). Section II is devoted to the model of the magnetic configurations with a two parameters Ising model. Tight-binding calculation results are summarized in Sec. III and we conclude in Sec. IV.

II. ISING MODEL

Our aim is to determine which of the $p(1\times1)$ ferromagnetic (P) and of the $c(2\times2)$ ferrimagnetic (AP) case is the most stable state for a given two-dimensional (2D) cluster. The relative stability is obtained by calculating the difference $\delta E_{P-AP}=E_P-E_{AP}$ between the band energy of both magnetic configurations. The lattice parameter of Fe and Cr being very similar, we do not expect buckling like in the case of Mn on Fe(001).[16]

If we consider a closed packed 2D cluster with any shape, the inner adatoms look like monolayer adatoms and the AP configuration should be more stable than the P one. On the other hand, adatoms located at the cluster sides look like less-coordinated adatoms in the small ferromagnetic clusters. Therefore a competition between these two contributions occurs: (i) one contribution favors the AP configuration and is proportional to the cluster area (surface effect) and (ii) the second one favors the P configuration and is proportional to the perimeter area (side effect). In order to confirm this phenomenological description, we derive the analytical expressions for δE_{P-AP} using a simple Ising model. We consider only the Cr–Fe first neighbors (J_1) and Cr–Cr second neighbors (J_2) magnetic interactions. We expect $J_1<0$ favoring the antiferromagnetic coupling between the Cr adatom and the Fe surface and $J_2<0$ favoring the $c(2\times2)$ antiferromagnetic order in the cluster. The magnetic energy for a given configuration is

$$E_m=\sum_{i=1}^{N_{\mathrm{ad}}}\left(-\sum_{\langle i,j\rangle}J_1\mathbf{S}_i^{\mathrm{Cr}}\mathbf{S}_j^{\mathrm{Fe}}-\frac{1}{2}\sum_{\langle i,j\rangle}J_2\mathbf{S}_i^{\mathrm{Cr}}\mathbf{S}_j^{\mathrm{Cr}}\right) \tag{1}$$

with N_{ad} being the adatoms number in the cluster. We consider two different configurations, a square-shaped cluster (Fig. 1) and a diamond-shaped cluster. We expect a strong side effect for the first one because of several Cr adatoms

 0021-8979/96/79(8)/5834/3/$10.00

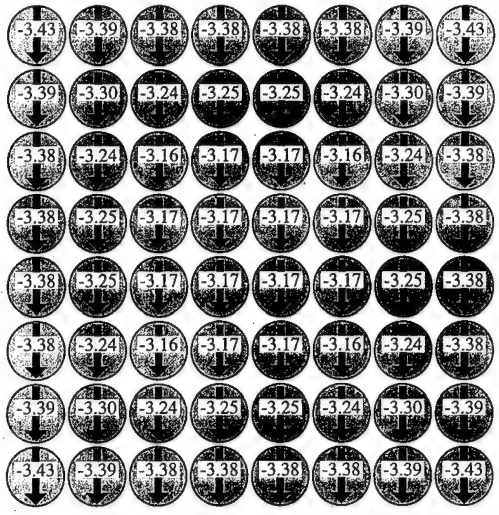

FIG. 1. Magnetic moments of a Cr 64 adatoms square-shaped cluster with a ferromagnetic order and antiferromagnetically aligned with Fe(001) (P configuration). The arrows display magnitude and direction of the local magnetic moment.

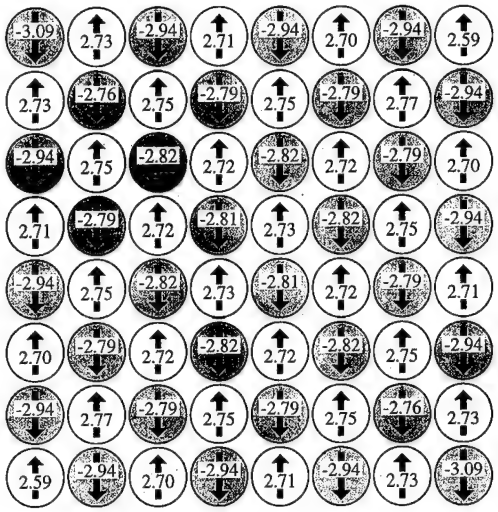

FIG. 2. Magnetic moments of a Cr 64 adatoms square-shaped cluster with a $c(2\times2)$ ferrimagnetic order (AP configuration).

located on the edges and ferromagnetically aligned with Fe (Cr–Fe frustrated link). On the other hand we consider diamond-shaped clusters which keep the $c(2\times2)$ magnetic order and include only Cr adatoms antiferromagnetically aligned with Fe (Cr–Fe nonfrustrated link) on the edges. Therefore the side effect must be very weak.

If x is the cluster size parameter (in units of a_0 for square-shaped clusters and $\sqrt{2}a_0$ for diamond-shaped clusters), we derive the following expression for the square:

$$\delta E_{P-AP}=4x^2(J_1-J_2)+4x(2J_1-J_2)+4J_1 \tag{2}$$

and, for the diamond,

$$\delta E_{P-AP}=4x^2(J_1-J_2). \tag{3}$$

The surface effect depends on the competition between J_1 and J_2 in both geometries. It is expected that the Cr–Cr interaction J_2 is stronger than the Cr–Fe one and the surface effect contribution is positive ($|J_1|<|J_2|$) to favor the AP configuration. We also note that (i) the constant term in the square case comes from the corners and (ii) the AP configuration is already the most stable state for the smallest diamond cluster (5 adatoms).

III. TIGHT-BINDING CALCULATIONS

We report here the results of tight-binding calculations with the two cluster geometries considered above. This study is still our of reach for *ab initio* techniques[17] due to the large number of inequivalent atoms. For example, we investigate a cluster composed of 400 Cr adatoms which yield about 1100 inequivalent atoms in the Cr/Fe system. The self-consistent calculations have been done in the mean-field approximation, with the local neutrality approximation.[13] The Cr and Fe lattice parameters being very close, we assume that the atoms are located on a perfect Fe lattice and are not allowed to relax.[1,2,11–13] Calculations made with our parameters[13] give a Cr AP monolayer deposited on Fe(001) as the most stable state, the energy difference per adatom with P being $\delta E_{P-AP}=22.4$ meV. The Cr magnetic moments are equal to $-3.19\ \mu_B$ in the P state and $-2.81\ \mu_B$ and $2.72\ \mu_B$ in the AP state. These value agree with *ab initio* calculations of Freeman *et al.*[2] who found $-3.1\ \mu_B$ (P case).

The x parameter of the first section is the square or diamond side length. For both cases, we compute for P (Fig. 1) and AP (Fig. 2) magnetic configurations with x ranging from 1 until an asymptotic value for which the monolayer properties are recovered. Figure 1 shows the Cr adatoms magnetic moments for $x=7$ (64 adatoms square) in the P configuration. The adatoms located in the center of the cluster carry a magnetic moment close to the P monolayer values. The AP configuration in Fig. 2 also shows the same feature. This shows that the magnetic interaction is short ranged and this justifies the use of only nearest-neighbor interactions in the Ising model. The empirical rule predicting an enhanced moment for less-coordinated atoms is here well suited for the nonfrustrated adatoms. On the contrary, in the wedges for example, the frustrated less-coordinated adatoms carry a reduced moment (Fig. 2). The calculations for large x do not lead to strong modifications of these conclusions. We only note that we have to compute clusters with very large x in order to recover the exact monolayer magnetic moment in the cluster center. For the diamond-shaped configuration the same main features remain valid.

Figures 3 and 4 show the energy difference between P and AP configurations versus the size parameter x for both the square and diamond geometries. A quadratic expression fits our calculated data with an excellent agreement in both cases. We deduce that the phenomenological argument exposed in the second section and the Ising expressions derived are well suited for this problem. For the diamond curve, we found that the transition $P-AP$ ($\delta E=0$) does not happen for $x=0$ as expected but for $x\simeq1.7$. In fact, for small clusters, there are large variations of the Cr adatoms magnetic moment whereas the Ising model suppose J parameters are constant. Large clusters are more suited for such a description.

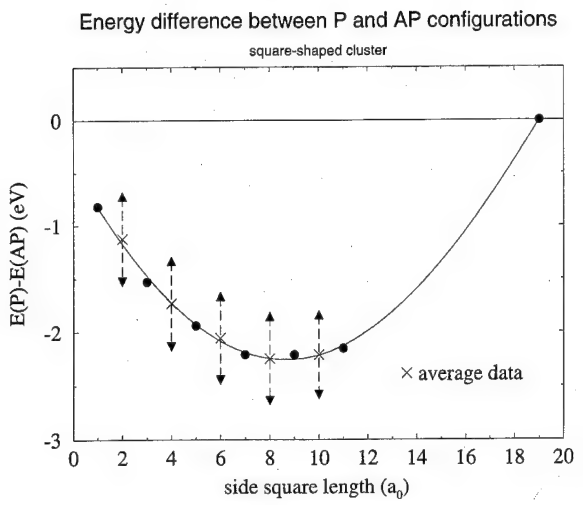

FIG. 3. Energy difference between P and AP configurations (square-shaped cluster) vs the length of one edge (size parameter x). The filled circles show the results of the tight-binding calculations and the curve is the quadratic fit. For an odd number of adatoms, there are two possible AP configurations, one with one more spin up atom (filled triangle up) and the other with one more spin down atom (filled triangle down). The analytical expressions of the first section being derived for geometries with an even number of adatoms, we use the arithmetical mean (crosses). Note that the transition ($\delta E = 0$) happens for a large size (400 adatoms cluster).

Anyhow it does not matter since the considered energy difference in this range is small. For the other case, we investigated a 400 adatoms square ($x=19$) and more than 1100 inequivalent atoms to get a transition for $x \simeq 19$. The curves associated with expressions (2) and (3) allow us to determine the J_1 and J_2 parameters. We found that $J_1 = -105.7$ meV and $J_2 = -111.3$ meV. As explained in Sec. II, both are negative to favor antiparallel coupling between Cr and Fe on the one hand, and between Cr and Cr on the other hand. Moreover, we get $|J_1| < |J_2|$ meaning that the Cr–Cr interaction is stronger than the Cr–Fe interaction and the AP configuration is favored for the monolayer as expected.

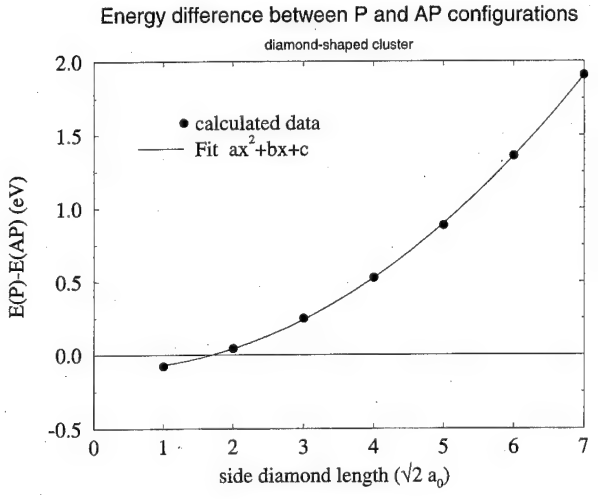

FIG. 4. Energy difference between P and AP configurations (diamond-shaped cluster) vs the length of one edge (size parameter x). The filled circles show the results of the tight-binding calculations and the curve is the quadratic fit.

IV. CONCLUSION

In spite of the lack of experimental confirmations, the most stable state for a Cr monolayer adsorbed on Fe(001) was expected to be ferromagnetic. But recent theoretical investigations have suggested that the $c(2\times2)$ ferrimagnetic configuration may be the most stable state. In this framework, we have investigated the onset of $c(2\times2)$ magnetism in small clusters as a function of their sizes. First we model the magnetic interactions with a simple two-parameters Ising model, for two geometries (a square and a diamond). Then self-consistent tight-binding calculations have been done for each cluster as a function of the size from which we deduced the magnetic transition for a 400 adatoms square-shaped cluster. The Ising parameters, i.e., the pair magnetic energy, have been estimated to $J_1 = -105.7$ meV for the first neighbor Fe–Cr interaction and to $J_2 = -111.3$ meV for the second neighbor Cr–Cr interaction.

New magnetic configurations are under study and may give us more insights for the magnetism of Cr/Fe(001). In spite of its crudeness, the Ising model accurately reproduces the magnetic properties. However, for more complex structures, it seems necessary to take into account more parameters as the third-neighbor Cr–Cr interaction for example. Results about these calculations will be reported soon.

On the γ-like surface of α-Ce: Theory (abstract)

O. Hjortstam, J. Trygg, B. Johansson, and O. Eriksson
Department of Physics, Uppsala University, Box 530, S-751 21 Uppsala, Sweden

J. M. Wills
Theoretical Division, Los Alamos National Laboratory, Los Alamos, New Mexico 87544

We have shown theoretically, by means of a full-potential LMTO method in a slab geometry, that the topmost surface layer of α-Ce is γ-like. The calculations are fully relativistic and include all electrons. Also an orbital correction to the f-electron states is included to allow for f localization. For the topmost layer the spin moment is found to be 0.70 μ_B for the f electrons and 0.08 μ_B for the d-electron states while the orbital moment from the f electrons is found to be -1.07 μ_B. These moments correspond well to the moments calculated for bulk γ-Ce which are 0.63, 0.07, and -0.87 μ_B, respectively. The subsurface and lower lying layers are calculated to have spin and orbital moments close to zero. We therefore conclude that the topmost layer on the α-Ce surface is γ-like while the subsurface and lower lying layers are similar to bulk α-Ce. Our findings explain recent photoemission experiments on this material and provide a theoretical foundation for the interpretation of these experiments. The fact that our theory assumes that α-Ce has delocalized f electrons, and the agreement with the interpretation of photoemission experiments, gives support that the Mott transition model for the $\alpha \rightarrow \gamma$ phase transition is correct. Spin polarization of the conduction bands and secondary electrons of Gd(0001)

Dongqi Li, J. Pearson, and S. D. Bader
Materials Science Division, Argonne National Laboratory, Argonne, Illinois 60439

D. N. McIlroy, C. Waldfried, and P. A. Dowben
Department of Physics, University of Nebraska, Lincoln, Nebraska 68588

Angle- and spin-resolved photoemission was utilized to investigate the $5d$ bulk bands and the surface state of Gd(0001) in the temperature range of 130–350 K. The bulk bands at 1–2 eV below the Fermi energy E_F show Stoner-like behavior, while the temperature dependence of the surface state near E_F indicates spin-mixing behavior due to fluctuating local $5d$ moments. The secondary electron spectra of the Gd surfaces both before and after initial oxygen adsorption show a polarization dip at low kinetic energies due to the extra scattering channel for minority electrons via the unoccupied $4f$ level. The temperature dependencies of the surface and bulk magnetization are separated using the spin polarization of the surface state and the bulk exchange splitting. © *1996 American Institute of Physics.* [S0021-8979(96)21508-5]

Surface magnetism of the heavy rare earth metals has been the subject of great interest because of the unique phenomena exhibited. The Curie temperature T_C of the Gd and Tb surfaces are reported to be significantly higher than that of the bulk.[1–4] There is also evidence that the magnetic moments at the surface are canted out of the surface plane,[3,5] while the bulk of the Gd(0001) films, <400 Å thick, have in-plane anisotropy.[6] The enhanced surface magnetic order is believed to originate from the surface electronic structure, namely, a magnetic surface state near the Fermi energy E_F located around the Brillouin zone center.[7–9] The $5d$ bulk bands appear in spin-integrated photoemission at binding energies of 1–2 eV and exhibit a temperature-dependent exchange splitting Δ_b.[10,11]

The study of surface magnetic order depends on separating the surface signal from that of the bulk. This has been accomplished previously by comparing relatively surface-sensitive techniques, like spin-polarized low energy electron diffraction,[1] spin-polarized secondary electron spectroscopy,[3] to a bulk measurement, or taking advantage of the surface core level shift of the Gd $4f$ levels.[3–5] Even with these techniques, it is still difficult to unambiguously distinguish the surface and the bulk. In the present work, we use the spin polarization of a magnetic surface state as an indicator of the surface magnetic order, and Δ_b as the bulk indicator to separate the two. The temperature dependance of the exchange splitting itself is a very interesting issue, since theories for finite temperature magnetism of itinerant electron systems are less developed than ground state theories. In addition, we examine the spin polarization of the secondary electrons, both as an additional indicator of the magnetization and to understand the anomalous polarization dip at low energy.[12]

Spin-polarized photoemission experiments were performed on the U5 undulator beamline of NSLS at Brookhaven National Laboratory. The ultrahigh vacuum chamber is equipped with low energy electron diffraction and a hemispherical electron energy analyzer with a low-energy spin detector. The details of the experimental setup are described elsewhere.[13] The sample preparation followed previous procedures.[10,14] The W(110) single-crystal substrate was cleaned by flashing and annealing in oxygen. The nominally 80-Å-thick epitaxial Gd(0001) films were deposited thermally onto the room-temperature substrate and subsequently annealed to 780 K to improve the structural ordering and magnetic properties.[15] The chamber pressure remained $<5\times10^{-11}$ Torr during the process to ensure cleanliness. Films made by similar procedures are known to have single domains with in-plane magnetization and low coercivities. The spin polarization was measured in the remanent state after the sample was magnetized in-plane with a pulse field. The samples show no sign of hydrogen or carbon contamination, although the annealed films have a trace amount of oxygen that is equivalent to <0.05 L (1 L$=1\times10^{-6}$ Torr s) oxygen exposure at room temperature. All photoemission spectra were taken at normal emission with the light incident at an angle of 65°. The photoemission spectra of the conduction bands were taken at $h\nu=32.7$ eV and the secondary electrons at 69.5 eV. The sample was biased to −30 V to minimize the stray field effects.

Typical spin-polarized photoemission spectra at different temperatures are shown in Fig. 1. The peak near E_F is the surface state of Gd(0001), which is responsible for the enhanced magnetic ordering of the Gd surface.[7–9] This feature is strongly spin polarized at low temperature, and the polarization has the same sign as that of the occupied $4f$ feature at 8.6 eV binding energy (not shown in the figure). With increased temperature, the spin polarization of the surface state decreases and approaches zero, while the peak position and intensity show no change. The minority-spin counterpart of this state has been observed as an unoccupied state above E_F with inverse photoemission.[16,17]

The bulk bands at 1–2 eV exhibit a different temperature dependence. At low temperature there are two well-defined peaks with opposite spin polarization. They are the majority and minority spin branches of the $5d$ bulk band at Γ, separated by Δ_b (with the former at higher binding energy). Note that the sign of the spin polarization of the surface state is the same as that of the majority-spin bulk band. This confirms that the surface state is of majority spin character and that the surface couples to the bulk ferromagnetically[5,18] instead of

 0021-8979/96/79(8)/5838/3/$10.00

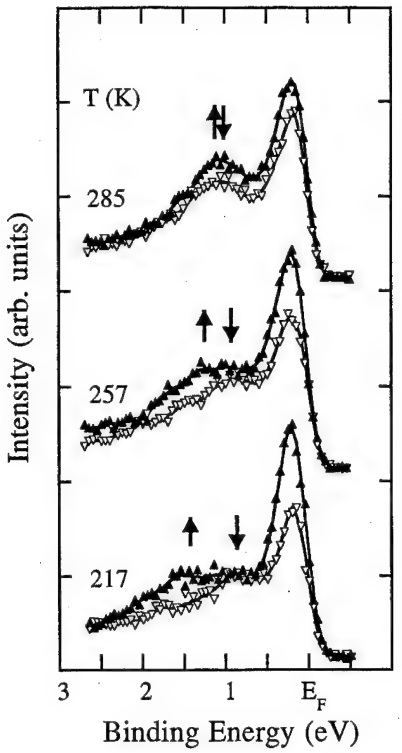

FIG. 1. Spin-polarized photoemission spectra at different temperatures at normal emission. The majority- and minority-spin components are shown with solid (up) and open (down) triangles, respectively. The majority- and minority-spin bulk bands are marked with up and down arrows. The solid lines are to guide the eye.

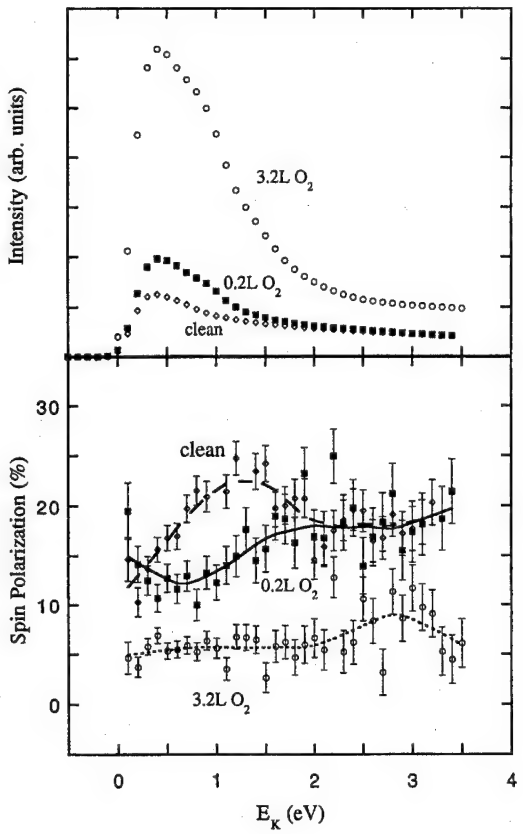

FIG. 2. Intensity and spin polarization of the secondary electron emission vs electron kinetic energy E_k. The measurements were taken at 130 K on clean Gd(0001) and after 0.2 and 3.2 L of oxygen exposure. The lines are to guide the eye.

antiferromagnetically.[1] With increased temperature the two peaks with distinct spin character shift toward each other and eventually overlap to form one peak with no spin polarization. In other words, Δ_b decreases and approaches zero upon warming to T_C.

The temperature dependence of the bulk bands is characteristic of Stoner-like[19] behavior, where the exchange splitting Δ of the itinerant electrons directly correlates with the macroscopic magnetization and approaches zero as $T \rightarrow T_C$. The surface state, however, does not show an energy shift or intensity change near T_C, while the spin polarization varies significantly. This suggests that, instead of Stoner-like behavior, the local Δ of the surface state (Δ_s) does not go to zero at the surface Curie temperature T_{Cs}. Such non-Stoner-like behavior is common among transition metals, although they were the original subject of the Stoner model.[19] This is usually attributed to the existence of local moments or short range order above T_C.[20–22] We believe that the difference originates from the different degree of itinerancy of the electrons, as discussed elsewhere.[14]

The secondary electrons are also spin polarized, as shown in Fig. 2. The intensity of the secondary electron emission increases with oxygen exposure as oxygen atoms enhance the inelastic scattering in Gd. For the clean Gd(0001) surface, the spin polarization shows a dip when the kinetic energy of the electrons $E_k < 1.5$ eV. This polarization anomaly, first observed by Tang *et al.*,[12] is in contrast to the polarization increase at low E_k for transition metal surfaces. Tang *et al.* suggested that an additional channel for the emission of minority spin electrons exists. The ordinary inelastic scattering of the hot electrons is determined by the unoccupied conduction bands, which provides the available states to scatter into. The unoccupied $4f$ state above the vacuum level, i.e., $4f$,[8] could behave as an additional intermediate, where the minority hot electrons experience quasielastic scattering and emit to vacuum. This channel should selectively enhance the emission of minority spin electrons with $E_k \sim E_{4f} - E_v$, where E_{4f} is the energy of the empty $4f$ level above E_F and E_v is the vacuum level. For the clean Gd surface, the unoccupied $4f$ level is at 4.1 eV above E_F and $\sim$0.8–0.9 eV above E_v. Taking the width of the empty $4f$ levels ($\sim$1.5 eV)[23] into consideration, this possible mechanism explains the drop of spin polarization for $E_k < 1.5$ eV. Our data from the samples with initial oxygen adsorption supports such a hypothesis. Figure 2 shows that 0.2 L of oxygen exposure causes the onset of the spin-polarization dip to shift to higher energy by $\sim$0.6 eV. This is consistent with the shift of the empty $4f$ level away from the E_F with oxygen adsorption due to reduced screening.[23] With 0.2 L of oxygen, the empty $4f$ levels shift away from E_F by 0.2–0.3 eV (Ref. 23) while the work function drops by 0.2–0.3 eV.[24] This results in the empty $4f$ levels shifting up $\sim$0.5 eV with respect to E_v, consistent within experimental error with the 0.6 eV shift of the onset of the polarization dip. Other pos-

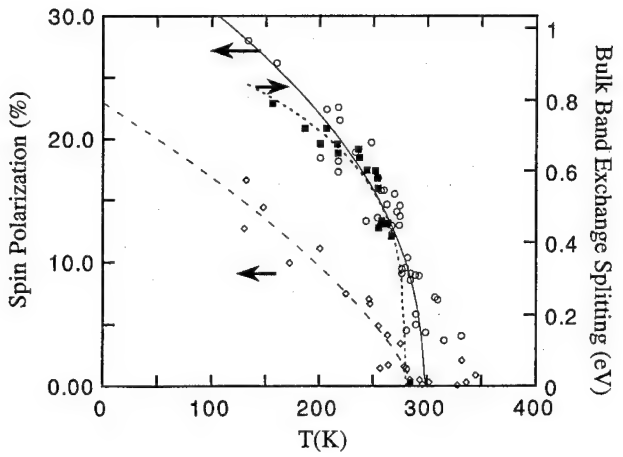

FIG. 3. Temperature dependence of the bulk band exchange splitting (squares), and the spin polarization of the surface state (circles) and secondary electrons (diamonds). The lines are to guide the eye.

sible scattering channels fail to provide the correct energy or the oxygen-induced shift of the dip. With additional oxygen dosing, the overall spin polarization drops further as the oxygen destroys the surface magnetic order of Gd, and the dip disappears as both the $4f$ and the valence band lose the net spin polarization. The effect of oxygen adsorption on the surface magnetization of Gd(0001) will be discussed further elsewhere.[25]

The spin polarization of the surface state and the secondary electrons and Δ_b are all correlated to the magnetization of the Gd(0001), though in somewhat different ways. The surface-state polarization reflects the purely magnetic order of the surface, and Δ_b reflects that of the bulk. The polarization of the secondary electrons should provide the mixed information from both the surface and the bulk. Figure 3 shows the temperature dependence of all three quantities. The spin polarization of the secondary electrons was measured at $E_k=3-4$ eV to avoid the anomaly at low energy, as discussed above. All quantities decrease with increasing temperature. The spin polarization of the secondary electrons and Δ_b approach zero before the surface-state polarization, as is consistent with $T_{Cs}>T_{Cb}$. This enhanced magnetic order can also be seen from Fig. 1, where $\Delta_b=0$ within experimental error, while the surface state and the background remain spin polarized. From Fig. 3, we find $T_{Cb}=283\pm10$ K and $T_{Cs}=297\pm10$ K, with the accuracy limited by the signal-to-noise ratio.

In conclusion, we have studied the spin polarization of the conduction bands and secondary electrons of Gd(0001) at different temperatures. The $5d$ bulk band shows Stoner-like behavior at the Brillouin zone center, while the surface state has a nonzero exchange splitting even above T_C. The anomaly in secondary electron polarization for both the clean and oxygen-adsorbed surfaces is discussed in terms of an extra scattering channel via the empty $4f$ levels. The shift in the polarization dip to higher kinetic energy with initial oxygen adsorption is consistent with the chemical shift of the empty $4f$ levels. In addition, our results are consistent with the enhanced magnetic order of the Gd(0001) surface.

Spin-resolved electron spectroscopies of epitaxial magnetite (001) (abstract)

Kimberly A. Shaw, Eric Lochner, David M. Lind, Rebecca C. DiBari, Plamen Stoyanov, and Brian Singer
Florida State University, Department of Physics, MARTECH, and the National High Magnetic Field Laboratory, Tallahassee, Florida 32306-3016

We will present the first spin-resolving electron spectroscopic studies of a magnetite (Fe_3O_4)(001) surface. Magnetite is a semimetal with a high density of states in the minority band, but a large band gap in the majority states at the Fermi energy. The polarization of the secondary emission cascade is measured using spin-resolved secondary electron emission spectroscopy (SRSEES), and reflects the semimetallic spin structure of Fe_3O_4. The polarization plateau of spin-resolved secondary emission (29.8%) matches the average 3D band polarization of stoichiometric Fe_3O_4 as determined from spin-resolved band structure calculations (34.2%). An enhancement of the polarization of the secondary electrons at lowest energies will also be discussed. Spin-resolved Auger emission spectroscopy (SRAES) of the Fe_3O_4 films have been measured and show correlation effects in the valence-valence Auger transitions. Suppressed intensity and polarization of $M_{23}M_{45}M_{45}$ Auger emission relative to $M_1M_{45}M_{45}$ Auger emission is observed, as well as strong resonant emission with shake-up. Conversely, no spin polarization is detected in the spin-resolved oxygen *LMM* Auger features, although oxygen Auger emission (in which we can distinguish between adsorbed and bonded oxygen) is used to verify surface cleanliness of the samples. The synthesis of Fe_3O_4 films grown on magnesium oxide (001) substrates using oxygen plasma-assisted molecular beam epitaxy will be discussed, as will thin-film characterization using SQUID magnetometry and x-ray and electron diffraction. A unique angle-, energy-, and spin-resolved electron spectrometer has been designed and built for the study of magnetic surfaces, and these studies represent its' first use. That spectrometer is based on a tandem configuration of an energy-dispersive energy analyzer and Mott spin polarimeter. [S0021-8979(96)82608-0]

Origins of giant biquadratic coupling in CoFe/Mn/CoFe sandwich structures (abstract)

Norman C. Koon
Code 6342, Naval Research Laboratory, Washington, DC 20375

Recently Filipkowski *et al.*[1] reported extremely strong, near 90 degree coupling of 2.5 erg/cm^2 for epitaxial sandwiches of CoFe/Mn/CoFe, where the CoFe composition was chosen to be a good lattice match to Mn. Both CoFe and Mn have the bcc structure, but Mn is antiferromagnetic while CoFe is ferromagnetic. It was found that the data were very well described by a simple model due to Slonczewski,[2] in which the interlayer coupling is given by $F_c = C_+(\varphi 1 - \varphi 2)^2 + C_-(\varphi 1 - \varphi 2 - \pi)^2$. While this model describes the data much better than the usual biquadratic form, it still does not connect directly to the microscopic origins of the effect. In the present work we seek to explain the results[1] in terms of normal bilinear exchange and magnetocrystalline anisotropy, together with reasonable assumptions about the structure of the interfaces. We obtain excellent agreement with both the experimental results and the Slonczewski model under the assumptions that at least one of the two CoFe/Mn interfaces is smooth (i.e., atomically flat) on a length scale comparable to or greater than the thickness of the Mn layer and at least one interface is rough on a scale less than approximately a domain wall thickness. A micromagnetic study for the spin–reorientation transition in ultrathin magnetic films is reported. Phase diagrams of the magnetization configuration are presented. Scaling relations among the film thickness, exchange coupling, and magnetic anisotropies are revealed. Formulas are given for the energy stored in the film per unit area, which enable one to evaluate the surface anisotropy by ferromagnetic resonance techniques. © *1996 American Institute of Physics.*

I. INTRODUCTION

Much attention has been paid to metallic thin films in recent years, since sophisticated epitaxial techniques enable one to control the film thickness, surface condition, and interface smoothness between films, and many new phenomena such as giant magnetoresistance[1] and square hysteresis loops and giant magneto-optical effects[2] have been observed. It is found experimentally in ultrathin transition metals sandwiched by noble metals that the easy-axis direction of magnetization changes as a function of thickness of the magnetic films:[3] At lower thickness it is normal to the film plane, while at higher thickness it lies in the film plane. This spin–reorientation transition is the result of competition between two different magnetic anisotropies: a surface anisotropy normal to the film exists because of the breaking of translational symmetry in the electronic structure at the interface,[4] and it has been measured by ferromagnetic resonance techniques.[5] On the other hand, the dipole–dipole interaction in thin films produces a strong in-plane shape anisotropy. The understanding of the stable magnetization state and magnetization reversal by external field is the most important issue of magnetism of ultrathin film. In this paper we concentrate on the zero-field case.

II. DISCRETE MODEL

The energy per unit area of a thin magnetic film with normal surface anisotropy can be described by the following discrete model:[6]

$$\gamma = -JM_s^2 \sum_{i=1}^{N-1} \cos(\varphi_i - \varphi_{i+1}) - K_v' \sum_{i=2}^{N-1} \sin^2 \varphi_i + K_s'(\sin^2 \varphi_1 + \sin^2 \varphi_N), \quad (1)$$

where the direction of magnetization is measured from the normal of film plane. The first term covers the exchange coupling between magnetizations on adjacent atomic layers. The second and third terms are for the in-plane shape anisotropy and the normal surface anisotropy, respectively. The stable magnetization configuration is determined by minimizing the energy functional (1). For numerical calculation in this section, we take $\frac{1}{2}JM_s^2 = 1$ and $\hat{a} = 1$ (lattice constant).

Fixing the magnetic constants, we have found a spin–reorientation transition from the perpendicular uniform configuration to a canting one as the number of layers increases from $N=2$. A further transition has also been observed, where the canting configuration is switched into the uniform in-plane one. The phase diagram with the number of atomic layers and the surface anisotropy as variables is depicted in Fig. 1 for two different values of volume anisotropy. The region below/above and to the right/left of the right/left phase boundary is one of perpendicular/in-plane magnetization, the region in between is one of canting magnetic structure. The phase boundaries consist of steps, as a result of the discrete variation of the number of atomic layers. The locations of the phase boundaries depend sensitively on the value of volume anisotropy. We have calculated magnetic configurations in films of $N=2$–20 and various values of K_s' and K_v'. We then find that scaling into variables $(N - \Delta N)\sqrt{K_v'}$ and $K_s'/\sqrt{K_v'}$, where ΔN is a fitting parameter, all the phase boundaries for $K_v' \leqslant 0.1$ in units of JM_s^2 such as those shown in Fig. 1 fall into two smooth curves as in Fig. 2. Here $\Delta N = 2.2$ is selected in order to obtain the best fitting.[6] For realistic materials like Fe, one has $K_v' \simeq 0.003$ in unit of JM_s^2 and thus the criterion on the volume anisotropy for scaling is satisfied well. This fact implies the presence of the following two scaling relations in spin–reorientation transitions, one among the film thickness, volume anisotropy, and exchange stiffness: $(N-\Delta N)\sqrt{K_v'/(JM_s^2)}$, the other among the surface anisotropy, volume anisotropy, and exchange stiffness: $K_s'/\sqrt{K_v' JM_s^2}$.[6]

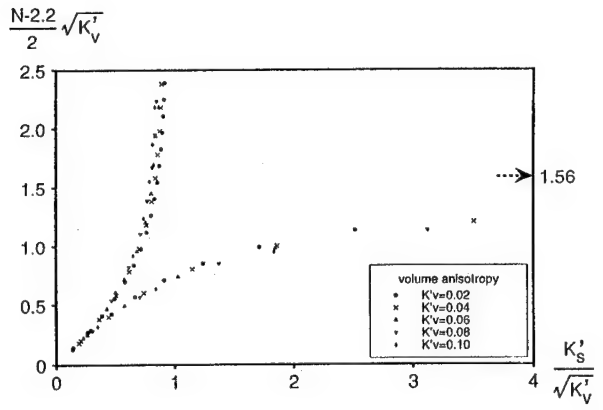

FIG. 2. Scaled phase diagram (Ref. 6).

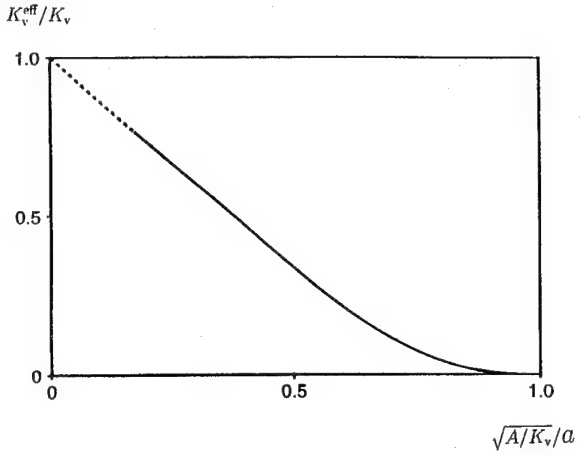

FIG. 4. Thickness dependence of the effective anisotropy (Ref. 9).

III. CONTINUUM MODEL

In order to understand the above numerical results, we introduce the continuum model. Consider a thin magnetic film of thickness $2a$: On the surfaces there exist perpendicular anisotropies K_s. Within the film the volume anisotropy K_v is in the film plane. The exchange stiffness A is ferromagnetic and finite. We assume that the magnetization is uniform in the in-plane directions. Then, half of the total magnetic energy per unit area is expressed by[7–9]

$$\gamma=\int_0^a\left[A\left(\frac{d\varphi}{dz}\right)^2-K_v\sin^2\varphi\right]dz+K_s\sin^2\varphi(0), \qquad (2)$$

where the z axis is taken to be normal to the film plane and the origin at the bottom surface. The relations among the magnetic quantities in functionals (1) and (2) are given as

$$\tfrac{1}{2}JM_s^2\hat{a}=A,\quad K_v'/\hat{a}=K_v,\ \text{and}\ K_s'=K_s.$$

The stable magnetization configuration is determined by solving the variational problem for energy functional (2). It is then revealed that there exists the first critical thickness[9,8] $a_{c1}=\sqrt{A/K_v}\tan^{-1}(K_s/\sqrt{AK_v})$, so that for $a\leqslant a_{c1}$ the stable configuration is uniform and magnetization stands normally to the film plane. For materials with surface anisotropy satisfying $K_s<\sqrt{AK_v}$, there exists the second critical thickness[9,8] $a_{c2}=\sqrt{A/K_v}\tanh^{-1}(K_s/\sqrt{AK_v})$, so that for $a\geqslant a_{c2}$, the magnetization is aligned uniformly within the film plane. For $a_{c1}<a<a_{c2}$, the spin configuration is not uniform in the vertical direction: The spin direction at $z=a$ is determined by[9]

$$\frac{K_s}{\sqrt{AK_v}}=\frac{\mathrm{sn}[a\sqrt{K_v/A},\sin\varphi_a]\,\mathrm{dn}[a\sqrt{K_v/A},\sin\varphi_a]}{\mathrm{cn}[a\sqrt{K_v/A},\sin\varphi_a]}, \qquad (3)$$

with $\varphi_a\equiv\varphi(a)$, and the magnetization configuration is expressed by φ_a as[9]

$$\varphi(z)=\sin^{-1}\left\{\sin\varphi_a\,\frac{\mathrm{cn}[(a-z)\sqrt{K_v/A},\sin\varphi_a]}{\mathrm{dn}[(a-z)\sqrt{K_v/A},\sin\varphi_a]}\right\}$$

$$\text{for}\ 0\leqslant z\leqslant a, \qquad (4)$$

where $\mathrm{sn}[x,k]$, $\mathrm{cn}[x,k]$, and $\mathrm{dn}[x,k]$ are Jacobi elliptic functions. The phase diagram of magnetization configuration obtained from the above formalism is given in Fig. 3. The dashed arrow in Fig. 3 denotes $a\sqrt{K_v/A}=\pi/2$, where the phase boundary a_{c1} saturates. Good coincidence is found between the phase diagrams in Figs. 2 and 3. Thus, the results derived by the discrete model have been explained analytically. On the other hand, this coincidence implies the sufficiency of the continuum approach in study of magnetic properties of ultrathin magnetic films of several atomic layers.

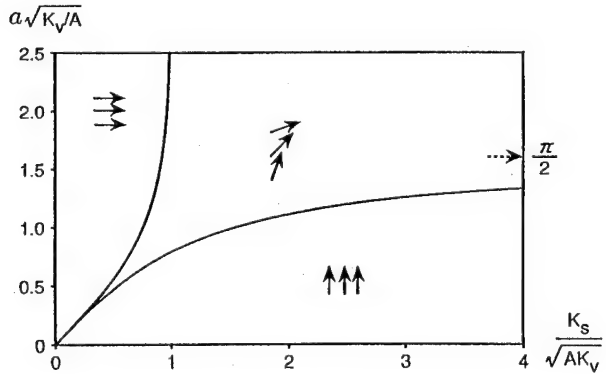

FIG. 3. Phase diagram derived by the continuum model (Ref. 6).

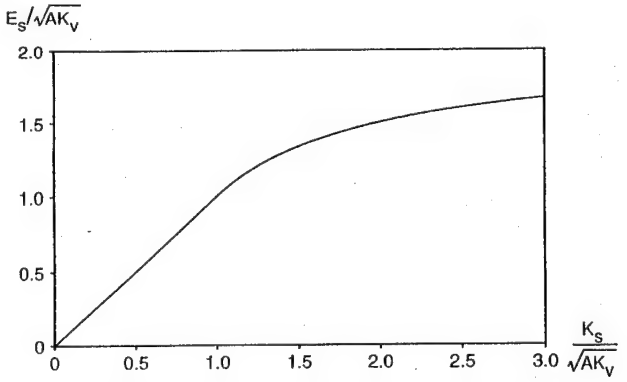

FIG. 5. Relation between the surface anisotropy and surface energy.

IV. ESTIMATION OF SURFACE ANISOTROPY

Let us investigate the energy stored in the film per unit area at large thicknesses. For this purpose, we only have to study the continuum model, since for film thicknesses much larger than the lattice spacing the continuum approximation is sufficient. Integrating Eq. (2) one obtains the following expression for magnetic energy as a function of φ_a for $a > a_{c1}$:[9]

$$\gamma = -aK_v \sin^2\varphi_a + K_s\left(\frac{\mathrm{cn}[a\sqrt{K_v/A},\sin\varphi_a]}{\mathrm{dn}[a\sqrt{K_v/A},\sin\varphi_a]}\right)^2 \sin^2\varphi_a + 2\left\{E\left[\frac{\pi}{2},\sin\varphi_a\right] - E\left[\sin^{-1}\left(\frac{\mathrm{cn}[a\sqrt{K_v/A},\sin\varphi_a]}{\mathrm{dn}[a\sqrt{K_v/A},\sin\varphi_a]}\right),\sin\varphi_a\right]\right\}$$
$$-2\cos^2\varphi_a\left\{F\left[\frac{\pi}{2},\sin\varphi_a\right] - F\left[\sin^{-1}\left(\frac{\mathrm{cn}[a\sqrt{K_v/A},\sin\varphi_a]}{\mathrm{dn}[a\sqrt{K_v/A},\sin\varphi_a]}\right),\sin\varphi_a\right]\right\}, \tag{5}$$

where $F[x,k]$ and $E[x,k]$ are elliptic integrals of the first and second kind, respectively. As φ_a can be determined by Eq. (3) as a function of film thickness, we can evaluate the thickness dependence of the effective anisotropy K_v^{eff} defined by $K_v^{\mathrm{eff}} \equiv -\gamma/a$ using the above relation. The result is depicted in Fig. 4. It is found that the asymptote of the effective anisotropy for large thickness is given as

$$K_v^{\mathrm{eff}} \simeq K_v - \frac{E_s}{a}, \tag{6}$$

where $\varphi_a = \pi/2$ for large thicknesses has been used.[9]

The coefficient E_s in Eq. (6) is the physical quantity observed in ferromagnetic resonance experiments,[5] which should be considered as a surface energy. In the case of $K_s > \sqrt{AK_v}$, where the canting configuration remains stable even at large thicknesses, we obtain[9]

$$E_s = 2\sqrt{AK_v} - \frac{AK_v}{K_s}. \tag{7}$$

Since the large surface anisotropy is relaxed into the canting structure, the surface energy has two contributions, one from the surface anisotropy and the other from wall energy of the canting structure. The surface anisotropy, usually defined in the same way as in energy functionals (1) and (2), is not equal to the slope E_s of extrapolation formula (6) in the case of $K_s > \sqrt{AK_v}$. Instead it should be estimated from E_s as

$$K_s = \frac{AK_v}{2\sqrt{AK_v} - E_s}. \tag{8}$$

In the case of $K_s < \sqrt{AK_v}$, uniform in-plane magnetic configuration is stable for $a > a_{c2}$ and Eq. (6) is established exactly in this region of thickness. Since no wall energy is involved in this case, one has simply

$$K_s = E_s. \tag{9}$$

For iron in Fe(100)/Ag(100) superlattice, one has $K_s/\sqrt{AK_v} \simeq 0.14$. Therefore, relation (9) is applicable for samples of transition metals. Relation (8) should be used where the wall energy $\sqrt{AK_v}$ is small, the case possibly realized in samples of rare earth metals. The relation between the surface energy and the surface anisotropy is summarized in Fig. 5.

V. SUMMARY

Spin–reorientation transitions with the variation the film thickness and the magnetic constants are clarified. Scaling relations among the relevant quantities in these transitions are derived. It is shown that the continuum approximation is sufficient in the study of the spin–reorientation transitions in magnetic ultrathin films of several atomic layers. A complete formula is presented for the evaluation of surface anisotropy via ferromagnetic resonance techniques.

Perpendicular magnetization and surface magnetoelastic anisotropy in epitaxial Cu/Ni/Cu (001)

Gabriel Bochi, C. A. Ballentine, H. E. Inglefield, C. V. Thompson, and R. C. O'Handley
Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Epitaxial Ni films (2.0 nm$<h<$14 nm) have been grown on Cu/Si (001) and capped with 2.0 nm of Cu in a molecular beam epitaxy chamber. Their magnetic anisotropy has been measured *ex situ* in a vibrating sample magnetometer. Perpendicular magnetization is preferred over a broad Ni-thickness range: $25 \leqslant h \leqslant 140$ Å. The quantitative anisotropy data are not well described by a model including bulk and surface magnetocrystalline anisotropy, $K^b + K^s h$, magnetostatic energy, and bulk magnetoelastic energy, $B^b e(h)$. If surface magnetoelasticity $B^s e/h$ is considered, the data are well described and values for K^s and B^s consistent with Néel's model are determined. © *1996 American Institute of Physics.* [S0021-8979(96)21708-8]

The effective magnetic anisotropy in thin films is altered due to reduced atomic coordination symmetry at the surface,

$$K^{\text{eff}} = K^{\text{bulk}} + \frac{K^{\text{surface}}}{h}. \tag{1}$$

Magnetic surface anisotropy is often justified in terms of Néel's phenomenological model.[1] It is not widely recognized that strain-dependent magnetic surface anisotropy comes as naturally from Néel's pair-interaction model as does the strain-dependent surface magnetocrystalline anisotropy of Eq. (1),[2]

$$B^{\text{eff}} = B^{\text{bulk}} + \frac{B^{\text{surface}}}{h}. \tag{2}$$

Here, B is the magnetoelastic (ME) coupling coefficient related to the negative of the magnetostriction constant by elastic moduli. The total magnetic surface anisotropy energy is then given by a relation of the form $E^{\text{surface}} = K^s + B^s e$, where e represents the appropriate components of the strain tensor in the magnetic thin film.[3]

Several experimental results have unambiguously demonstrated that ME interactions at surfaces and in thin films can be significantly different than in the bulk. Zuberek *et al.*[4] found that the effective magnetostriction constant of Ni/Ag multilayers goes from negative to positive values as the Ni film thickness approaches zero. Sun and O'Handley[5] found that the surface ME coupling coefficient can differ sharply from the bulk value in Co-rich and Fe-rich amorphous alloys. More recently, Song *et al.*[6] measured the effective ME coupling coefficient in polycrystalline NiFe/Ag/Si, NiFe/Cu/Si, and Ni/SiO_2/Si thin films by a direct *in situ* method. B^{eff} was shown to diverge from the bulk value to more positive values for film thicknesses below 150 Å and to take giant positive values in films thinner than 40–60 Å due to a significant surface contribution. The magnetostriction of ultrathin polycrystalline Fe films has also been measured directly *in situ*.[7] Significant deviations from the bulk value were observed for Fe film thicknesses below 100 Å. The effective magnetostriction constant was shown to change sign when the Fe film thickness was between 80 and 30 Å. Bochi *et al.*[8] showed that published data on the magnetic anisotropy in epitaxial fcc (111) Co/Cu superlattices can be more effectively interpreted by inclusion of a surface ME term. Their analysis implied that the effective ME coupling coefficient of fcc Co/Cu (111) multilayers changes sign around a Co thickness of 9 Å.

In the present work, we report the behavior of both the magnetic anisotropy and the ME coupling in epitaxial Cu/Ni/Cu/Si(001) sandwiches. We show that the interpretation of the dependence of the magnetic anisotropy energy on Ni film thickness is severely wanting without the inclusion of a strain-dependent magnetic surface anisotropy term (the surface ME anisotropy energy). Using a phenomenological model developed recently,[8] we are able to determine the surface magnetocrystalline (K^s) and surface ME ($B^s e_0$) anisotropy energies corresponding to the Ni/Cu (001) interface. The variation of the effective ME coupling coefficient, B^{eff}, with Ni film thickness is also determined.

Our (20 Å Cu)/Ni/(2000 Å Cu) sandwiches were deposited at room temperature on Si (001) substrates by molecular beam epitaxy. The details of the experimental procedures are given elsewhere.[9–11] The crystallographic quality of the sandwiches was studied *in situ* by reflection high-energy electron diffraction and *ex situ* by x-ray diffraction and transmission electron microscopy (TEM). Using plan-view TEM, we observed both 60° and 90° misfit dislocations (MDs) at the Ni/Cu (001) interface and we measured their densities as a function of Ni film thickness.[10,11] MDs were present in Ni/Cu (001) thin films with Ni thicknesses of 25 Å and greater but not in the 15-Å-thick films. This indicates that the critical thickness h_c for the onset of MDs is between 15 and 25 Å. For Cu/Ni/Cu (001) sandwiches, we observed dislocations in Ni films as thin as 30 Å, indicating that $h_c < 30$ Å.[12] We also measured the average in-plane biaxial tensile misfit strain in the Ni films as a function of film thickness in Ni/Cu/Si (001) epitaxial thin films by measuring the substrate curvature using an optical interferometry technique.[9,11] The effective magnetic anisotropy, K^{eff}, of Cu/Ni/Cu (001) was measured *ex situ* as a function of Ni film thickness, h, using a vibrating sample magnetometer where 10 kOe fields were available to saturate the sandwiches both in-plane and perpendicular to the plane. *In situ* magneto-optic Kerr effect measurements on Ni/Cu/Si (001) were reported earlier.[9]

Our measurements of $K^{\text{eff}}h$ vs h are shown in Fig. 1. The

 0021-8979/96/79(8)/5845/3/$10.00

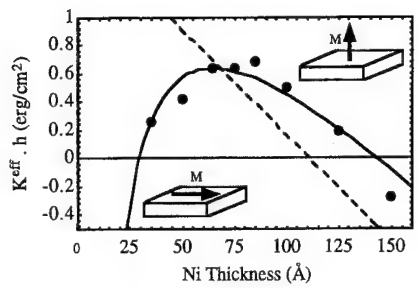

FIG. 1. $K^{\text{eff}}h$ vs Ni film thickness for our Cu/Ni/Cu (001) sandwiches. The solid curve is a plot of $K^{\text{eff}}(h)$ vs h using Eq. (6) and the magnetic surface energies in the first row of Table I. The dashed straight line is the best fit to the data using Eq. (3).

first important result is that perpendicular magnetic anisotropy dominates up to Ni thicknesses of approximately 135 Å in Cu/Ni/Cu (001) sandwiches. This is in agreement with the results of Naik *et al.*[13] and the ones of Jungblut *et al.*[14] The region of perpendicular magnetization is exceptionally broad in Cu/Ni/Cu (001) and is twice as large as the one of Ni/Cu (001) thin films.[9] The second important result of Fig. 1 is that the magnetization easy axis exhibits *two* switching thicknesses: one near 135 Å, which our measurements confirm, and another one near 20 Å.[14] Two switching thicknesses for the magnetization easy axis have also been reported for Ni/Cu(001) thin films.[9]

It is common practice to explain the behavior of the magnetic anisotropy of epitaxial (001) thin films sandwiched between two identical nonmagnetic layers in terms of a phenomenological model, where K^{eff} is the sum of the bulk magnetostatic (MS) energy, $2\pi M_s^2$, the bulk ME anisotropy energy, and a magnetic surface anisotropy energy K^s,[8]

$$K^{\text{eff}}h=[2B_1e_0(h)-2\pi M_s^2]h+2K^s. \tag{3}$$

In Eq. (3), we omitted the bulk magnetocrystalline anisotropy because it is negligible for Ni/Cu (001) thin films. B_1 is the Ni bulk ME coupling coefficient and $e_0(h)$ is the average biaxial in-plane misfit strain in the magnetic film. For $h<h_c$, $e_0(h)=\eta$, the film–substrate lattice mismatch [η=2.6% in Ni/Cu (001)]. Equation (3) then predicts $K^{\text{eff}}h$ to be a linear function of h with a slope given by $2B_1\eta-2\pi M_s^2$ and intercept equal to $2K^s$. For $h>h_c$, $e_0(h)$ decreases with film thickness as the misfit strain is accommodated by MDs. Using the form of strain suggested by Chappert and Bruno,[15] $e_0(h)=\eta h_c/h$, Eq. (3) predicts that, for $h>h_c$, a plot of $K^{\text{eff}}h$ vs h is a straight line with a slope of $-2\pi M_s^2$ and intercept $2[B_1\eta h_c+K^s]$. The above two straight lines would intersect exactly at h_c, thus forming a kink in the $K^{\text{eff}}h$ vs h data. Although the model of Eq. (3) could fit to our data reasonably well, a major problem exists. The change in slope in our data is centered at $h\approx 75$ Å but the critical thickness was observed to be below 30 Å.[12] Since our data points are all above 35 Å, they should fall along a straight line of slope $-2\pi M_s^2$ according to Eq. (3). The best fit to the data with such a model is the dashed line in Fig. 1. The model of Eq. (3) is therefore clearly inadequate for Cu/Ni/Cu (001).

The inadequacy of the model is not related to the fact that the bulk MS energy of Ni does not apply to Ni thin films. Our films show essentially constant magnetization ($\pm 10\%$ relative to bulk) with thickness down to 30 Å. Further, a careful study by Huang *et al.*[16] showed that the Curie temperature of bulk Ni is valid for Ni films as thin as 35 Å. Another possible source of discrepancy between the model of Eq. (3) and the data could be the $1/h$ film thickness dependence generally accepted for the misfit strain $e_0(h)$. Our own measurements of the thickness dependence of the strain in Ni/Cu/Si (001) thin films yield[9,11]

$$e_0(h)\approx\frac{0.2}{h^{0.7}}, \tag{4}$$

expressed in percent with h in Å. Whether we use the strain of Eq. (4) or other powers of h, there remains a strong divergence between the measured effective magnetic anisotropy energy of Fig. 1 and the model of Eq. (3). The source of discrepancy in the interpretation of Fig. 1 must therefore lie elsewhere.

By including in the free energy the surface ME anisotropy term predicted by the strain-dependent Néel model,[2] we obtain the following phenomenological equation for (001) epitaxial films sandwiched between two identical nonmagnetic layers:[8,9]

$$K^{\text{eff}}h=-2\pi M_s^2h+2\left(B_1+\frac{B^s}{h}\right)e_0(h)h+2K^s. \tag{5}$$

Substituting in the Chappert–Bruno strain[15] yields

$$K^{\text{eff}}h=-2\pi M_s^2h+2(B_1\eta h_c+K^s)+2\frac{B^s\eta h_c}{h}. \tag{6}$$

Fitting our data points with Eq. (6), we obtain the solid line shown on Fig. 1. The figure clearly shows that the presence of the B^s/h term significantly improves the fit to the data and offers a rational explanation for the behavior of the data. Comparing the equation of the solid line and Eq. (6), and using $B_1=6.2\times 10^7$ ergs/cm^3 and $h_c=18$ Å, we obtain B^s(Ni/Cu)(001)≈ -67 ergs/cm^2 and K^s(Ni/Cu)(001)$\approx +0.98$ erg/cm^2.

We have also fit our experimental data using the measured strain of Eq. (4). In this case, we obtained the following surface energies: B^s(Ni/Cu)(001)≈ -52 ergs/cm^2 and K^s(Ni/Cu)(001)$\approx +0.88$ erg/cm^2. Clearly, the thickness dependence of the misfit strain in the magnetic thin film affects the parameters deduced. We have also analyzed the data of Jungblut *et al.*[14] using the strain $e_0(h)=\eta h_c/h$ (with $h_c=15$ Å) in our phenomenological model, and found a good fit of

TABLE I. Magnetic surface anisotropy energies of the Ni/Cu(001) interface. The results obtained by applying Eq. (6) to our data and to those of Jungblut *et al.* (Ref. 14) are summarized in the first three rows. The energies reported by Jungblut *et al.* using the model of Eq. (3) are shown in the last row.

Cu/Ni/Cu (001)	B^s (ergs/cm^2)	K^s (erg/cm^2)
$e_0(h)=\eta h_c/h$	−67	+0.98
$e_0(h)=0.2/h^{0.7}$	−52	+0.88
Jungblut *et al.* data	−37	+0.73
$e_0(h)=\eta h_c'/h$ Results of Jungblut *et al.* (Ref. 14)	...	−0.40

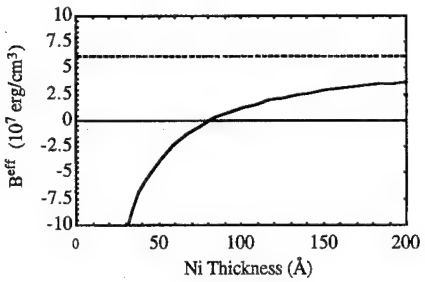

FIG. 2. Dependence of the effective ME coupling coefficient on Ni film thickness in Cu/Ni/Cu (001) sandwiches. We used the average value $B^s(\text{Ni/Cu})(001)\approx -50$ ergs/cm^2 obtained from the data in Table I. The dashed line indicates the bulk ME coupling coefficient of Ni.

their data only if we included a surface ME term with $B^s(\text{Ni/Cu})(001)\approx -37$ ergs/cm^2 and $K^s(\text{Ni/Cu})(001)\approx +0.73$ erg/cm^2. When Jungblut *et al.* analyzed their data with Eq. (3), they found $K^s(\text{Ni/Cu})(001)\approx -0.40$ erg/cm^2, assuming that $h_c\approx 40$ Å.

The above results on the surface magnetocrystalline anisotropy energy and the surface ME coupling coefficient of the Ni/Cu (001) interface are summarized in Table I. The surface magnetocrystalline anisotropy energies are all large and positive indicating that $K^s(\text{Ni/Cu})(001)$ together with the *bulk* ME anisotropy energy, $2B_1e_0(h)$, account for the remarkable perpendicular magnetic anisotropy in Cu/Ni/Cu (001) sandwiches. On the other hand, the surface ME coupling coefficients are negative indicating that the *surface* ME anisotropy energy $2B^se_0(h)/h$ favors an in-plane magnetization. At small Ni thicknesses ($h<20$ Å), this term becomes very large and is responsible for keeping the magnetization in plane. The magnetostatic energy, $2\pi M_s^2$, on the other hand, is responsible for bringing the magnetization back in plane for $h>135$ Å. Our model therefore gives a consistent explanation as to why the magnetization easy axis changes orientation twice. Double magnetization easy-axis transitions are also observed in bcc Fe/Ag (001)[17] and fcc Fe/Cu (001)[18] thin films. In both cases, both transitions occur for $h<h_c$, which means once again that they cannot be explained by Eq. (3) and that Eq. (5) or Eq. (6) does not apply.

The average values of the surface energies in the first three rows of Table I are $B^s\approx -50$ ergs/cm^2 and $K^s\approx +0.85$ erg/cm^2. In agreement with the predictions of the strain-dependent Néel model[2] for fcc (001) interfaces, K^s and B^s have opposite signs. Using the average surface ME coupling coefficient, we plot $B^{\text{eff}}=B_1+B^s/h$ for Cu/Ni/Cu (001) sandwiches in Fig. 2. The figure indicates that significant deviations from the bulk value B_1 occur for films as thick as 200 Å and that B^{eff} changes sign around 80 Å. This striking result questions the assumption, often encountered in the literature, that bulk ME coupling coefficients apply to ultrathin films and is supported by the recent direct measurements of magnetostriction by Song *et al.*[6] and Weber *et al.*[7] We emphasize that ME coupling in ultrathin films depends strongly on the *symmetry and chemistry* of the interfaces, not just on the film thickness, h.[9]

Using x-ray lithography we have patterned dot arrays in Au/Co/Au(111) sandwiches based on ultrathin Co layers with perpendicular anisotropy. Large area arrays of dots with diameters of 1 and 2 μm have been obtained, keeping mostly undamaged the ultrathin Co layer. Hysteresis loops of the arrays depend drastically on the dot diameter. Magneto-optical domain visualization experiments confirm a magnetization reversal mechanism based on a large distribution of nucleation fields in the film, with complete reversal of the magnetization of one dot through the domain wall propagation after a local nucleation process. This could give information on the magnetization reversal processes in Au/Co/Au(111) continuous films. © *1996 American Institute of Physics.*
[S0021-8979(96)21808-4]

The study of magnetization reversal processes in thin and ultrathin (a few atomic layers thick) magnetic films is of wide interest both for fundamental research and for applications to magnetic recording and sensors. One way to get information on the intrinsic processes could be to reduce the lateral dimensions of the films to values comparable to the fundamental lengths of magnetism, like domain wall width or minimum domain size.[1] Such patterned films have also been proposed as new media for magnetic[2] or magneto-optical[3] recording. Defining geometrically the magnetic bit borders could indeed be a path toward drastic reduction of the bit size, without increasing the wall jaggedness, detrimental to the signal-to-noise ratio.[3]

We present a magnetic study of dot arrays patterned in Au/Co/Au(111) sandwiches based on ultrathin Co layers with perpendicular magnetic anisotropy. Large area arrays of dots with diameters of 1 and 2 μm have been obtained using x-ray lithography and ion-beam etching. Hysteresis loops of the arrays depend drastically on the dot diameter. Domain visualization experiments confirm a magnetization reversal mechanism based on a large distribution of nucleation fields in the film, coupled to complete reversal of the magnetization of one dot through domain wall propagation after a local nucleation process, in agreement with previous similar measurements on continuous films.[4]

Preparation techniques and the crystalline structure of our Au/Co/Au samples have already been published.[5,6] Depositions are made in a ultrahigh vacuum unit (below 5×10^{-10} mbar) using Joule heating and electron beam evaporation. The first step is to grow a polycrystalline, atomically flat, fully textured, 28-nm-thick Au(111) buffer layer on a flat amorphous substrate. For regular magnetic studies we use float glass platelets. For the present study, float glass was replaced by a thermally oxidized Si(001) wafer, without loss of structural quality. On this Au(111) buffer, Co grows nearly layer by layer under its stable hcp(001) structure. The Co layer is then covered by a 7.5-nm-thick Au coverage to ensure protection during patterning processes and magnetic studies. Magnetic and magneto-optical properties of this Au/Co/Au(111) system have been extensively studied (cf. Ref. 7 and references herein). Note that up to about 10 atomic layers (AL) of Co, the easy magnetization axis remains perpendicular due to strong magnetic interface anisotropy. The magnetization reversal process shows two different behaviors, depending on the structural quality and Co thickness of the sample.[4] On top quality samples with up to about 7 AL of Co, one observes rare nucleation of reverse domains followed by rapid domain wall propagation throughout the sample. This gives almost perfectly square hysteresis loops in the perpendicular applied field. On "bad" samples, for instance deposited on a rough Au buffer, domain wall propagation is blocked by the defects and magnetization reversal occurs mostly through nucleation processes, which results in rounded hysteresis loops.

The magnetic properties thus depend drastically on the interface quality. Due probably to the polycrystalline character of the Au buffer layer, further heat treatment of the sample above 100 °C can easily damage it. Moreover, the adhesion of the Au layer on the amorphous substrate is very weak.[8] Patterning the sample without modifying its magnetic properties thus required careful adaptation of all microtechnology processes.[9]

X-ray lithography was used to define the structure of the dot arrays. This technique has demonstrated excellent resolution as low as 50 nm,[10] which will allow the exploration of mesoscopic magnetic phenomena from the classical to the quantum limit. It is furthermore a parallel process (like optical lithography), allowing us to rapidly treat large areas with a high throughput, which is of crucial importance for applications. Exposures were done using synchrotron radiation in the L2M facility at Super-ACO (Lure—orsay), through a mask realized using a current technology[11] based on a silicon carbide membrane and tungsten or gold absorber patterns.

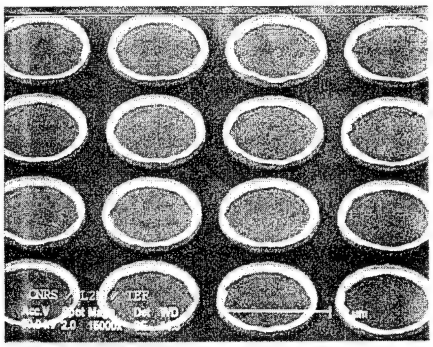

FIG. 1. Scanning electron microscopy view of a 2 μm diam by 2.2-μm spacing dot array, patterned on a Au/Co/Au(111) sandwich.

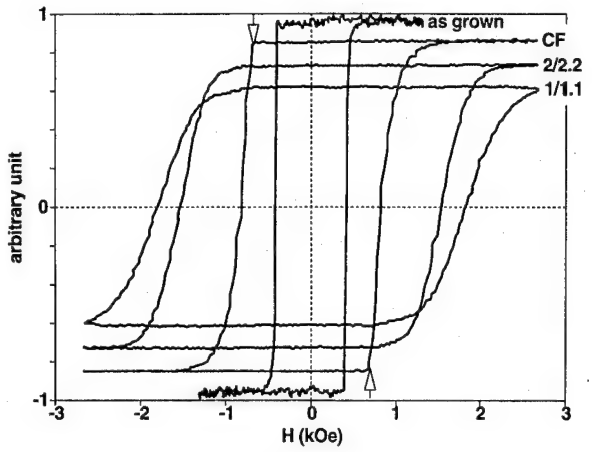

FIG. 2. Evolution of hysteresis loops vs dot diameter, for an Au/Co/Au(111) sample with 5 AL Co thickness.

Resist dot arrays were obtained on the magnetic sandwiches with a positive resist PMMA/MAA.

Ion milling was then used as the etching technique, with Ar^+ ions at 500 eV and 0.5 mA/cm^2, which corresponds to an Au etch rate of about 40 nm/min at normal incidence. Being anisotropic, this technique is in principle well adapted to image transfer down to nanometer scale, as it preserves very well the lateral dimensions and shape of the mask. However, it produces some Au redeposition on the resist walls.[9] After resist removal in a 20% O_2 plasma, thin Au "crowns" remain on top of the dots, as shown in Fig. 1. These crowns should be of no importance to the standard magnetization measurements reported here (polar magneto-optical Kerr effect at normal incidence), and are not expected to change the magnetic properties of the dots. Besides that, excellent topological qualities of the patterned structures could be obtained (Fig. 1 and Ref. 9).

For this study, a mask with four 1×1 mm^2 arrays has been used. Each array is composed of round dots with respective diameter over lattice spacing ratios of 1/1.1, 2/2.2, 1/2, and 2/4, all lengths given in μm. Finally, all etching processes have been performed through a metallic aperture, which keeps unetched a large area of the sample. This unetched part, which has nevertheless undergone all other nanofabrication steps, will hereafter be referred to as "continuous film" (CF), as opposed to the "as-grown" sample coming out of the deposition chamber.

Hysteresis loops were taken on each sample, using a sensitive magnetoptical Kerr effect experiment[7] with a laser beam focused to a diameter of 0.4 mm, for all different configurations of the samples (as grown, CF, and dot arrays). Typical results are displayed in Fig. 2 for a sample with 5 AL Co thickness and an excellent as-grown quality. Note first that we could find no significant effect of the dot spacing, as expected for such ultrathin films for which dipolar coupling is negligible. The hysteresis loop of the as-grown film appears perfectly square.[4] The loop measured on the CF is already quite rounded, with a surprisingly much higher coercive field. However, the beginning of the magnetization reversal remains abrupt, which could indicate that some initial domain propagation still exists in part of the sample, together with the existence of hard centers responsible for the slow approach to saturation. This shows that limited structural modifications have been induced in our samples by the nanofabrication process (a similar behavior was induced by substrate patterning in Ref. 3). The loops measured on the dot arrays are much more rounded, the coercive field increasing dramatically with decreasing dot diameter (Fig. 2). However, the magnetization reversal starts for CF and dot arrays at the same value H_N, a sign of some intrinsic origin for the process.

Indeed, one expects that, in micrometer size dot arrays patterned in high quality samples, the global magnetization reversal will be modified through the blocking of the domain wall propagation by the border of the dot. Assuming that each dot has its magnetization fully reversed by wall propagation following a nucleation event, the behavior will depend on the dot diameter through the spatial distribution of nucleation centers, leading to more rounded hysteresis loops and higher coercive fields with decreasing dot diameter. This looks like the crossover from a continuous film behavior to that of an assembly of magnetically independent grains with a large distribution of nucleation fields.

This picture has been confirmed by domain visualization experiments. For these experiments, we have used a polarization microscope. A cooled charge-coupled device camera acquires the images which are stored and processed in the camera's processing unit and a linked microcomputer. The spatial resolution of the camera (1 pixel) corresponds to 0.2 μm on the sample, but due to diffraction effects, the resolution is of the order of 0.5 μm. The light source is a high intensity blue light emitting diode (Nichia Chemical). Our experimental setup allows us to obtain images of the magnetization state of the sample by using an image of the saturated sample as a reference in order to cancel out intensities of nonmagnetic origin. Besides, analysis of the images yields hysteresis loops of an assembly of dots as well as of single dots.

We now present polar Kerr measurements on the 1/2 and 2/4 arrays. Figure 3(a) displays the magnetic image of the unetched part of the sample (CF) obtained after partial reversal of the saturation magnetization following the application of a bias field H_b of 700 Oe for 1 s. One observes many nucleation centers, together with a large domain developing by propagation of its domain wall. The presence of numerous

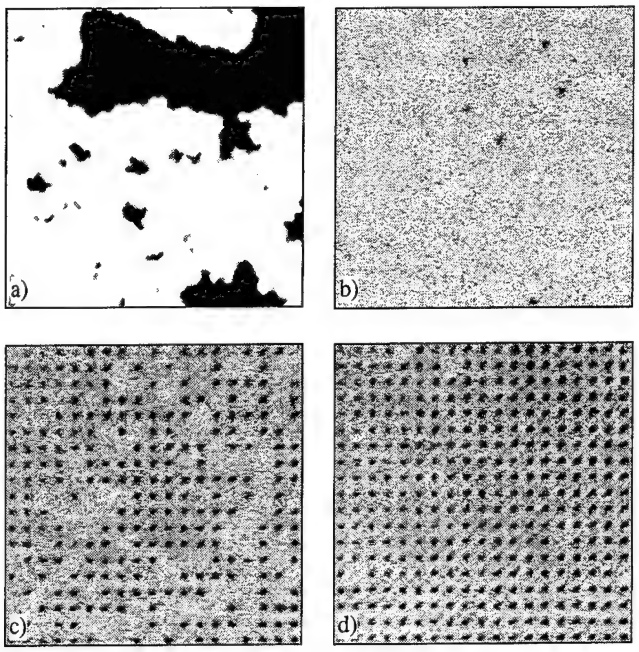

FIG. 3. Magneto-optic images of a 1/2 array of dots, taken after applying a bias field H_b for 1 s: (a) unetched part with $H_b = 0.96$ kOe; (b) $H_b = 0.96$ kOe; (c) $H_b = 1.44$ kOe; (d) $H_b = 2.35$ kOe.

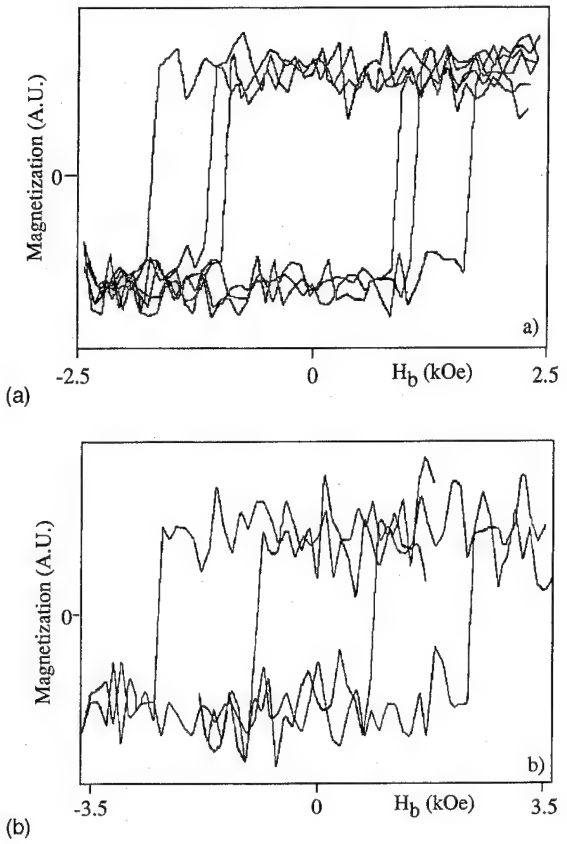

FIG. 4. Examples of hysteresis loops of individual dots: (a) single dots of a 2/4 array; (b) single dots of a 1/2 array.

nucleation centers confirms that the photolithographic process has somewhat damaged the sample, as suggested by Fig. 2, but without totally suppressing domain wall propagation. Figures 3(b)–3(d) present magnetic images of large areas (including several hundred dots) of the 1/2 array, taken for increasing values of a bias field H_b applied for 1 s, after saturation in reverse field. In these images, one observes an increase of the number of reversed dots with an increase of H_b.

From the images obtained for increasing values of H_b, one can rebuild the hysteresis loop of the sample: The result is in perfect agreement with the loops displayed in Fig. 2. But it is also important to measure the hysteresis loops of individual dots which have been seen to reverse their magnetization for different field values. As an example, Figs. 4(a) and 4(b) display the hysteresis loops of dots which flip for different values of the reversed bias field. These last pictures demonstrate that each dot has its own and very well-defined coercive field, with a square hysteresis loop which confirms that a dot is fully reversed by wall propagation once a nucleation event has occurred. Repeating the same experiment several times shows that each dot always reverses its magnetization for the same value of the coercive field. Thus, the spread of the coercive field which is observed on an assembly of dots, Fig. 2, comes from the distribution of the individual nucleation fields of the dots. Also, the above results confirm that there is no detectable magnetic coupling between the dots, contrary to other observations.[3]

It is also easy to reconcile the partial domain wall blocking on defects observed for the CF [Fig. 3(a)], and the picture developed above of complete magnetization reversal of individual dots through domain wall propagation. Indeed, as can be seen in Fig. 2, due to the large distribution of nucleation fields, most of the dots begin to reverse their magnetization at high fields—higher than the propagation field necessary to overcome the blocking on defects in the CF area.

Numerical simulations are in progress on the theoretical basis outlined above that will allow us to extract the distribution of nucleation fields in the films.

Lithographic patterning techniques have been used to fabricate arrays of submicron particles from a [110] single-crystal iron thin film with a strong uniaxial surface anisotropy and with an easy axis of magnetization lying in the [001] direction (in the plane of the film). Magnetic force microscopy images indicate that these islands are single domain over a wide range of island shapes and sizes. The uniaxial surface anisotropy is stronger than the shape anisotropy for the island geometries used, so the easy axes of the islands all lie roughly in the [001] direction, regardless of the island shape. Magnetic force images were also taken as both the magnetic tip and sample were subjected to a gradually increasing externally applied field. This technique allows us to monitor the magnetization reversal of individual islands and provides a direct measure of their switching fields. © *1996 American Institute of Physics.* [S0021-8979(96)21908-0]

INTRODUCTION

The application of lithographic patterning techniques to the study of fine magnetic particles has permitted experimental measurements of single-domain magnetic islands with well-controlled sizes and shapes.[1,2] Most of these experiments have used soft magnetic materials with negligible magnetocrystalline anisotropy,[1–5] so the easy axis of magnetization of each patterned island was determined solely by its shape, and could be controlled by lithography. For hard magnetic materials with strong magnetocrystalline anisotropy it is more difficult to obtain small particles with predictable and well-defined easy axes: one must control not only particle shape, but also the crystallographic structure of the magnetic material.

In previous work, we studied the behavior of single-domain islands fabricated from a hard polycrystalline magnetic film.[6] Because of the inherent microstructural inhomogeneities in these polycrystalline films, the magnetic islands did not have predictable magnetic properties.[7,8] To obtain single-domain particles with more predictable magnetic properties, we have patterned islands from a 200-Å-thick single-crystal [110] iron film with an easy axis of magnetization (due to surface anisotropy) along the [001] direction.

MAGNETIC FILM PREPARATION AND CHARACTERIZATION

The magnetic film to be patterned was deposited in a custom-built dc magnetron sputtering system using a procedure similar to that outlined in Refs. 9 and 10: a 200-Å-thick layer of single-crystal [110] iron was deposited onto an 890-Å-thick seed layer of [110] molybdenum, which was in turn deposited on a $[11\bar{2}0]$ sapphire substrate. Both the molybdenum and iron layers are bcc, and grow with their $[\bar{1}11]$ axes parallel to the [0001] axis of the sapphire. The sapphire substrate was a 2-in.-diam wafer with its wafer flat perpendicular to the [0001] direction. The orientation of the the iron [001] direction (which turns out to be the easy axis of magnetization) was therefore roughly 35° away from the wafer flat as shown in Fig. 1.

The crystal structure of the [110] iron film was examined using x-ray diffraction. Figure 2 shows the stereographic projection of a cubic system onto a [110] plane, as well as the locus of scattering vectors sampled during the x-ray scan. This locus intercepts only four allowed scattering vectors which are separated by 70° and 110°. The experimental data (Fig. 3) show peaks at the appropriate locations, indicating that the film is single crystal. Rocking curves taken across the [011] peak showed a full width at half-maximum width of 1.7°, consistent with good quality epitaxial growth.

Previous experiments[10] have shown that iron/molybdenum multilayers have a strong uniaxial anisotropy with an easy axis oriented along the [001] direction in the iron. Figure 4(a) shows a torque curve obtained from a multilayer sample. It has been shown that the anisotropy is due to surface effects and is not due to either bulk magnetocrystalline anisotropy or strain-induced anisotropy.[10] For a single-layer 200-Å-thick iron film, the anisotropy is also uniaxial and still believed to be due primarily to surface

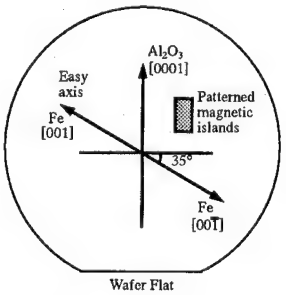

FIG. 1. This diagram indicates the orientation of the easy axis of magnetization with respect to the sapphire wafer flat. Note that the edges of the patterned features (to be shown later) will lie parallel and perpendicular to the wafer flat, and will not be aligned with the easy axis of magnetization.

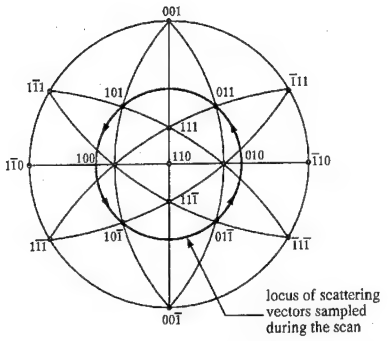

FIG. 2. The stereographic projection of a cubic system onto the [110] plane. The heavy line shows the locus of x-ray scattering vectors probed during the x-ray scan. For a single-crystal substrate, the scan should yield four peaks ([001], [101], [10$\bar{1}$], and [01$\bar{1}$]) separated from each other by 70° and 100°.

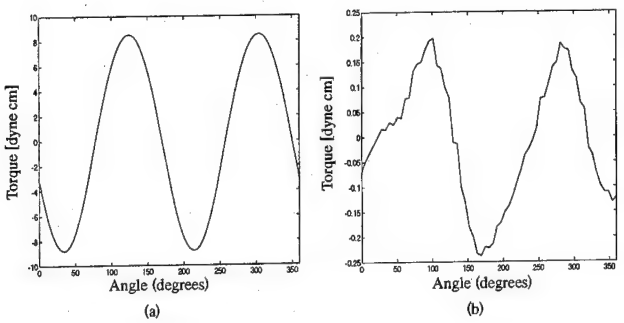

FIG. 4. Graph (a) is a torque curve for a [110] Fe/Mo multilayer film consisting of 40 bilayers, with each bilayer containing 25 monolayers of Fe and 25 monolayers of Mo. The combined thickness of Fe is 2030 Å. Graph (b) is a torque loop taken from a 9 mm^2 section of a 200-Å-thick [110] single-layer iron film on a molybdenum underlayer. The applied field was 15000 Oe.

effects. Figure 4(b) shows a torque loop from a single 200-Å-thick iron layer. The size of the anisotropy in a single layer is much smaller than for multilayers, however it is still significantly larger than the expected contribution from bulk magnetocrystalline anisotropy. For both single and multilayers, the easy axis is along the [001] axis of the iron. Hysteresis loops (not shown) were also used to confirm the easy-axis direction. Classic easy- and hard-axis loops were obtained for fields applied along the [001] and [1$\bar{1}$0] directions, respectively, and the coercivity for the easy axis loop was 60 Oe.

The sample used to obtain the torque loop of Fig. 4(b) was a 9 mm^2 area of 200-Å-thick iron with a total magnetic volume of 1.8×10^{-7} cm^3. A frequency domain analysis of the torque loop indicates that the strongest harmonic (which gives rise to the uniaxial anisotropy) has an amplitude of 0.50 dyn cm. As long as the magnetization remains in plane, the anisotropy energy of the magnetic sample will be of the form $E=VK\sin^2\theta$, where θ is the angle between the magnetization and the [001] easy axis, V is the magnetic volume of the sample, and K is a uniaxial anisotropy constant. The torque measured by the torque magnetometer is $\tau=-VK\sin 2\theta$, so we have $VK=0.50$ dyn cm, and the uniaxial anisotropy constant is therefore $K=28\times10^5$ ergs/cm^3. This value is the bulk magnetocrystalline anisotropy constant which is equivalent to the surface anisotropy for a film thickness of 200 Å.

The patterning procedure of Ref. 11 was applied to the single-crystal iron films described above. A large area of film was patterned with rectangles of various shapes, sizes, and aspect ratios, with dimensions ranging from 0.1 to 3 μm.

MAGNETIC FORCE MICROSCOPY

Atomic and magnetic force images of the magnetic islands (Figs. 5–7) were obtained using a commercial Nanoscope III scanning probe microscope. Two striking features emerge from these images. The first is that all of the particles, even the very large 1.0 by 3.0 μm islands, appear to be single domain. The second is that the magnetizations of the particles are all oriented roughly along the [001] or [00$\bar{1}$] directions (that is along the easy axis defined by the surface anisotropy of the unpatterned film) regardless of particle shape.

We can compare the shape and magnetocrystalline anisotropies for a 0.2 by 0.6 μm iron island patterned from a 200 Å thin film. We treat the island as an ellipsoid so that we can easily calculate demagnetizing coefficients. If α is the angle between the magnetization (assumed uniform) and the long axis of the island then the shape anisotropy energy density can be written as $E_{\text{shape}}=(1/4)M^2(N_a-N_b)\cos 2\alpha$, where N_a and N_b are demagnetizing factors for the long and

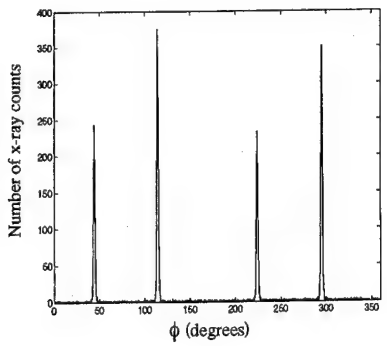

FIG. 3. An x-ray scan of the [110] iron film. There are four peaks, separated by 70° and 110° (see Fig. 2).

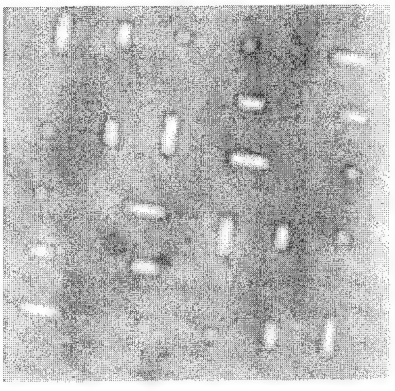

FIG. 5. Topographical atomic force microscopy image of single-crystal iron islands ranging in size from 0.2 by 0.2 μm to 0.2 by 0.6 μm.

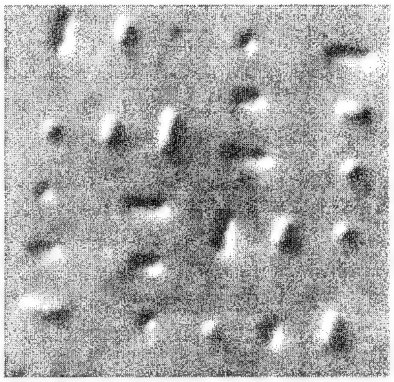

FIG. 6. Magnetic force image of the patterned islands shown in Fig. 5. The orientation of the easy axis of magnetization with respect to the edges of the patterned features is shown in Fig. 1. All of the particles are single domain, and the magnetizations are all directed roughly along the easy axis defined by the 001 crystallographic direction.

short axes of the island, respectively. Using $N_a=0.07\pi$ and $N_b=0.34\pi$, we obtain $E_{\text{shape}}=6\times10^5$ ergs/cm^3 $(\cos 2\alpha)$. We can compare this with the surface anisotropy energy density: $E_{\text{surface}}=-(1/2)K\cos 2\theta=-14$ ergs/cm^3 $(\cos 2\theta)$, where θ is the angle between the magnetization and the [001] axis of the iron. Since the surface anisotropy is larger than the shape anisotropy, we expect the easy axis to be determined primarily by the crystalline orientation rather than island shape.

Magnetic images were also taken as the sample and tip were subjected to a gradually increasing externally applied field. Although we observed that switching fields generally increased with particle size, we attribute this to tip-induced switching: fields from the imaging tip have a greater effect on smaller islands. Interpretation of images such as those of Fig. 8 is complicated by the effect of the external field on the magnetic tip. At high fields the tip magnetization is almost horizontal and images of single-domain particles are quite different from those of Figs. 6 and 7 in which the tip is vertically magnetized.[12,13]

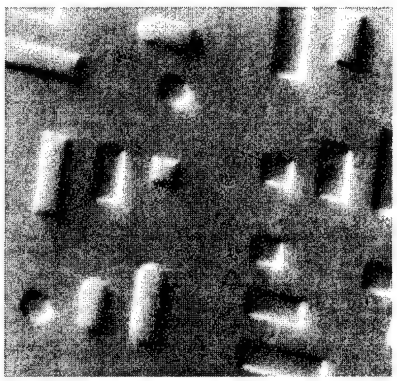

FIG. 7. Magnetic force images of single-crystal iron islands with sizes ranging from 1.0 by 1.0 μm to 1.0 by 3.0 μm. Some of the islands have deliberately smoothed corners or serrated edges. Unlike polycrystalline cobalt islands (Ref. 6), the patterned features are single domain even for large island sizes. For this sample, the silicon dioxide mask was not completely removed, so the magnetic signal is slightly stronger at the edges of the islands. The islands appear to be either sticking up out of the surface or receding into the surface, depending on their magnetization state.

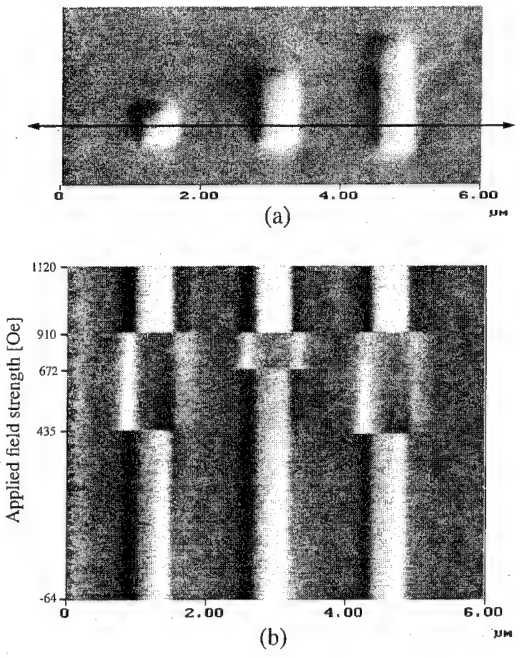

FIG. 8. Figure (a) shows a magnetic force image of three islands, each with a width of 0.5 μm, but with different lengths. In (b), the vertical scan direction has been turned off, and the magnetic tip moves back and forth along a horizontal line ($\leftrightarrow$) as an externally applied field from an electromagnet is ramped up. The field is applied within five degrees of the easy axis of magnetization as shown in Fig. 1. Both the electromagnet and the islands are initially in a saturation remanent state [at the bottom of (b)]. As the field is increased, the left and right islands are the first to reverse their magnetizations (at 435 Oe) followed by the center island (at 672 Oe). At 910 Oe, the magnetization of the tip reverses so as to align itself with the applied field.

Surface-induced miscibility gap in vapor deposited $Co_{1-x}Pt_x$ (abstract)

M. Q. Tran, A. L. Shapiro, P. W. Rooney, and F. Hellman
Department of Physics, University of California at San Diego, La Jolla, California 92093-0139

We have deposited (100) and (111) oriented single-crystal $Co_{1-x}Pt_x$ films (x=0.65, 0.75, and 0.86) over a range of growth temperatures from −50 to 800 °C. The Curie temperature is increased by up to 200 °C over the value expected for the homogeneous, chemically disordered alloy in the as-deposited films (of both orientations) grown near 400 °C. Measurements of the onset of magnetic ordering below the Curie temperature indicate separation into Co-rich and Pt-rich regions. High resolution x-ray measurements show no shift in the lattice constant or broadening of the x-ray peaks, and no observable strain for x=0.75, suggesting that the separated regions are small and epitaxially coherent. We interpret this as evidence for a previously unobserved miscibility gap. The bulk phase diagram shows no phase separation, but magnetic energy tends to drive the system toward immiscibility as demonstrated by the calculations of several workers. We suggest that the observed miscibility gap is an equilibrium *surface* effect, trapped into the bulk film by low bulk mobility.[1] Preliminary work by Rosengren and Kundrotas supports this idea. Large perpendicular magnetic anistropy is found in those films that exhibit an anomalously high Curie temperature (films grown near 400 °C). This anisotropy is likely related to the phase separation. After annealing at high temperatures, the Curie temperature approaches the homogeneous values and the anisotropy relaxes. [S0021-8979(96)43408-X]

Effects of magnetostatic interaction between two single-domain cobalt bars on crystal anisotropy and switching field (abstract)

Stephen Y. Chou and Linshu Kong
NanoStructure Laboratory, Department of Electrical Engineering, University of Minnesota, Minneapolis, Minnesota 55455

Understanding the magnetostatic field effects of a single-domain particle on its neighbors during thin film deposition and magnetic recording is essential to the development of magnetic recording media. Here, we present a unique study of such effects using nanofabrication technology and magnetic force microscopy (MFM). We fabricated pairs of single-domain cobalt bars. Each bar is 35 nm thick, 50 nm wide, and 1 μm long. The twin bars were oriented side-by-side on a silicon substrate with a spacing that varied from 50 to 1000 nm. In fabrication, a resist template was first created on a silicon substrate, followed by e-beam evaporation of cobalt into the bar-shaped openings of the template as well as on the top of the template. Then, the resist was dissolved making the cobalt on top of the template lift off. MFM showed that as-fabricated bars are single magnetic domain. We polarized the magnetic moment of the twin single-domain bars in the same direction and measured the magnetic field needed for the following three cases: (a) switching the magnetization direction of only one of the twin bars, H_a; (b) switching both bars, H_b; and (c) switching one bar after the other bar was physically removed by a nanotechnique, H_c. Two important facts can be seen. First, for a given bar spacing, $H_a<H_c<H_b$. The difference is due to the demagnetization field of the neighbor which is on the order of 150 Oe depending upon the bar spacing. Second, all three switching fields decrease significantly as the bar spacing becomes larger. For example, H_c is 2050 Oe for a 300 nm bar spacing and 1700 Oe for 1000 nm spacing. The spacing dependence of H_c clearly indicates that the intrinsic switching field of a bar has been significantly affected, during the cobalt deposition, by the demagnetization field of its neighbors. One explanation is that as soon as the first few atomic layers of cobalt were deposited into a nanoscale bar shaped opening in the resist template, a single domain is formed immediately creating a magnetostatic field. This field forces the c axis of the cobalt that was later deposited into the neighboring bar to align with the field, therefore enhancing the crystal anisotropy and intrinsic coercivity of the neighboring bar. This study implies that a small topology variation on a magnetic disk substrate may cause a large local coercivity variation due to the enhancement of crystal anisotropy and coercivity induced during the deposition by the demagnetization field of neighboring single-domain particles. Synthesis and physical properties of RNi_2B_2C and related materials (invited) (abstract)

R. J. Cava
AT&T Bell Laboratories, Murray Hill, New Jersey 07974

Copper oxides have dominated superconductivity research since 1987. The interplay between superconductivity and magnetism lies at the center of the controversy concerning the appropriate microscopic model for their superconductivity. We have recently been exploring a broad new family of materials which represent the first true quaternary intermetallic superconductors. Although their superconducting T_c's are not competitive with the copper oxides, several of the members of the family have T_c's equivalent to the highest T_c's ever reported for intermetallic compounds. The materials are especially surprising in that they are not based on niobium alloys, but rather are based on the borides of nickel, palladium, and platinum. The presence of square planes of the normally magnetic transition metals nickel and palladium suggests that magnetism might play some role in the superconducting mechanism. There are experimental results on both sides of the magnetic/conventional mechanism question, and although at this time the community is leaning largely toward a conventional mechanism, this should still be considered an open question. The presence of superconductivity for some of the magnetic rare earth analogs results in interesting phenomena, especially in the case of $HoNi_2B_2C$ where the magnetic transition on the Ho sublattice is very close to the superconducting T_c. This talk will serve as an introduction to the chemistry, structure, and basic physical properties of these new materials, and will draw on the results of other groups, as well to present a summary view of these materials.

Neutron diffraction has been used to investigate the magnetic order of RNi_2B_2C. For R=Er the system orders antiferromagnetically at T_N=6.8 K, and this long range order coexists with superconductivity (T_c=11 K). The magnetic structure is an incommensurate, transversely polarized spin-density-wave state, with the modulation wave vector δ along the a axis and the moments along b. δ has a temperature-independent value of 0.5526 ($2\pi/a$), with the structure squaring up at low temperatures. For R=Ho the moments also prefer to reside in the $a-b$ plane, but initially an incommensurate c-axis spiral state forms upon cooling, with $T_N \approx T_C \approx 8$ K. This c-axis spiral consists of ferromagnetic sheets of holmium moments in the $a-b$ plane, but with each sheet rotated by ~163° as one proceeds along the c axis. Small a-axis peaks are also observed above the reentrant superconducting transition over a narrow temperature range, but the c-axis peaks dominate. Just below the reentrant transition at ~5 K the magnetic system locks-in to a simple commensurate antiferromagnetic structure, which permits superconductivity to be restored. The c-axis spiral, the a-axis component, the commensurate antiferromagnetic structure, and the superconducting phase are all in a delicate balance energetically, and this balance may be easily shifted by subtle changes in composition, magnetic field, and pressure. $DyNi_2B_2C$ orders antiferromagnetically at T_N=11 K, with the same commensurate antiferromagnetic structure as found for the holmium material at low temperature. The existence of superconductivity in some samples of $DyNi_2B_2C$ is consistent with the antiferromagnetic structure observed. © *1996 American Institute of Physics.*

I. INTRODUCTION

The interaction between magnetic long range order and superconductivity has been an active area of interest for many years. In the Chevrel-phase and related compounds[1] the magnetic ordering temperatures are typically much lower than the superconducting transitions, and are in the temperature range where dipolar interactions play a crucial role. An even more extreme situation is found for the high-T_c cuprate superconductors, where the rare earth ordering is typically ~1 K while the superconducting transitions are one to two orders of magnitude higher in temperature.[2] The new classes of quaternary intermetallic borocarbide superconductors such as the RNi_2B_2C (R=magnetic rare earth ion) materials[3] have therefore attracted considerable attention because the magnetic ordering of the rare earth ions typically occurs at a much higher temperature,[4–12] which requires that exchange interactions dominant the energetics rather than dipolar interactions. The T_c's are also comparable to the magnetic transition temperatures so that the interplay between these two cooperative phenomena is enhanced. Moreover, the evidence to date suggests that the superconductivity is three-dimensional in nature, unlike the layered cuprates, and that it originates from a relatively strong electron–phonon interaction so that the theories advanced to explain the original systems can be more readily compared and tested experimentally in these new materials. We have therefore been carrying out neutron scattering experiments to explore the nature of the magnetism and its interaction with superconductivity.[4–8]

The samples were prepared by melting the elements Y, Er, Ho, Dy, or Ce (purity 99.9%), Ni (99.9%), B (99.8%), and C (99.7%) in an arc-furnace under a protective atmosphere of flowing argon. The ^{11}B isotope was used to reduce the effects of nuclear absorption in the samples. The powder diffraction measurements were carried out on the diffractometers at National Institute of Standards and Technology (NIST), and more recently at the high-flux-isotope reactor (HFIR) spectrometers at the Oak Ridge National Laboratory when the NIST facilities were unavailable. A standard top-loading pumped He cryostat with a low T capability of 1.7 K was employed to control the sample temperature. Data were collected on samples of Er, Ho, Dy, Ce, and Y. No magnetic order was found in either the Y[6] or Ce systems, and so no further discussion of these materials will be given here.

II. RESULTS AND DISCUSSION

A. $HoNi_2B_2C$

The first system to be investigated with neutrons was $HoNi_2B_2C$ because of the doubly reentrant superconducting behavior exhibited by this material.[3] Both the magnetic order and the superconductivity begin to develop at ~8 K, and

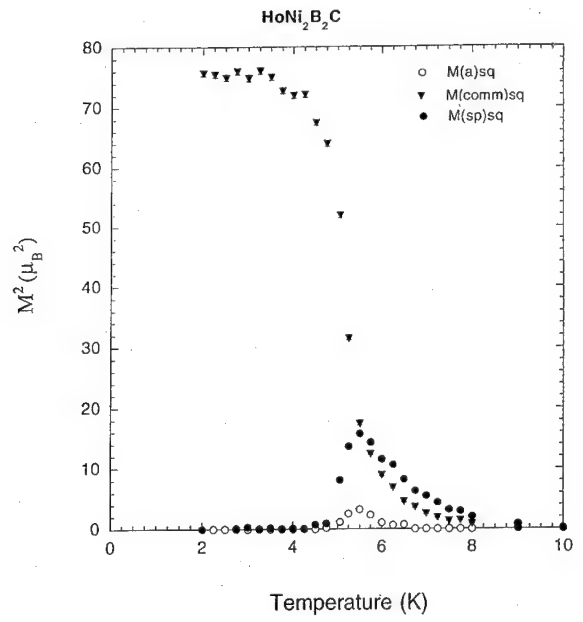

FIG. 1. Temperature dependence of the commensurate antiferromagnetic (▼) Bragg peaks, the incommensurate c-axis spiral peaks (●), and incommensurate the a-axis magnetic peaks (○) for this sample of $HoNi_2B_2C$. These data were taken on cooling.

initially two types of magnetic peaks were observed.[4] One set of peaks originates from a long-wavelength c-axis spiral antiferromagnetic structure, where the moments in the tetragonal plane are ferromagnetically aligned, but they spiral along the c axis with a relative alignment of 163°. Thus this magnetic periodicity is incommensurate with the underlying chemical unit cell. The second set of peaks originates from a commensurate magnetic structure in which the Ho moments are again ferromagnetically aligned within the tetragonal plane, but are antiferromagnetically coupled along the c axis (i.e., a relative alignment of 180°). The temperature evolution of these two types of peaks is shown in Fig. 1, where the intensities have been normalized to the nuclear peaks. Upon cooling through the ordering temperature we see that the intensity of the spiral peak in this sample is about twice the intensity of the (001) commensurate antiferromagnetic peak, which is quite different than found for other samples.[4,5,7–9] Thus the relative ratio of these two types of peaks varies dramatically from sample to sample, and demonstrates that these two types of magnetic order occur in distinct regions of the sample. Indeed, it is now clear[12] that both the magnetic and superconducting states are very sensitive functions of the sample composition for all these materials.

Upon further cooling the antiferromagnetic intensity begins to rapidly increase, while the intensity of the spiral state drops rapidly. This is just the temperature regime where the reentrant superconductivity is observed; the superconducting state that initially forms on cooling is quenched, but then is regained at lower temperature as the spiral intensity disappears and the antiferromagnetic state becomes fully established. At low T only the commensurate antiferromagnetic order survives in this sample, and this magnetic order readily coexists with the superconductivity. Hence we believe that the spiral magnetic order and superconductivity are strongly coupled and competing states, with the development of the spiral amplitude driving the system normal.[4,5,7,8,13] The simple commensurate antiferromagnetic state, on the other hand, is not strongly coupled to the superconductivity, which allows the coexistence at low temperature.

Finally, we note that there is also a small component of the magnetism associated with an incommensurate a-axis modulation found by Goldman *et al.*,[9] as also shown in Fig. 1. The intensity of this peak is much smaller than for the spiral peaks, and exists over a narrower temperature range. In particular, note that the development of the c axis and antiferromagnetic intensities occur together, and they start at a higher temperature where the a-axis intensity is zero. We also note that the maximum in intensity for the a-axis and c-axis reflections occurs at about the same temperature for this particular sample, while for other samples they occur at quite different temperatures. The relative intensity of these a-axis peaks and the temperature range where they appear also vary substantially from sample to sample. These results suggest that these a-axis peaks again originate from separate regions of the sample, and emphasizes that the antiferromagnetic, c-axis spiral, a-axis, and superconducting states are all delicate functions of the sample composition.

B. $DyNi_2B_2C$

The Dy ions in $DyNi_2B_2C$ order antiferromagnetically at a T_N just above 10 K. Within the $a-b$ plane the moments are ferromagnetically aligned, while the structure is antiferromagnetic along the c axis.[10] This is the same commensurate, collinear antiferromagnetic structure that is found in the $HoNi_2B_2C$ material at low temperature. The superconducting state is very sensitive to the precise composition of the sample, and is present in some samples while absent in others.[14,15] If the superconducting state is present then there appears to be little interaction between it and the magnetic order parameter, with the two coexisting to low temperatures as found for $HoNi_2B_2C$.

The intensity of the (001) antiferromagnetic Bragg peak is shown in Fig. 2 as a function of temperature. The intensity varies smoothly with temperature, with no evidence of any hysteresis (in contrast to the case of $HoNi_2B_2C$). The solid curve is a fit to the $S=1/2$, $2d$ Ising model, with the fit being restricted to the data below 9 K to avoid the effects of critical scattering. The overall fit is relatively good, with $T_N=10.16$ K. However, this curve should be regarded primarily as a "guide-to-the-eye" rather than as establishing the $2d$ Ising model as appropriate; a more definitive test could be made with an extinction-free single crystal. We also tried fitting the data to a mean field model with a variable spin, but the fitted curve was not steep enough and the fit was not nearly as good. Finally, we obtained a low temperature ordered moment of 8.47(9) μ_B from the profile refinements of the full diffraction pattern.

C. $ErNi_2B_2C$

For the Er system the superconducting transition occurs at $T_c \approx 11$ K, and superconductivity persists to low temperatures with no reentrant transitions or evidence of strong cou-

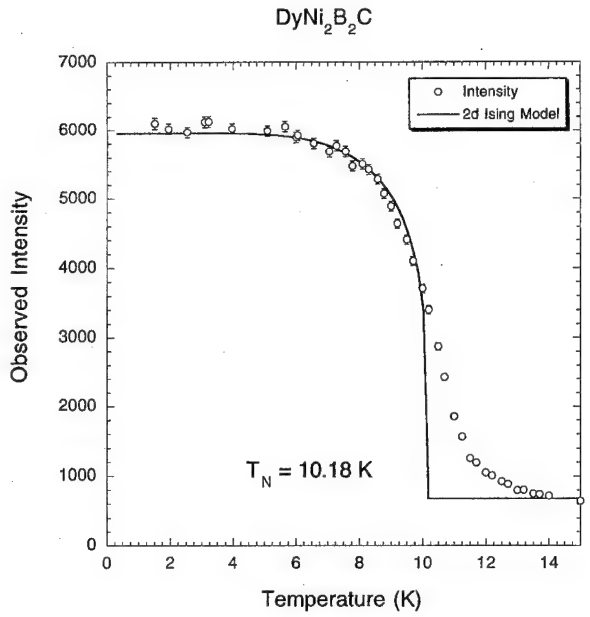

FIG. 2. Temperature dependence of the intensity of the (001) magnetic reflection for $DyNi_2B_2C$. The solid curve is a fit to the $2d$ Ising model.

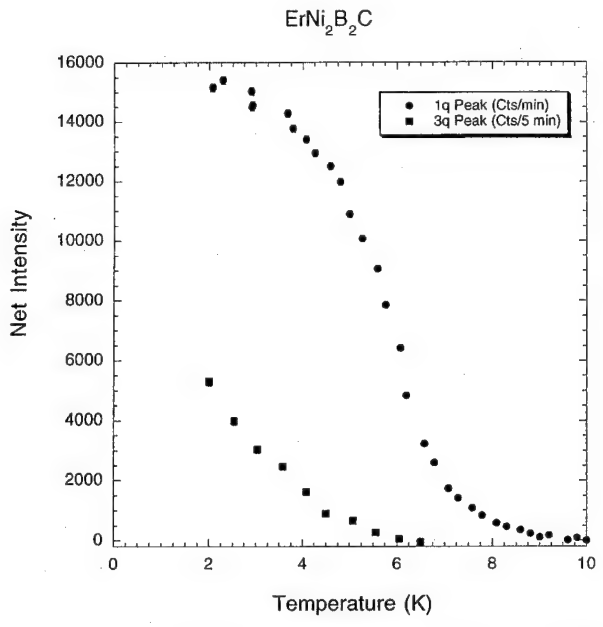

FIG. 3. Temperature dependence of the primary spin density wave intensity, and the third harmonic, in $ErNi_2B_2C$.

pling to the magnetic state. The antiferromagnetic ordering develops at T_N=6.8 K,[6,11] with the Er ions forming a transversely polarized, incommensurate spin density wave state. The modulation wave vector for this state is δ=0.5526 ($2\pi/a$) and is approximately temperature independent, with the direction along the a axis (or equivalently along the b axis in this tetragonal system) with the spins directed along b (or a). The staggered magnetization increases smoothly as the temperature is decreased below T_N as shown in Fig. 3, and is nonhysteretic. Higher-order harmonics of δ also develop at lower temperatures, as also shown in Fig. 3, and indicate a squaring-up of the magnetic structure as we go to low T. This squaring-up of the spin density wave is expected, since a purely sinusoidal spin density wave cannot be the ground state of a local-moment system because this leaves many of the moments in a partially disordered state.

A refinement of the magnetic structure gives an ordered moment of 7.8 μ_B/Er ion. There is also evidence of an induced moment of -0.35 μ_B on the Ni ions, as the refinement gives a small improvement when a Ni moment is included. However, such a small Ni moment is difficult to resolve unambiguously from the large Er moment, and it might indicate that a small adjustment in the model is needed rather than an actual Ni moment. In particular, from a physical standpoint an ordered Ni moment is difficult to reconcile with the coexistent superconducting state since it is believed that the Ni electrons are the ones that are predominantly involved in the Cooper pairing. The spin-depairing would then be expected to suppress the superconductivity if indeed the superconducting state originates from conventional BCS-type electron–phonon pairing. Clearly additional work will be needed to clarify this issue.

We note that the magnetic structure observed in $ErNi_2B_2C$ is reminiscent of the small a-axis peaks found in the $HoNi_2B_2C$ material as discussed above. Since this large-moment magnetic structure readily coexists with superconductivity in the Er system, it seems unlikely that the weak a-axis peaks in the Ho material could be the cause of the reentrant behavior in $HoNi_2B_2C$. Thus this is additional evidence that the reentrant superconducting behavior in the holmium system is associated with the incommensurate c-axis magnetic ordering.

Superconducting metastable phase in rapid quenched Y–Pd–B–C borocarbides

Valter Ström, K. S. Kim, A. M. Grishin, and K. V. Rao
Department of Condensed Matter Physics, Royal Institute of Technology, S-100 44 Stockholm, Sweden

Rapid quenched (RQ) palladium-based borocarbides with large fractions of the superconducting phase (T_c>20 K) have been obtained. Superconductivity is found to exist only in the RQ state. Thus, while the as cast YPd_2B_2C is nonsuperconducting, the RQ material superconducts and has an x-ray diffraction (XRD)-pattern characteristic of a face-centered cubic fcc lattice with a lattice parameter of 4.15 Å. A sequential annealing study shows decay of the superconducting phase above 750 °C which correlates well with the reduction in the integral intensities of the XRD fcc peaks. A tentative phase diagram for superconductivity in the Y–Pd–B–C systems is presented. © *1996 American Institute of Physics.* [S0021-8979(96)40708-3]

I. INTRODUCTION

In early 1994 a new family of intermetallic superconductors named *borocarbides* was discovered. Among these materials, the Pd-based borocarbide, i.e., $YPd_5B_3C_{0.35}$, has the highest reported T_c (=23 K) for any intermetallic bulk superconductor.[1] Soon after, the crystal structure for Ni-based $LuNi_2B_2C$ was reported suggesting that the superconducting phase in the Pd system has a similar structure to that of the Ni-based borocarbides.[2–4] However, few studies have been reported on Pd-based borocarbides, because superconductivity in this system is due to a metastable phase for which conventional synthesizing methods like arc-melting will not be efficient yielding only a minor superconducting fraction if at all.

We use rapid quenching technique to identify the metastable superconducting phase. This approach makes it possible to suppress phase separation and obtain a more homogeneous material. As far as we know there are no other reports on RQ borocarbides except our earlier study on melt-spun YNi_2B_2C-ribbons.[5,6] In this article we present a detailed study of rapid quenched YPd_2B_2C in which we find the x-ray diffraction (XRD)-pattern characteristic for a face-centered cubic (fcc)-structure (a=4.15 Å). The thermal stability of this phase shows that superconductivity is suppressed simultaneously with the intensities of the peaks of the fcc-like XRD-pattern. We also present a phase-diagram showing the optimum composition regimes for superconductivity in the Y–Pd–B–C system.

II. EXPERIMENT

Ingots were prepared by arc-melting in pure (99.9997%) Ar gas. Bulk pieces, (99.9+% Y, C, Pd, 99.7% B), were used with sample batches of ~3 g. Ingots were remelted several times. Splat-quenching as well as melt spinning methods have been used. Melt-spinning was performed in pure Ar on a copper wheel with a peripheral velocity of 47 m/s. Splat-quenching was performed in an arc melter with a copper rod impinging at a hammer blow on a small droplet of the molten sample.

Magnetization was measured in a Quantum Design SQUID. XRD data were obtained in a Siemens D5000 diffractometer with Cu anode. For the annealing sequence we used the same sample of splat-quenched material with nominal composition YPd_2B_2C. The annealing was performed in a Perkin Elmer thermo-gravimetry instrument (TGS) in pure Ar atmosphere. The annealing system was purged with pure Ar for 7 h prior to each annealing (1 h).

III. RESULTS AND DISCUSSIONS

A. Rapid quenched Y–Pd–B–C

The pseudo-ternary phase-diagram in Fig. 1 shows the T_c's for the as-melted and RQ samples. In Table I the T_c's and zero-field cooled susceptibility (M/H) at 5 K are given. The as-melted Pd-samples show superconductivity only when the compositions lie *outside* the composition region around YPd_2B_2C and YPd_3B_3C (hereafter referred to as the "1221 region") of the phase-diagram and in these cases displaying a very shallow fraction of the superconducting phase. A T_c as high as 21.5 K is found in the as-melted $YPd_5B_3C_{0.35}$, consistent with i.e., Ref. 1.

In contrast to what is observed in as-melted ingots, the best RQ Pd samples are found *within* the 1221 region. The compositions on the verge to superconductivity in the as-melted state are no longer superconducting. This may be understood in terms of two mechanisms: initial formation and the subsequent transformation of a superconducting

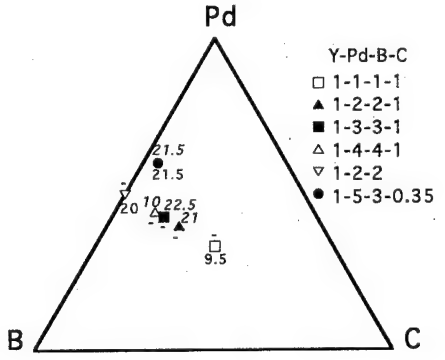

FIG. 1. Pseudoternary phase diagram showing the investigated compositions. T_c (K) for RQ samples are in italics above symbol, for "as-melted" samples below symbol. "–" means T_c<5 K. Solid symbols denote large fractions of the superconducting phase when RQ.

metastable phase. Since the formation and transformation occur sequentially, a dynamic equilibrium will develop yielding both the metastable phase and its derivatives depending on the time-scale of the cooling. During the natural cooling of the as-melted samples with compositions from outside the 1221 region, we expect a multiphase situation, which slows down the crystallization process. Even a relatively slow cooling after arc-melting is enough to prevent the crystallization to reach the ground state. In this case long-term annealing should put the system into the ground state which means complete transformation of the superconducting phase. This is in agreement with the observation of vanishing superconductivity in as-melted $YPd_5B_3C_{0.35}$ after annealing.[1,3,4] When RQ, the time-scale is too short for transformations so the originally formed metastable phase is retained.

The XRD-spectra for melt-spun ribbon and splat-quenched samples before and after annealing at 900 °C are shown in Fig. 2. The main feature of the spectra for the RQ samples are peaks at positions characteristic for a fcc lattice. The fcc line spectrum (a=4.15 Å) is also shown. The spectra for the nonsuperconducting material after annealing above

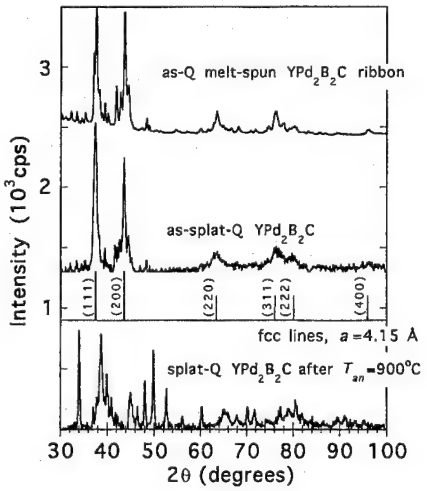

FIG. 2. XRD spectra for as-Q ribbons and splat-Q samples before and after annealing at 900 °C. Background contribution from the sample holder has been subtracted. For clarity the curves are offset. Also inserted is the line spectrum for a fcc lattice (a=4.15 Å).

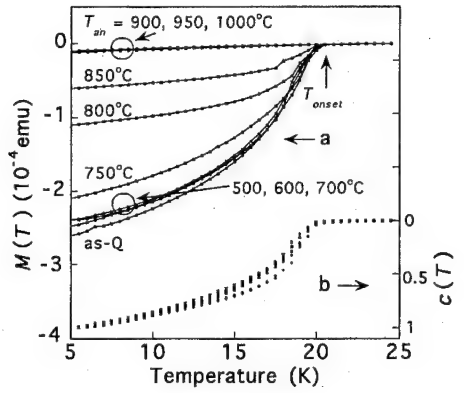

FIG. 3. (a) Zero-field cooled response in 10 G field of RQ YPd_2B_2C prior to and after each annealing. (b) The same data but now normalized with respect to its value at 5 K.

900 °C are quite different. This transformation has been studied by a step-by-step annealing sequence.

B. Thermal stability of the metastable phase in rapid quenched YPd_2B_2C

As-melted YPd_2B_2C- and YPd_3B_3C-ingots are not superconducting. However, on RQ large fractions of the superconducting phase are found. Therefore, we have investigated the anticipated decay of this metastable phase upon annealing by monitoring the relevant intensities in the XRD-spectra and quantify the changes of superconductivity. This is done by annealing an originally superconducting sample at increasingly higher temperatures (T_{an}=400, 500, 600, 700, 750, 800, 850, 900, 950, and 1000 °C) and after each stage take an XRD pattern and measure the magnetic properties of the superconducting state. To quantify the decrease of intensity of the peaks in the original spectrum, the peaks were integrated and normalized with respect to their original values as-Q yielding XRD integral intensity as a function of annealing temperature:

$$I(T_{an})/I(\text{as-Q}). \tag{1}$$

The first three peaks were measured, and the 2θ intervals integrated were 36.7°–38.1°, 43.1°–44.3°, and 61.2°–64.4°. We deduce the loss of superconducting fraction upon annealing from the magnetization in 10 G field in zero-field cooled state. The full set of zero-field cooled curves is presented in Fig. 3(a). Above T_{an}=750 °C, the superconducting fraction begins to decrease and totally disappears on annealing at T_{an}=900 °C. When the magnetization data for samples annealed up to 850 °C is normalized with respect to the value at T=5 K they essentially collapse into a universal curve, Fig. 3(b), indicating that the superconducting phase has the same T_c during the various annealing states.

To quantify the decrease of superconducting fraction as a function of annealing temperature, we normalize the moment at 5 K after each annealing with respect to the as-Q value

$$c(T_{an})=M(T_{an})/M(\text{as-Q}) \quad \text{at 5 K.} \tag{2}$$

In Fig. 4 we plot XRD integral intensities and superconducting fraction versus annealing temperature. The close cor-

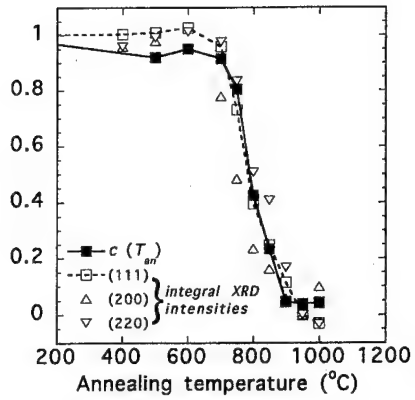

FIG. 4. XRD integral intensities $I(T_{an})/I(\text{as-Q})$, and superconducting fraction $c(T_{an})$ vs annealing temperature for RQ YPd_2B_2C.

respondence between the two quantities implies that *the phase responsible for these fcc-peaks corresponds to the superconducting phase in this system.*

There are two reports on superconductivity and structure determination in Pd-based borocarbides.[3,4] From Fig. 5, the XRD-spectra for our three RQ superconducting Pd-based samples, we cannot identify the *tetragonal 1221-phase* suggested in Refs. 3 and 4 neither in YPd_2B_2C nor in the other compositions. Moreover, we observe that the YPd_2B_2C composition has the simplest XRD-pattern which suggests that this composition is closest to the stoichiometry of the fcc-like phase. However, when we try to deduce the existence of this fcc-phase in the other two XRD-patterns, we are unable to identify this phase except for the (111)-peak.

Thus, while our study is consistent with Refs. 3 and 4, in that superconductivity in Pd-based borocarbides is metastable and found in the composition regime close to YPd_2B_2C, our XRD analysis *appears to contradict* the suggestions of a tetragonal structure. We cannot find this structure in *any* of our samples.

IV. CONCLUSIONS

We show that superconductivity in rapid quenched YPd_2B_2C is related to a metastable phase which closely correlates with an XRD pattern which is characteristic for a

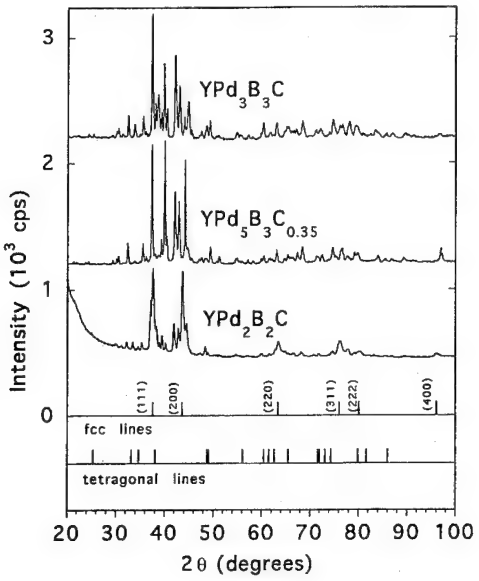

FIG. 5. XRD spectra for the three RQ superconducting compositions. The spectra are offset for clarity. Also inserted are the linespectra for a fcc lattice (a=4.15 Å) and the tetragonal structure from Refs. 3 and 4 (a=3.71 Å, c=10.81 Å).

fcc-structure with a lattice parameter of a=4.15 Å. The compositions having the best superconducting properties are found to lie in the YPd_2B_2C region of the pseudoternary phase-diagram.

Field dependence of magnetic transitions for magnetic superconductors RNi_2B_2C (R=Dy, Ho)

H. C. Ku, M. S. Lin, Y. Y. Hsu, J. H. Shieh, and Y. B. You
Department of Physics, National Tsing Hua University, Hsinchu, Taiwan 300, Republic of China

High field (up to 5 T) magnetization measurements were performed on both bulk and field-aligned powder samples of RNi_2B_2C (R=Dy, Ho) magnetic superconductors. For $T_c=3.8$ K, a $DyNi_2B_2C$ superconductor with antiferromagnetic Néel temperature T_N of 10–11 K, and anomalous field-induced weak-ferromagnetic transitions were observed above the superconducting upper critical field $H_{c2}(2\text{ K})$ of 1.75 kG. The aligned powders show distinct hysteresis characteristics for both fields applied parallel and perpendicular to the tetragonal basal plane. For $T_c=7.8$ K, $HoNi_2B_2C$ has an incommensurate magnetic ordering temperature T_m of 6 K and T_N of 5.2 K. Anomalous field-induced weak-ferromagnetic transitions were also observed below T_N. No hysteresis can be detected for $T_N<T<T_m$. © *1996 American Institute of Physics.*
[S0021-8979(96)02108-4]

The coexistence of antiferromagnetic ordering and superconductivity, with Néel temperature (T_N) higher than superconducting transition temperature (T_c), was first observed in the metastable ternary boride $HoIr_4B_4$ and the related pseudoternary boride systems $R(Rh_{1-x}Ir_x)_4B_4$ (R=Ho, Dy) with composition factor $x>0.6$.[1–3] For example, in the partial Rh-substituted $Ho(Rh_{0.3}Ir_{0.7})_4B_4$ compound, T_c (1.6 K) was below T_N (2.7 K).[2]

Recently, a new magnetic superconducting system was reported in the quaternary borocarbide RNi_2B_2C compounds (R=Sc, Y, Th, U, or a rare earth).[4–11] Among nonmagnetic compounds, $LuNi_2B_2C$ exhibits the highest T_c of 16.6 K,[5] followed by 15–16 K for YNi_2B_2C and metastable $ScNi_2B_2C$,[4,5,7] 8 K for $ThNi_2B_2C$, and no superconducting transition was found down to 2 K for $LaNi_2B_2C$.[9–11] For compounds containing magnetic rare earth elements such as R=Dy, Ho, Er, and Tm, lower T_c values were observed due to the magnetic pair breaking effect.[5–8] A nearly reentrant superconductivity was observed for $HoNi_2B_2C$ with $T_c=8$ K, which is higher than the T_N of 5.2 K associated with commensurate magnetic structure and T_m of 6 K due to a transition to an incommensurate state.[5,8,12–16]

For a magnetic $DyNi_2B_2C$ compound, T_c of 3.8 K with onset around 5.2 K was observed below T_N around 10–11 K, which provides another interesting example of the coexistence of superconductivity and antiferromagnetism.[8,17] The low-temperature electrical resistivity shows no reentrant behavior down to 0.3 K and indicates a perfect coexistence between superconductivity and antiferromagnetism below T_c.[17] The observed T_N around 10–11 K from magnetic measurements is associated with the long-range Dy^{3+} magnetic ordering through the RKKY indirect exchange interaction. The magnetic transition can be clearly corroborated by low-temperature specific heat data $C(T)$ where a very distinct transition peak was observed around 10 K.[17] The magnetic entropy S_m of 10.3 J/mol K is close to 90% of R ln 4 and indicates the antiferromagnetic ordering of Dy^{3+} with a possible quadruplet ground state in the tetragonal crystal field.

Magnetic hysteresis $M(H)$ data at temperature below T_c for $DyNi_2B_2C$ provide the precise information on the temperature dependence of superconducting upper critical field $H_{c2}(T)$ and lower critical field $H_{c1}(T)$. The $DyNi_2B_2C$ samples were prepared using high-purity elements under an argon atmosphere in a Zr-gettered arc furnace. As shown in Fig. 1, the upper critical field $H_{c2}(T)$ of 1.75 kG at 2 K and 750 G at 3 K were determined from the merging point of the hysteresis curve. Similarly, H_{c2} of 1.25 kG at 2.5 K, 450 G at 3.3 K, and 100 G at 3.7 K were obtained. Lower critical field $H_{c1}(T)$ is defined as the deviation from linearity in the initial magnetization in each $M(H)$ curve. The values thus obtained are 100 G at 2 K and 30 G at 3 K. Similarly, H_{c1} of 50 G at 2.5 K and 10 G at 3.3 K were obtained. From the temperature dependence of critical fields, the extrapolated $H_{c2}(0)$ of 3 kG and the extrapolated $H_{c1}(0)$ of 200 G are derived. From $H_{c1}(0)$ and $H_{c2}(0)$, the Ginzburg–Landau parameter $\kappa=3.7$ is evaluated.[17] As a comparison, the κ value of 3.5 was reported for $HoNi_2B_2C$.[16] The relative low H_{c2} in all quaternary borocarbides implies a long coherence length ξ, and three-dimensional superconductivity.

Since each $M(H)$ curve at 2 or 3 K has a slightly nonlinear background due to the field dependence of antiferromagnetic order with T_N(Dy) of 10–11 K, high field $M(H)$ isotherm data up to 5 T were measured for bulk sample at 2 K to understand the normal state magnetism and possible field-induced magnetic transitions. As shown in Fig. 2, above

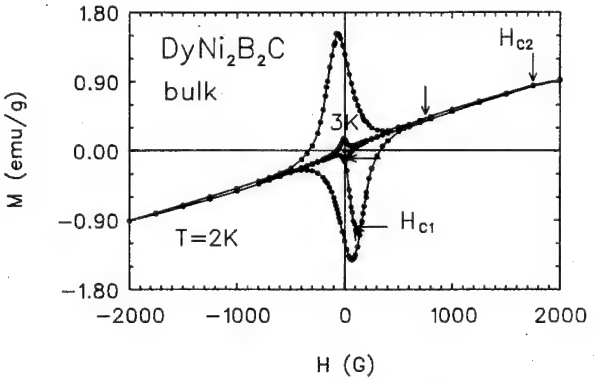

FIG. 1. Intermediate field (up to ±2 kG) magnetic hysteresis curves $M(H)$ at 2 and 3 K for $DyNi_2B_2C$ bulk sample. Upper critical field H_{c2} and lower critical field H_{c1} are indicated by arrows.

 0021-8979/96/79(8)/5863/3/$10.00

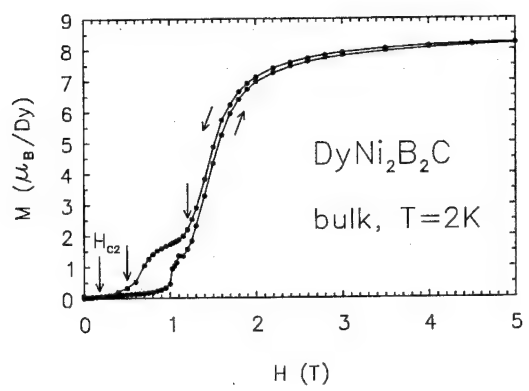

FIG. 2. High field (up to 5 T) magnetic hysteresis curve $M(H)$ at 2 K$<T_N$ for a $DyNi_2B_2C$ bulk sample.

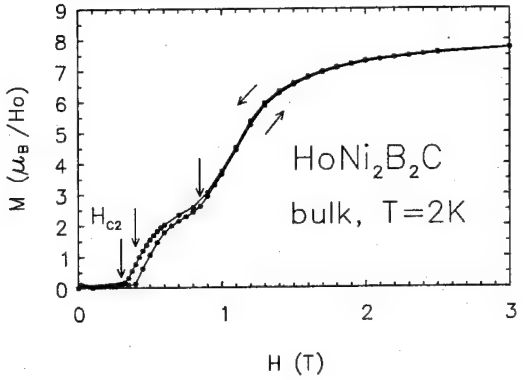

FIG. 4. High field (up to 3 T) magnetic hysteresis curve $M(H)$ at 2 K$<T_N$(5.2 K) for a bulk $HoNi_2B_2C$ sample.

H_{c2}(2 K) of 1.75 kG where the sample is no longer superconducting, two distinct weak-ferromagnetic-like hysteresis curves were observed indicating two possible field-induced magnetic transitions at 5 kG and at 1.2 T, respectively. The hysteresis characteristics persist up to a maximum applied field of 5 T where a saturated magnetic moment of 8.3 μ_B per Dy is achieved, very close to the calculated free ion Dy^{3+} $g_J J=10$ μ_B magnetic moment.

The anisotropy of these magnetic transitions with field applied parallel and perpendicular to the tetragonal basal plane is studied by using aligned $DyNi_2B_2C$ powder at 2 K as shown in Fig. 3. Farrell's method was employed for the powder alignment. Powders were first obtained by grinding the bulk sample into fine microcrystalline grains with average size 1–10 μm, then mixed with SPAR-5-min epoxy/hardener in a 8 mm quartz holder, with a typical powder-epoxy ratio of 1:7, and then aligned in a 9.4 T magnetic field at room temperature. Because of the intrinsic normal-state magnetic anisotropy, the degree of easy tetragonal basal plane alignment is close to 90%. Slightly higher T_N around 13 K was observed from magnetic measurement for aligned powder. Below T_N, for field H perpendicular to the easy basal plane, initial magnetization curve increases slowly to magnetic moment 0.5 emu at 1.7 T, then increases sharply to 2.7 emu at 1.8 T, and then saturates to 3.0 emu at 5 T. Broad hysteresis behavior occurs only below 1.8 T with two distinct magnetic transitions at 5 kG and 1.2 T as observed in bulk samples. For field parallel to the basal plane, initial magnetization increases sharply above 8 kG with fairly broad low field and very narrow high field hysteresis features. The same magnetic transition fields were observed. The preliminary $M(H)$ data at other temperatures below T_N(Dy) indicate that there are weak temperature dependencies associated with these transitions.

For a nearly reentrant $HoNi_2B_2C$ superconductor with a T_c of 8 K, a T_N of 5.2 K, a T_m of 6 K, and a complex $H_{c2}(T)$ upper critical field curve,[16] a coexistence between superconductivity and antiferromagnetism will prevail only below 5.2 K. Magnetism above $H_{c2}(T)$ will create a very complex phase diagram. As shown in Fig. 4, the magnetization measurement $M(H)$ of bulk sample at 2 K with field higher than H_{c2}(2 K) of 3 kG shows similar field-induced magnetic transitions around 4 and 8.5 kG, respectively.[16] A saturated magnetic moment of 7.8 μ_B per Ho is achieved at 3 T field and is very close to the calculated free ion Ho^{3+} $g_J J=10$ μ_B magnetic moment. At higher temperature of 4.6 K which is close to T_N and with a low H_{c2}(4.6 K) of 500 G, these field-induced transitions decrease to around 3 and 6 kG, respectively. For $T=T_N=5.2$ K with a minimum, nearly reentrant H_{c2}(5.2 K) of 400 G,[16] field-induced transitions decrease further to around 1 and 3 kG, respectively. Above T_N

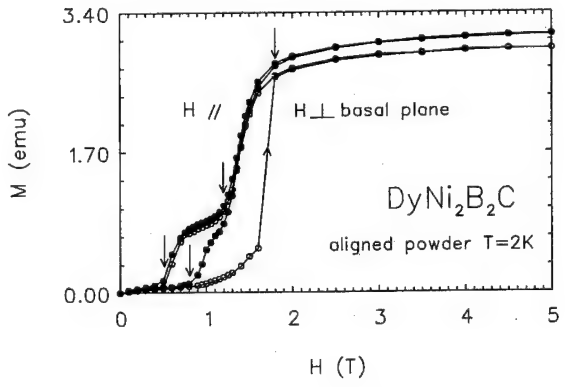

FIG. 3. Anistropic high field (up to 5 T) magnetic hysteresis curve $M(H)$ at 2 K for $DyNi_2B_2C$ aligned powder, with field parallel and perpendicular to the tetragonal basal plane.

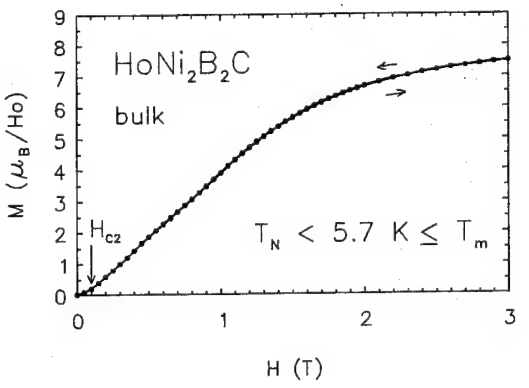

FIG. 5. High field (up to 3 T) magnetic hysteresis curve $M(H)$ at 5.7 K$<T_m$(6 K) for a bulk $HoNi_2B_2C$ sample.

at 5.7 K but is still lower than $T_m = 6$ K as shown in Fig. 5, no hysteresis or a very small effect can be detected above H_{c2}(5.7 K) of 1 kG due to the intrinsic, complex incommensurate magnetic structure.

In conclusion, field-induced weak-ferromagnetic transitions were observed only at a temperature below the antiferromagnetic ordering temperature T_N for both $DyNi_2B_2C$ and $HoNi_2B_2C$ magnetic superconductors. No hysteresis can be detected for $HoNi_2B_2C$ at temperature below the higher incommensurate ordering temperature T_m.

Systematic variation of T_N(Pr) for the two-CuO_2-layer cuprate $m212$ ($m=1, 2, 3$) systems

H. C. Ku, C. L. Yang, C. H. Chou, Y. Y. Hsu, Y. B. You, and J. H. Shieh
Department of Physics, National Tsing Hua University, Hsinchu, Taiwan 300, Republic of China

The systematic variation of anomalous Pr antiferromagnetic ordering temperature T_N(Pr) for the two-CuO_2-layer cuprate system $MA_2PrCu_2O_y$ (M=Cu, Hg, Tl, Pb; A=Ba, Sr) was verified through the observation of a new Hg-1212 $HgSr_2PrCu_2O_{6+\delta}$ tetragonal compound with a T_N(Pr) of 6 K and a Pr—O bond length of 2.492 Å between Pr and oxygen in the adjacent CuO_2 layers. For the tetragonal/orthorhombic 1212 compounds including the $PrBa_2Cu_3O_{7-y}$ system, T_N(Pr) was found to decrease monotonically with increasing Pr—O distance. The importance of Pr-O-Pr superexchange magnetic coupling is expected for all two-CuO_2-layer $M_mA_2PrCu_2O_y$ $m212$-type ($m=1, 2, 3$) compounds. A similar Pr anomaly in the 2212-type system was first observed on the new tetragonal $(Pb_{0.5}Cu_{0.5})_2(Ba_{0.5}Sr_{0.5})_2PrCu_2O_8$ compound with a high T_N(Pr) of 9 K. © *1996 American Institute of Physics.* [S0021-8979(96)02208-0]

The orthorhombic $PrBa_2Cu_3O_7$ compound with an anomalously high Pr antiferromagnetic ordering temperature T_N(Pr) of 17 K is the only nonsuperconducting member of the $RBa_2Cu_3O_7$ system (R=Y or a rare earth).[1–6] With further oxygen deficiency, T_N decreases to 10 K in tetragonal $PrBa_2Cu_3O_6$.[5,7] In comparison, other magnetic rare earth compounds have a maximum T_N(R) of 2.2 K in $GdBa_2Cu_3O_7$.[8,9] Since Pr is one of the lightest elements of rare-earth series, its $4f$ wave function is more extended and the anomalously high T_N observed indicates the importance of the quasi-two-dimensional (quasi-2D) Pr-O-Pr superexchange magnetic coupling through the strong hybridization between the Pr $4f$ and the eight O $2p_\pi$ orbitals in the adjacent two-CuO_2 layers.[6]

From the structural viewpoint, the 123-type $PrBa_2Cu_3O_{7-y}$ system can be recategorized as either the Cu-1212C-type (C stands for chain) for orthorhombic $[Cu]Ba_2PrCu_2O_7$ (space group $Pmmm$) or Cu-1212 $TlBa_2CaCu_2O_{7-\delta}$-type for tetragonal $[Cu]Ba_2PrCu_2O_6$ (space group $P4/mmm$),[10] analogous to other two-CuO_2-layer Pr compounds in the Tl-1212 $Tl(Ba,Sr)_2PrCu_2O_{7-\delta}$ system[11–15] and (Pb,Cu)-1212 $(Pb,Cu)Sr_2PrCu_2O_{7-\delta}$.[13] They also exhibit the common feature of having anomalous high T_N(Pr) values ranging from 4 to 8 K. The 12 K tetragonal $PrBa_2Cu_2NbO_8$ or $[Nb]Ba_2PrCu_2O_8$ compound can also be recategorized as the Nb-1212 $TlBa_2CaCu_2O_{7-\delta}$-type compound.[16]

Recently, a new Hg-1212 compound $HgSr_2PrCu_2O_{6+\delta}$ with the tetragonal $HgBa_2CaCu_2O_{6+\delta}$-type structure was reported where the mercury sample was prepared by two-stage solid-state reaction techniques where the precursor $Sr_2PrCu_2O_y$ powders were mixed with HgO powder, pressed into pellets, sealed in a 2 mm wall quartz tube in vacuum, and reacted at 1000 °C in vacuum for 8 h then quenched in liquid nitrogen.[17] A similar Pr anomaly is expected for this new compound. As shown in Fig. 1, a T_N(Pr) value of 6 K was identified from the minimum in the temperature derivative of the molar magnetic susceptibility $d\chi_m/dT$ in 1 T applied magnetic field. At higher temperatures, the temperature dependence of the magnetic susceptibilities indicates a magnetic Cu^{2+} ordering near 300 K or above. A simple Curie–Weiss fit $\chi_m=C^*/(T+\theta_p)$ below 200 K gives an antiferromagnetic-like, negative paramagnetic intercept $\theta_p=-13$ K and an effective magnetic moment of 3.31 μ_B per Pr from the Curie constant C^* if the small Cu^{2+} moment is neglected.[17] As in many other Pr cuprates, this effective moment is closer to that of the free Pr^{3+} ion (3.58 μ_B) rather than the Pr^{4+} ion (2.54 μ_B). Indeed, most experimental results on such compounds imply a Pr^{3+} state. The Pr magnetic transition of $HgSr_2PrCu_2O_{6+\delta}$ is clearly corroborated by low-temperature specific heat data $C(T)$ which show a distinct but broad magnetic transition prevails at T_N(Pr)=6 K and a very high onset around 11 K.[16] The broad transition indicates that a truly three-dimensional (3D) or quasi-2D long-range magnetic ordering set in at T_N(Pr)=6 K, while the 2D ordering effect persists up to the onset near 11 K.

The high T_N(Pr) observed in $HgSr_2PrCu_2O_{6+\delta}$ again indicates the importance of the quasi-2D Pr-O-Pr superexchange magnetic coupling through the strong hybridization between the Pr $4f$ and the eight O $2p_\pi$ orbitals in the adjacent CuO_2 layers. This degree of hybridization can be readily reflected in the Pr—O bond length, which can be accurately derived from the Rietveld analysis. X-ray Rietveld refinement on powder samples of tetragonal $HgSr_2PrCu_2O_{6+\delta}$ ($a=3.8532$ Å and $c=12.1199$ Å) gives a refined bond length d(Pr—O) between Pr and O(1) in the adjacent two-CuO_2 layers of 2.492 Å and the O(1)—Pr—O(1) bond angle is

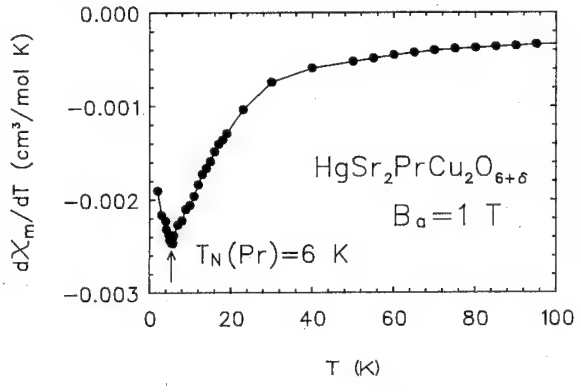

FIG. 1. Low-temperature differential molar magnetic susceptibility $d\chi_m/dT$ for a Hg-1212 $HgSr_2PrCu_2O_{6+\delta}$ compound revealing a T_N(Pr)=6 K.

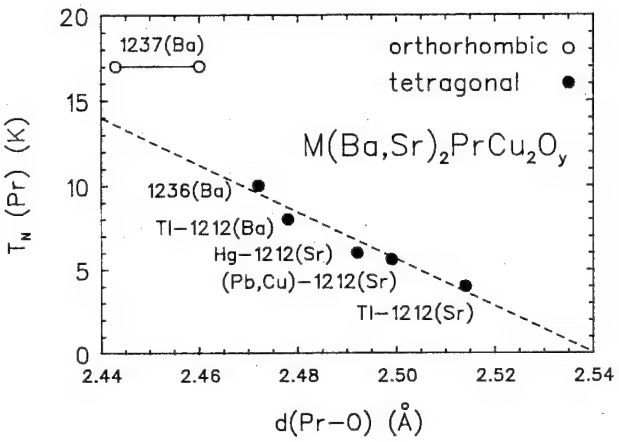

FIG. 2. T_N(Pr) vs Pr—O distance in various $M(Ba,Sr)_2PrCu_2O_y$ (M=Cu, Hg, Tl, Pb) 1212-type compounds. The dashed line is a guide to the eyes only.

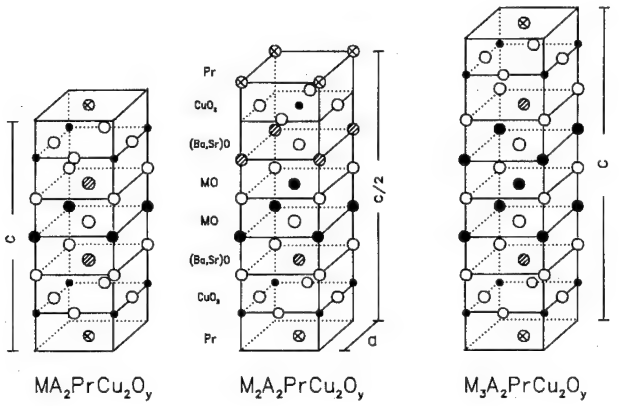

FIG. 3. Crystal structures of $M_mA_2PrCu_2O_y$ $m212$ ($m=1, 2, 3$; M=Cu, Hg, Tl, Pb; A=Ba, Sr) systems.

101.3°.[17] The d(Pr—O) for $HgSr_2PrCu_2O_{6+\delta}$ with T_N(Pr)=6 K, is shorter than 2.514 Å for Tl-1212(Sr) $TlSr_2PrCu_2O_{7-\delta}$ with $T_N=4$ K or 2.499 Å for (Pb,Cu)-1212 $(Pb_{0.6}Cu_{0.4})Sr_2PrCu_2O_{7-\delta}$ with $T_N=5.6$ K, but is longer than 2.478 Å for Tl-1212(Ba) $TlBa_2PrCu_2O_{7-\delta}$ with $T_N=8$ K.[13,14] This regularity forces us to study the systematic variation of T_N(Pr) for all reported $M(Ba,Sr)_2PrCu_2O_y$ (M=Cu, Hg, Tl, Pb) 1212-type compounds as a function of the Pr—O bond length as shown in Fig. 2. Note that for the orthorhombic T_N(Pr)=17 K 1237(Ba) $PrBa_2Cu_3O_7$ (Cu-1212C), instead of a single Pr—O bond length, there are two Pr—O bond lengths of 2.443 and 2.460 Å, respectively. For the oxygen-depleted tetragonal 1236(Ba) $PrBa_2Cu_3O_6$ (Cu-1212) compound, a single long Pr—O bond length of 2.472 Å with lower T_N(Pr) of 10 K was observed.[7] Clearly, T_N(Pr) decreases monotonically with increasing Pr—O bond length which reflects the degree of Pr $4f$–O $2p_\pi$ orbital hybridization or the strength of Pr-O-Pr superexchange coupling. Meanwhile, an effective coupling occurs between Cu and Pr moments through oxygen $2p_\pi/2p_\sigma$ as revealed by preliminary neutron and nuclear magnetic resonance studies on Tl-1212 $Tl(Ba,Sr)_2PrCu_2O_{7-\delta}$ system.[17] This competition should be taken into account before a final conclusion can be reached.

Various types of experiments have been performed to substantiate these anomalous Pr phenomena in the 123 or 1212 system to clarify the mechanism of magnetic order and/or superconductivity suppression, but a clear picture is still elusive. Obviously, additional information from more diverse systems would be extremely helpful toward delineating the various factors which may play crucial roles in this regard. Since in the high T_c cuprate systems, a total replacement of Ca by Pr between the CuO_2 layers can be achieved only in the tetragonal/orthorhombic two-CuO_2-layer $M_mA_2PrCu_2O_y$ $m212$-type structures ($m=1$, 2, 3; M=Cu, Hg, Tl, Pb and A=Ba, Sr), where the schematic structure comparison is shown in Fig. 3. Questions arise naturally whether the anomalous Pr effect occurs in 2212 $M_2A_2PrCu_2O_y$ or 3212 $M_3A_2PrCu_2O_y$ compounds. Only one 3212-type compound with a T_N(Pr) of 6–14 K was reported so far in the orthorhombic (Pb,Cu)-3212 $(Pb_2Cu)Ba_{2-x}Sr_xPrCu_2O_8$ system ($0\leqslant x\leqslant 1$), or commonly known as the 2213-type $Pb_2Ba_{2-x}Sr_xPrCu_3O_8$ system.[18] For the 2212-type compounds, no Pr ordering was observed down to 1.6 K for the orthorhombic Bi-2212 compound $Bi_2Sr_2PrCu_2O_8$.[19] However, via proper substitution, we are able to observe the first Pr anomaly in the tetragonal (Pb,Cu)-2212 $(Pb_{0.5}Cu_{0.5})_2(Ba_{0.5}Sr_{0.5})_2PrCu_2O_8$ compound ($a=3.878$ Å and $c=27.594$ Å). The sample was prepared by two-stage solid-state reaction techniques where the precursor $BaSrPrCu_3O_y$ powders were mixed with PbO powder and heated at 730 °C for 1 day and then pressed into pellets and sintered at 825–830 °C in flowing Ar for 3 days, then quenched in liquid nitrogen.[19] A fairly high T_N(Pr) value of 9 K was identified from the minimum in the temperature derivative of the molar magnetic susceptibility $d\chi_m/dT$ as shown in Fig. 4. In comparison, the isostructural compound $(Pb_{0.5}Cu_{0.5})_2(Ba_{0.5}Sr_{0.5})_2GdCu_2O_8$ exhibits a lower T_N(Gd) of only 2.2 K.[19] The magnetic transition can also be corroborated by low-temperature specific heat data $C(T)$ which show a distinct magnetic transition at T_N(Pr)=9 K with onset around 11 K.[19] The temperature dependence of the magnetic susceptibilities below 200 K indicates a simple Curie–Weiss fit $\chi_m=C^*/(T+\theta_p)$ which yields a negative paramagnetic

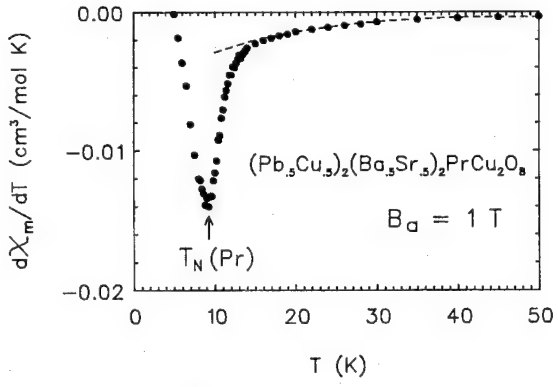

FIG. 4. Low-temperature differential molar magnetic susceptibility $d\chi_m/dT$ for (Pb,Cu)-2212 $(Pb_{0.5}Cu_{0.5})_2(Ba_{0.5}Sr_{0.5})_2PrCu_2O_8$ compound revealing a T_N(Pr)=9 K.

intercept $\theta_p = -10$ K and an effective magnetic moment of 3.22 μ_B per Pr.[19] The effective moment again is closer to that of the free Pr^{3+} ion. The magnetic entropy S_m associated with the Pr ordering has a lower limit, ~20% of $R \ln 3$ expected for Pr^{3+} with a quasi-triplet ground state. Accordingly, it seems reasonably to categorize the Pr ordering in this (Pb,Cu)-2212 compound as a three-dimensional-like ordering process. Confirmation requires detailed neutron diffraction studies.

The current results of anomalous Pr ordering on the new Hg-1212 compound $HgSr_2PrCu_2O_{6+\delta}$ and (Pb,Cu)-2212 compound $(Pb_{0.5}Cu_{0.5})_2(Ba_{0.5}Sr_{0.5})_2PrCu_2O_8$, along with earlier reports on other 1212- and 3212-type compounds, complete the demonstration of systematic of anomalous Pr ordering in all two-CuO_2-layer $M_mA_2PrCu_2O_y$ $m212$ ($m=1, 2, 3$) systems. Anomalously high T_N(Pr) observed for all compounds indicates the importance of the quasi-2D Pr-O-Pr superexchange magnetic coupling mechanism through the strong hybridization between the Pr $4f$ and the eight O $2p_\pi$ orbitals in the adjacent two-CuO_2 layers.

Magnetic structure and ordering of Nd ions in Ga substituted $NdBa_2Cu_3O_7$ (abstract)

Magnetic ordering of Nd^{3+} ion changes with oxygen concentration in $NdBa_2Cu_3O_{7-x}$.[1] In the oxygen-rich sample $NdBa_2Cu_3O_{6.9}$, Nd^{3+} ion orders antiferromagnetically with 2D-Ising type of ordering. Whereas, in the oxygen reduced compound $NdBa_2Cu_3O_{6.2}$ Nd ion orders three dimensionally at 1.73 K. Similar effects has been observed by specific heat measurements performed on $NdBa_2Cu_{3-y}Ga_yO_7$ ($0<y<0.5$).[2] In these samples, a small amount of Ga substitution changes the magnetic ordering of Nd ions from 2D Ising ($y=0$) to 1D or magnetic clusters ($y=0.01$, 0.03). With higher Ga substitution, the third magnetic ordering is restored.[2] The magnetic ordering seen in $NdBa_2Cu_{3-y}Ga_yO_7$ ($y=0.5$) is more isotropic in nature compared to $NdBa_2Cu_3O_{6.2}$. The critical exponent derived from the specific data show a 3D spherical type of ordering. Magnetic neutron diffraction are performed at low and high temperatures for $y=0.5$ to deduce the magnetic structure, which are compared with the unsubstituted compounds and to verify the isotropic nature. The second-order CEF parameter A_2^0 decreases for $NdBa_2Cu_{3-y}Ga_yO_7$ ($y=0.5$) which in turn reduces the magnetic anisotropy constant,[3] consistent with magnetic specific heat results. © *1996 American Institute of Physics.* [S0021-8979(96)80908-0]

Influence of the crystalline electric field on the magnetic properties of Ga-doped $NdBa_2Cu_3O_x$ (abstract)

P. Allenspach
Laboratory for Neutron Scattering, ETH Zurich & PSI, 5232 Villigen PSI, Switzerland

A. M. Niraimathi and E. Gmelin
Max-Planck-Institut für Festkörperforschung, 70569 Stuttgart, Germany

Crystal electric field (CEF) effects are of essential importance for the magnetic properties of rare-earth ions. For $NdBa_2Cu_3O_x$ the variation of the CEF due to a reduction of oxygen directly influences the character of the magnetic ordering[1] and partially explains the peculiar magnetic behavior of this system:[2] Oxygen reduction transforms the 2D-Ising system just below $x=6.9$ into a (short-range) 2D-Heisenberg system due to a reduction of the single-ion anisotropy. Since, magnetic specific heat data for Ga-doped $NdBa_2Cu_3O_x$[3] resemble very much the oxygen reduced data, neutron CEF spectroscopy of Nd^{3+} in $NdBa_2(Cu_{3-y}Ga_y)O_x$ was performed to deduce the behavior of the single-ion anisotropy. These neutron data in conjunction with paramagnetic susceptibility and specific heat data[4] confirm the strong influence of the CEF on the magnetic ordering of the Nd ions. © *1996 American Institute of Physics.* [S0021-8979(96)81008-5]

Synthesis and superconductivity of intermetallic compounds $Y_2Ni_xB_{8-x}C_2$, $YNi_xCu_{2-x}B_2C$, and $YNi_xCu_{2-x}Si_2C$

Wei Zhao and Jinke Tang
Department of Physics, University of New Orleans, New Orleans, Louisiana 70148

Young-sook Lee and Charles J. O'Connor
Department of Chemistry, University of New Orleans, New Orleans, Louisiana 70148

Borocarbide and silicocarbide intermetallic $Y_2Ni_xB_{8-x}C_2$ ($x=1$, 2, 3, 5), $YNiCuB_2C$, and $YNi_xCu_{2-x}Si_2C$ ($x=0$, 2) were prepared and their superconductivity was studied. The results indicated that with the change of the ratio of Ni to B in $Y_2Ni_xB_{8-x}C_2$, secondary phases were introduced into YNi_2B_2C phase. A T_c of 15.0 K was observed for the compounds $x=2$, 3, and 5, which originated from the major phase YNi_2B_2C in these samples. Partial substitution of Ni by Cu reduced the T_c to 11.0 K for $YNiCuB_2C$. For Si substitution system, no bulk superconductivity was found in YNi_2Si_2C and YCu_2Si_2C. But a minor superconducting phase ($T_c \sim 4$ K) with a volume fraction of the order of near 1% was observed in them. It was noticed that for the temperature-dependent magnetization of superconducting compounds containing Ni, a significant difference between zero-field cooling and field cooling curves before T_c was always observed, which was tentatively attributed to Ni-containing impurity.
[S0021-8979(96)02308-7]

I. INTRODUCTION

Superconductivity has been discovered recently in borocarbide intermetallic YNi_2B_2C with $T_c=15.6$ K.[1] Like $LuNi_2B_2C$, YNi_2B_2C displays a tetragonal body-centered layerlike structure with a I_4/mmm symmetry.[1,2] It may be viewed as alternate stackings of the NaCl-type (YC) and the inverse PbO-type (Ni_2B_2) layers. In the Ni_2B_2 layers, a Ni atom is tetrahedrally coordinated by four boron atoms. It is interesting to inspect the possibility of increasing T_c in this system through substitution of Ni and B by other elements such as Cu and Si and through changing the ratio of Ni and B. In this work, borocarbide and silicocarbide intermetallic $Y_2Ni_xB_{8-x}C_2$ ($x=1$, 2, 3, 5), $YNiCuB_2C$, and $YNi_xCu_{2-x}Si_2C$ ($x=0$, 2) have been prepared and their superconductivity is studied.

II. EXPERIMENT

Samples were prepared by the arc-melt technique. The starting materials were Y (Aldrich, 99.9%), Ni (Aldrich, 99.95%), Cu (Aldrich, 99.99%), B (99.999%), C (99.9%), and Si (99.9%). Stoichiometric amounts of the starting materials were melted under argon atmosphere on a standard water-cooled copper hearth at least four times, with the melted button turned over between melts in order to ensure homogeneity. The overall loss in weight of the samples during arc melting was less 1%.

The magnetic susceptibility was measured by a SQUID magnetometer (Quantum Design). The resistance was determined by the standard four-lead method. The x-ray diffraction patterns of samples were obtained on a SCINTAG powder diffractometer using Cu $K\alpha$ radiation.

III. RESULTS AND DISCUSSION

For $Y_2Ni_xB_{8-x}C_2$ ($x=1$, 2, 3, 5) system, their x-ray diffraction patterns indicated that all samples were multiphased. Except for the sample with $x=1$, all other three samples showed major diffraction patterns characteristic of YNi_2B_2C. Figure 1(a) shows the normalized x-ray diffraction patterns of $Y_2Ni_3B_5C_2$. One can see that the main peaks can be attributed to the YNi_2B_2C phase with lattice parameters $a=3.53$ Å and $c=10.57$ Å, agreeing with the data in Ref. 1. For $Y_2Ni_2B_6C_2$ ($YNiB_3C$) and $Y_2Ni_5B_3C_2$ samples, their major diffraction patterns can also been indexed with the YNi_2B_2C of the same lattice parameters. For the sample

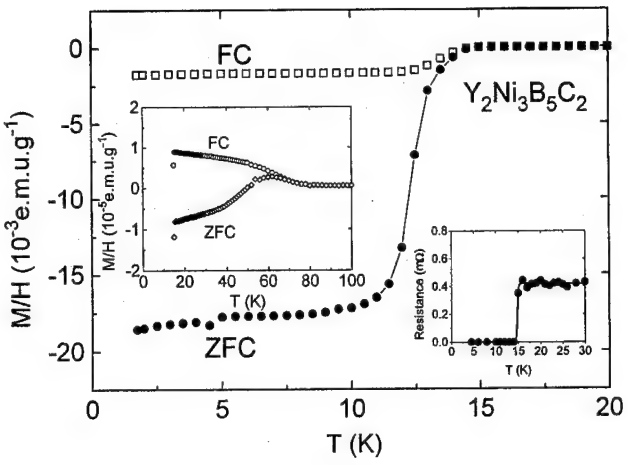

FIG. 2. Temperature-dependent magnetization (applied field $H=10$ G) for $Y_2Ni_3B_5C_2$. The left inset, expended view showing the magnetization before T_c. The right inset shows the resistance for this sample.

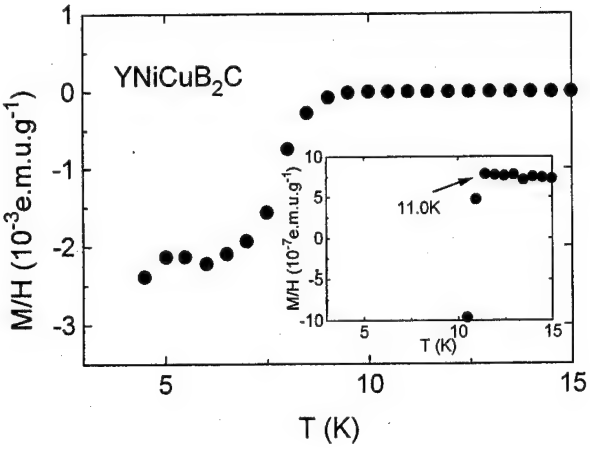

FIG. 3. Temperature-dependent magnetization ($H=20$ G) for $YNiCuB_2C$, showing the superconducting transition. The data were obtained during warming after zero-field cooling.

$Y_2NiB_7C_2$, no YNi_2B_2C phase was observed. The analysis of the secondary phases in these samples has been proven to be a difficult task and will be discussed elsewhere. The above results were consistent with those of Buchgeister *et al.*[3] and Chakoumakos and Paranthaman,[4] who reported that excess amounts of both Ni and B introduced secondary phases into the samples. These results also confirmed that defects such as planar defects or intergrowths were hard to exist in the YNi_2B_2C structure.[2]

The x-ray diffraction pattern of Cu-substituted $YNiCuB_2C$ consisted of a major pattern with tetragonal structure with lattice parameters $a=3.54$ Å and $c=10.63$ Å and some additional peaks which could not be identified. Gangopadhyay *et al.*[5] found that there was limited solubility in YNi_2B_2C for Cu and that with increasing the doping level of Cu, the impurity peaks grew stronger. Our data agreed with their results.

Silicocarbides YNi_2Si_2C and YCu_2Si_2C were prepared as shown in Figs. 1(b) and 1(c). In Fig. 1(b), most of the diffraction peaks can be indexed to the YNi_2B_2C-type structure with lattice parameters $a=3.94$ Å and $c=9.55$ Å. This suggests that a new silicocarbide intermetallic YNi_2Si_2C compound with YNi_2B_2C-type structure was formed. For YCu_2Si_2C, the diffraction pattern [Fig. 1(c)] showed that this sample was multiphased. The main peaks were identified to the YNi_2B_2C-type structure with $a=3.95$ Å and $c=9.98$ Å. There also existed peaks of secondary phases in Fig. 1(c) whose indentification is needed. The result of YCu_2Si_2C is similar to that of Cu-substituted $YNiCuB_2C$ in which pure, Cu-containing intermetallic compounds with a YNi_2B_2C-type structure are difficult to synthesize by means of an arc-melting technique.

Figure 2 shows the temperature dependence of the magnetization measured at 10 G and the resistance for the $Y_2Ni_3B_5C_2$ sample. The superconducting transition is seen at 15.0 K with a broader transition width as compared with that of the pure YNi_2B_2C sample.[1] The sample cooled in zero field shows a magnetic shielding equal to ~80%–100% of that of a perfect superconductor. On cooling in the field, it displays a Meissner effect of ~10% of that expected for perfect diamagnetism. The broader transition width may result from the secondary phases already seen in the x-ray pattern which separate the YNi_2B_2C phase grains so that weak links form. We found that before T_c, positive, upgrown field cooling and zero-field cooling curves were always observed in these Ni-containing samples. As shown in the left inset of Fig. 2, the zero-field cooling curve shows a broad maximum at ~60 K. More interestingly, for this sample, its ZFC susceptibility became negative at a lower temperature. Although ac susceptibility conducted on the sample indicated that this negative ZFC dc susceptibility was not due to a superconducting phase transition, its origin is yet

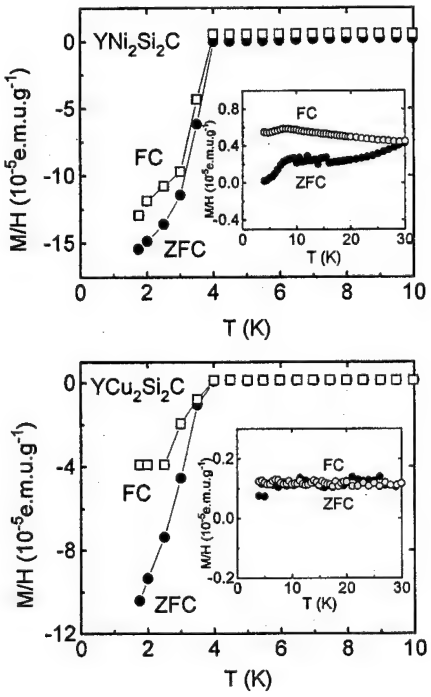

FIG. 4. Temperature-dependent magnetization ($H=10$ G) for YNi_2Si_2C and YCu_2Si_2C. The insets, expended view showing the magnetization before T_c.

to be found out. Its FC susceptibility, on the other hand, continued to increase with decreasing temperature until T_c was reached. This novel behavior is most likely to be associated with a Ni-containing impurity. For $Y_2Ni_2B_6C_2$ ($YNiB_3C$) and $Y_2Ni_5B_3C_2$ samples, they possess the same onset temperature at 15.0 K with a broader transition width. This result is consistent with the x-ray data which indicate that YNi_2B_2C is the major phase in these samples. For the sample $Y_2NiB_7C_2$, no superconductivity was found. Its susceptibility (in the order of 10^{-5}) seems to follow the Curie–Weiss law. Such a behavior may be due to a residual magnetic moment of Ni.[6]

The temperature-dependent magnetization data measured at 20 G for Cu-substituted $YNiCuB_2C$ are given in Fig. 3. The shield signal corresponds to ~25% of perfect diamagnetism. The inset to Fig. 3 shows an onset temperature at 11.0 K, indicating that Cu substitution for Ni reduces T_c, agreeing with that of Gangopadhyay *et al.*[5]

Superconductivity in small quantities can be observed in silicocarbides YNi_2Si_2C and YCu_2Si_2C. The temperature dependence of the magnetization at 10 G for both samples is shown in Fig. 4. The onset temperature is ~4 K for both samples. The magnitudes of the shielding and Meissner effect signals correspond to ~1.5% and ~1.2% of perfect diamagnetism for YNi_2Si_2C and ~1% and ~0.4% for YCu_2Si_2C, respectively. This suggests that the superconducting phase is a minor phase with a volume fraction of the order of 1%. From the insets of Fig. 4, the hysteresis between field cooling and zero-field cooling curves before T_c can also be seen in YNi_2Si_2C. While such curves were not observed in YCu_2Si_2C, which is Ni free, further suggesting that this history-dependent hysteretic magnetic behavior is associated with a Ni-containing impurity.

IV. CONCLUSIONS

Deviation from the stoichiometric composition of YNi_2B_2C by changing the ratio of Ni to B introduced impurity phases into the major phase YNi_2B_2C. In $Y_2Ni_xB_{8-x}C_2$ ($x=2$, 3, 5), the major phase YNi_2B_2C was responsible for superconductivity with $T_c=15.0$ K. For Cu-substituted $YNiCuB_2C$, an expansion in lattice was observed due to the substitution of Ni with Cu. Secondary phases emerged because of the limited solubility of Cu in this compound. The Cu substitution reduced the T_c to 11 K, in agreement with the argument that the Fermi level in the parent compound lies very near to a peak in the density of states so that further enhancement in T_c by chemical modification is rather unlikely.[5] For new silicocarbides YNi_2Si_2C and YCu_2Si_2C, they were not bulk superconductors. But there existed superconducting minor phases with $T_c=\sim 4$ K.

We have measured $\chi(T)$ for oxygen-annealed $YBa_2Cu_3O_x$ samples and observed a glass-like behavior at low magnetic fields which can be explained in terms of a Josephson weak link effect. The glass transition temperature T_g depends on the oxygen annealing temperature and sample pellet pressure. T_g disappears when a sample was powdered after receiving an oxygen anneal, indicating that the Josephson weak link effect occurs between intergranular boundaries. In addition, T_c shifts from 93 K for the air-sintered samples to 90 K for the oxygen-annealed materials. Under vacuum annealing, T_g disappears and T_c first shifts back to 93 K. Prolonged vacuum annealing or vacuum annealing at higher temperatures depresses T_c to below 90 K. The temperature dependence of the specific heat shows a single anomaly for samples sintered in air or annealed under high vacuum. But a double-peak specific heat anomaly occurs for the oxygen-annealed samples. [S0021-8979(96)02408-3]

I. INTRODUCTION

Although the high T_c cuprate superconductors[1,2] were discovered in 1986, the thermodynamic, electric, and magnetic properties are not clearly understood. From the magnetization $\chi(T)$ measurements on good quality oxygen-annealed $YBa_2Cu_3O_x$ ($x \approx 7$) samples we have observed[3] a glass transition at low magnetic fields which is different from the vortex glass–fluid transition at high fields.[4,5] This glass behavior can be explained in terms of Josephson weak link effects proposed by several theoretical researchers.[6,7] These effects may also explain the so-called "paramagnetic Meissner effect",[8,9] where the field-cooled magnetization below T_c becomes paramagnetic for very low fields. Whether the weak links originate from intergranular or intragranular junctions is not clear.

T_c as determined from the Meissner effect "onset" temperature is about 90 K for oxygen-annealed samples. This value differs significantly from the 93 K value which has usually been reported for $YBa_2Cu_3O_x$ with $x \approx 7$, but agrees with that observed for some single crystals.[10] The electrical resistivity measurements on oxygen-annealed samples have shown a two-step transition[11] with the first step at 93 K. Moreover, double-peak specific heat anomalies have been reported for both single-crystal and polycrystalline $YBa_2Cu_3O_x$ ($x \approx 7$) samples.[11–13] This double-peak behavior has led some researchers[14] to propose different pairing mechanisms to explain high T_c cuprate superconductors.

We have prepared $YBa_2Cu_3O_x$ samples sintered in air, annealed in oxygen at different temperatures, and annealed under high vacuum. The temperature dependence of the magnetic susceptibility and the specific heat has been measured. The results for these samples are discussed in terms of variations in their oxygen content.

II. EXPERIMENT

Polycrystalline $YBa_2Cu_3O_x$ samples were prepared using the solid-state reaction technique. The appropriate amounts of high-purity Y_2O_3, $BaCO_3$, and CuO were thoroughly mixed and then pressed into pellets 1/2 in. in diameter. The pellets were reacted in air at 950 °C for 24 h. They were then ground to a fine powder and the entire procedure was repeated twice. After the materials were sintered in air three times, they were again ground to a fine powder, pressed into pellets, and finally annealed in flowing oxygen at atmospheric pressure. The oxygen annealing temperature varied from 300 to 950 °C. X-ray diffraction measurements at room temperature were used to check sample homogeneity and determine lattice parameters. The results showed that the lattice parameters are essentially the same for all samples annealed in oxygen irrespective of the annealing temperatures and time intervals, and are consistent with those previously published.[15] We also investigated the microstructure and grain sizes of these samples using a scanning electron microscope. The typical grain size was found to be about 10 μm. A terrace-like circularly layered microstructure was observed and reported.[3] The temperature dependence of the magnetic susceptibility was measured using a commercial SQUID magnetometer. Since these measurements were performed in low fields, certain precautions were taken. In particular, a "zero-field" calibration was obtained by using a high-purity Pd sphere to determine the residual field in the magnetometer solenoid. The specific heat was measured from 15 to 150 K using a semiadiabatic heat pulse method.

III. RESULTS AND DISCUSSION

Shown in Fig. 1 curve (a) is the temperature dependence of the zero-field-cooled (ZFC) magnetic susceptibility $\chi(T)$ measured at $H = 10$ Oe for a sample that was sintered in air without receiving the final oxygen anneal. It shows a typical diamagnetic behavior for superconductors. The absolute value of χ at 10 K is close to $1/4\pi$ indicating a good quality sample. T_c is defined from the temperature where the onset of $\chi(T)$ occurs and is found to be about 93 K for this sample. Curve (O1), for a sample annealed in oxygen at 450 °C for

 0021-8979/96/79(8)/5873/3/$10.00

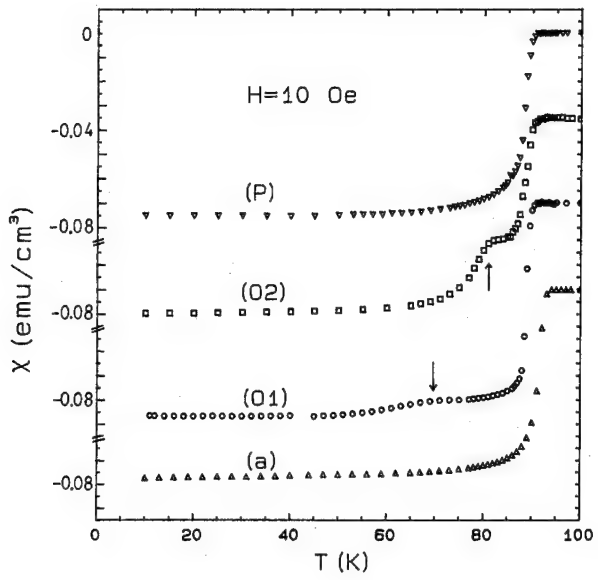

FIG. 1. The $\chi(T)$ data measured at $H=10$ Oe for samples (a) annealed in air, (O1) annealed in oxygen at 450 °C for 10 h, (O2) annealed in oxygen at 950 °C for 10 h and (P) powdered after receiving final oxygen anneal.

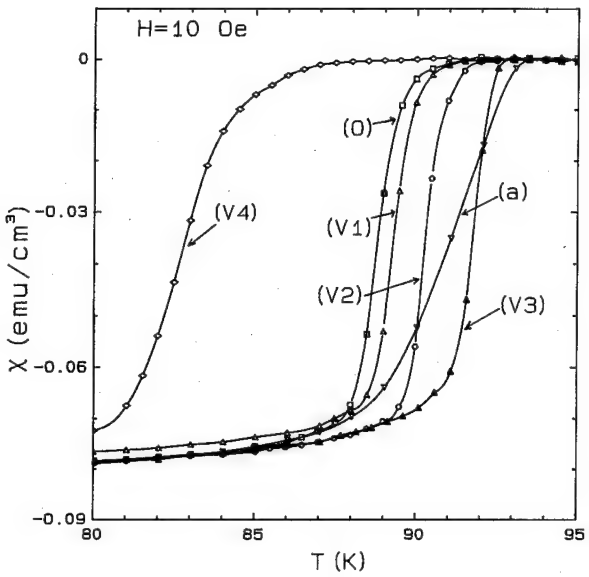

FIG. 3. The $\chi(T)$ data measured at $H=10$ Oe. (a) sample sintered in air. (O) sample annealed in oxygen at 450 °C for 10 h. (V1), (V2), and (V3) samples annealed under vacuum at 375 °C for 1, 3, and 5.5 h, respectively, after being fully oxygenated, and (V4) sample annealed under vacuum at 450 °C for 5 h.

10 h, shows a kink at $T_g=70$ °C. This kink can be attributed to a glass transition which will be discussed later. Note that T_c shifts from 93 to 90 K for this oxygen-annealed sample. Curve (O2), for a sample annealed in oxygen at 950 °C for 10 h, is similar to curve (O1), except T_g shifts to a higher temperature. We have measured $\chi(T)$ for several samples annealed in oxygen between 300 and 950 °C, and found that T_g increases monotonically with increasing oxygen annealing temperature.

We have performed thermal cycling measurements of $\chi(T)$ in order to understand the magnetic response below and above T_g. Shown in Fig. 2 is the $\chi(T)$ data for a sample annealed in oxygen at 950 °C for 10 h. The sample was first cooled to 5 K (point A) in zero field. Then a field of $H=5$ Oe was applied and held fixed for the remainder of the cycle. The sample was then taken through a heating–cooling reheating trajectory. It can be seen that the heating–cooling cycle (e.g., $A\rightarrow B\rightarrow C$) is far more irreversible than the cooling–reheating cycle ($B\rightarrow C\rightarrow B'$). However, the heating–cooling–reheating trajectory that starts at D, i.e., $D\rightarrow E\rightarrow D\rightarrow E$, is entirely reversible. Note that point D is at the kink temperature T_g. Hence it appears that $\chi(T)$ shows irreversible behavior below T_g and reversible behavior above T_g characteristic of a glass transition. Note that the value $H=5$ Oe is smaller than the lower critical field H_{c1} and hence this glass transition is completely different from the vortex–glass–fluid transition[4,5] observed at higher fields. It has been proposed by several theoretical groups[6,7] that this glass behavior at low fields can be explained in terms of Josephson weak link effects. We have shown[3] that T_g initially increases with increasing pellet pressure but saturates at high pressures, and that T_g decreases with increasing applied fields and in fact disappears at sufficiently high field.

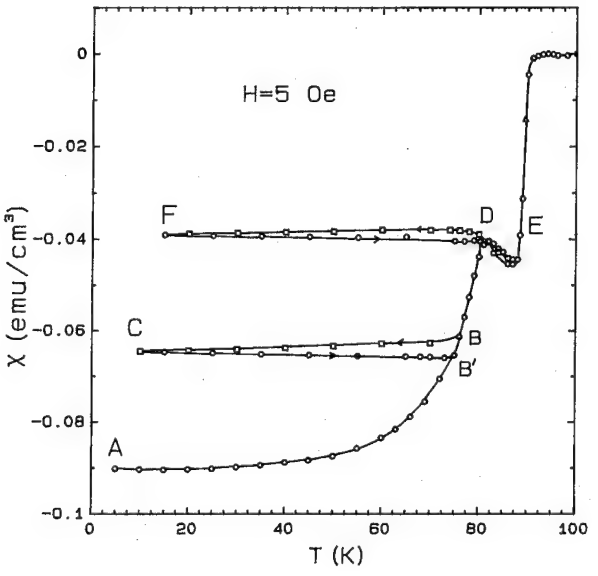

FIG. 2. The thermal cycling magnetic susceptibility measured at $H=5$ Oe for a sample annealed at 950 °C for 10 h.

Returning to Fig. 1, curve (P) shows $\chi(T)$ for a sample which was powdered after receiving an oxygen anneal at 950 °C for 10 h. The kink disappears suggesting that the glass behavior is due to Josephson weak link effects which occur at intergranular boundaries. However, T_c for the powdered samples remains at 90 K indicating that during the oxygen anneal oxygen not only enters the grain boundaries but also enters the entire material resulting in a change of the bulk superconducting properties.

In order to understand T_c as a function of oxygen content, we have measured $\chi(T)$ for several samples annealed in air, in oxygen, and under high vacuum at 375 °C. In Fig. 3 curve (a) shows $\chi(T)$ for an air-sintered sample. Curve (O) shows $\chi(T)$ for a sample annealed in oxygen at 450 °C for

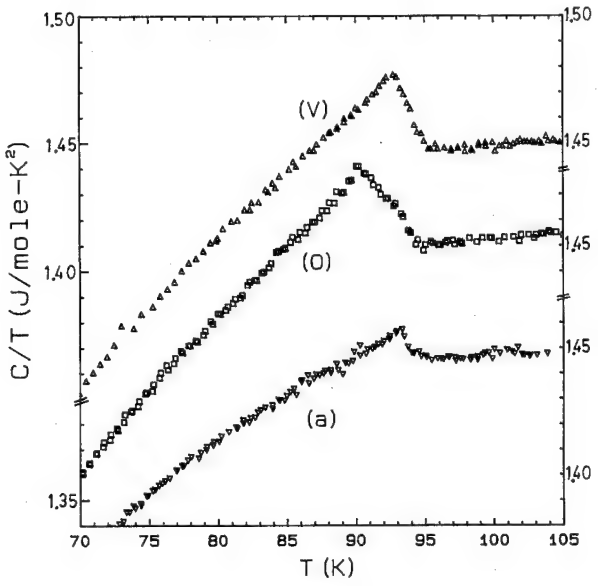

FIG. 4. The $C(T)/T$ data for samples (a) sintered in air, (O) annealed in oxygen at 450 °C for 10 h, and (V) annealed under vacuum at 375 °C for 5.5 h after being fully oxygenated.

10 h. Curves (V1), (V2), and (V3) show $\chi(T)$ for samples that were fully oxygenated by a 10 h oxygen anneal at 450 °C and then vacuum annealed at 375 °C for 1, 3, and 5.5 h, respectively. Curve (V4) shows $\chi(T)$ for a sample that was vacuum annealed at 450 °C for 5 h. Weight measurements before and after oxygen annealing allowed us to determine how the oxygen content varies with the temperature and time (duration) of the oxygen anneal. The oxygen content rises rapidly and saturates presumably at a value corresponding to ≈7. The time required for saturation depends on the anneal temperature. We found the saturation time to be about 3 h at 450 °C but only 30 min at 950 °C. It should be noted that a number of samples (not shown in Fig. 3) were annealed in oxygen for very long times (up to 60 h) at varying temperatures (from 300 to 950 °C). These samples as well as the sample shown in curve (O) of Fig. 3 (annealed in oxygen for 10 h at 450 °C) all show a T_c of 90 K indicating that 90 K is the T_c for fully saturated $YBa_2Cu_3O_7$.

Curves (V1), (V2), and (V3) are for samples that were first fully oxygenated and then vacuum annealed at 375 °C for 1, 3, and 5.5 h, respectively, to drive out oxygen. Note from Fig. 3 that T_c rises from 90 to 93 K. Finally curve (V4) of Fig. 3 shows a sample that was first fully oxygenated and then vacuum annealed at a higher temperature, namely, 450 °C for 5 h. This sample shows a considerably lower T_c presumably because too much oxygen has been removed. The T_c variation observed here is in good agreement with recently published results.[10,12,16]

Shown in Fig. 4 is specific heat data plotted as $C(T)/T$ vs T. Curve (a) is the data for a sample sintered in air. A small specific heat anomaly is present at about 93 K which is associated with the superconducting transition. After the sample was annealed in oxygen at 450 °C for 10 h the specific heat anomaly became more pronounced as seen in curve (O). In fact, curve (O) consists of a main peak at about 90 K and a shoulder at 93 K. Samples annealed in oxygen for 10 h at temperatures between 450 and 950 °C show the same behavior. This double-peak specific heat anomaly has been observed previously.[11–13] Curve (V) shows the data for a fully oxygenated sample that was then annealed under vacuum at 375 °C for 5.5 h. The anomaly shifts back to 93 K, but still remains more pronounced [than curve (a)]. A more extensive analysis of the specific heat data is under way and will be presented in a future paper. However, it seems clear at this point that a number of interesting phenomena besides the value of T_c are closely tied to the oxygen content including the presence of a weak link glass state and a double-peaked specific heat behavior.

Effects of Pr, Tb, and Zn doping into $YBa_2Cu_3O_7$ on magnetoresistivity and magnetic phase boundaries

F. Freibert, G. Cao, S. McCall, M. Shepard, and J. E. Crow
National High Magnetic Field Laboratory, Florida State University, Tallahassee, Florida 32306-4005

Transverse AB-plane magnetoresistivity ρ_{AB} (C axis $\|H$) of $(Y_{1-X}Pr_X)Ba_2Cu_3O_{7-\delta}$ and $YBa_2(Cu_{1-X}Zn_X)_3O_{7-\delta}$ thin films and $(Y_{1-X}Tb_X)Ba_2Cu_3O_{7-\delta}$ thin films and single crystals has been measured as a function of $0.0<X<X_C$, $2\text{ K}<T<300\text{ K}$, and $0\text{ T}<H<20\text{ T}$. Mean-field upper critical field H_{C2} and irreversibility field H_I phase boundaries have been determined and are discussed in terms of proposed theories. Tb doping of $YBa_2Cu_3O_7$ reflects an enhanced pinning or "stiffening" of the vortex system without apparent alteration to T_C or the slope of the mean-field normal phase-mixed phase boundary line, $dH_{C2}/dT|_{T=T_c}$. However, Pr and Zn doping of $YBa_2Cu_3O_7$ tends to depress both T_C and $dH_{C2}/dT|_{T=T_c}$ and shows a "softening" of the vortex system. This behavior may be understood in terms of the magnitude of the superconducting pair coherence length, which is controlled by doping, and the divergence of the vortex-glass correlation length as it relates to flux line coupling of vortices in the CuO_2 planes. These systems are compared with other high T_C superconducting systems which possess similar phase boundary properties.
 [S0021-8979(96)02508-X]

I. INTRODUCTION

Magnetoelectronic transport measurements of selectively doped high T_C superconductors can provide a direct gauge of structural and magnetic alterations as sensed by vortices in the superconducting state and electrons in the normal state. Local disorder introduced into the structure by doping has a great consequence both for the $H-T$ (magnetic field–temperature) phase diagram of the vortex system and for its dynamical properties. This is evidenced by shifts and novel structures seen in the magnetic phase boundaries of the $H-T$ plane, since these boundaries mark transition points between the different vortex system states within the superconductor. The magnitude of the extrapolated residual resistivity $\rho_O(T=0\text{ K})$ is indicative of electron-defect and electron-impurity scattering lifetimes and the temperature dependence of the normal state resistivity of characteristic of electron-exitation or electron-magnetic impurity spin scattering.

$YBa_2Cu_3O_{7-\delta}$ (YBCO) and the other Cu-based high T_C oxide superconductors have many features in common, including large anisotropies in their magnetic and transport properties, which reflect the role played by the CuO_2 planes common to all these systems. This article focuses on portions of a magnetotransport properties study of YBCO doped with Pr, Tb, and Zn where particular attention is devoted to dissipative properties of the normal and superconducting states, the onset of superconductivity H_{C2}, and the formation of the vortex–solid phase H_I. Many similarities and many differences exist between the impact of impurities on the normal and superconducting properties upon entering the lattice and preferentially perturbing the system. The superconducting properties of YBCO are insensitive to Y-site trivalent substitutions, except in the case of Ce, Pr, and Tb. Of these three exceptions, Pr and Tb can be doped onto the Y-site accompanied by altered superconducting and normal state properties. Increasing Pr concentration from $X=0.0$ to $X_C=0.55$ in $(Y_{1-X}Pr_X)Ba_2Cu_3O_{7-\delta}$ (YPBCO) produces a monotonic decrease in T_C and a monotonic increase in ρ_O from 90 to 0 K. However, Tb doped into $(Y_{1-X}Tb_X)Ba_2Cu_3O_{7-\delta}$ (YTBCO) epitaxial thin films and crystals shows T_C to be independent of doping up to the highest concentration measured, i.e., $X=0.50$. These differences are unusual since Pr- and Tb-doped YBCO have many features in common, e.g., both Pr and Tb appear to hybridize with carriers in the CuO_2 planes as reflected by large enhancements in γ (coefficient of the linear temperature-dependent contribution of the specific heat) and the large anisotropies in the normal state magnetic susceptibilities.[1–4] In contrast to the impact on the normal and superconducting properties due to Pr and Tb doping of YBCO, which indirectly modify the CuO_2 planes through hybridization, the impact due to Zn doping of YBCO accomplished by substitution for the Cu in the CuO_2 planes leads to a precipitous drop in T_C with $T_C\rightarrow 0$ K for $X_C=0.10$ in $YBa_2(Cu_{1-X}Zn_X)_3O_{7-\delta}$ (YBCZO). This behavior indicates the importance of the Cu ion magnetic moment to the superconducting mechanism in YBCO, since Zn is diamagnetic and isovalent with Cu^{+2} and distorts the unit cell volume less than 0.5% at X_C.

II. THEORETICAL BACKGROUND

All high T_C superconductors are anisotropic type II superconductors whose reduced dimensionality and high T_C have greatly enhanced the thermal fluctuations of the order parameter and altered the mixed phase behavior. These effects are apparent in the electrical resistivity of the superconductor cooled in a magnetic field. Near T_C, the fluctuation enhancement in the resistivity obeys scaling relations as expected on the basis of Ginzburg–Landau fluctuation theory for a three-dimensional superconducting system in a high magnetic field.[5] This scaling behavior provides a consistent method of determining the second-order mean-field upper critical field transition temperature, $T(H_{C2})$, and offers an alternative, more physically significant method to that of obtaining $T(H_{C2})$ from $0.5\rho(H)|_{T=T_c}$.

 0021-8979/96/79(8)/5876/3/$10.00

As the cooling process continues in field ($H_{C1}<H<H_{C2}$) below T_C, a vortex–liquid phase appears, and is soon replaced as vortex–vortex and vortex–defect interactions act collectively to bring about the transition from a vortex-liquid to a vortex-glass at a well-defined temperature T_G (in a dc measurement $T_G=T_I$). The vortex–glass phase onset is signaled by a vanishing electrical resistivity $\rho=|T-T_G|^{-s}$, where $s=\nu(z-1)$ for critical exponent ν and dynamical exponent z.[6] Thus, the $H-T$ (magnetic field–temperature) phase diagram possesses a vortex state ($H_{C1}<H<H_{C2}$) with regions of reversible and irreversible magnetic behavior separated by an "irreversibility" line. The theoretical vortex–glass transition line obeys the low-field ($H_{C2}\gg H>H_{C1}$) power-law temperature dependence $H_G = H_O(1 - T/T_C)^{2\nu'}$, where $\nu'=2/3$ for the zero-field critical region and is true for vortex systems in YBCO single crystals and thin films.[7,8] This temperature dependence is related to divergence in the correlation length of the order parameter, $\xi_G = |T - T_G|^{-\nu'}$, as T_G is approached from either higher or lower temperatures.

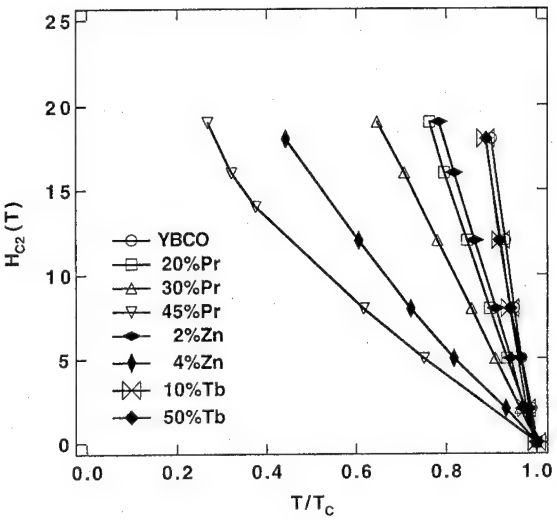

FIG. 1. Mean-field upper critical field H_{C2} phase boundaries for various dopant concentrations vs normalized temperature. (Solid lines are guides to the eye.)

III. EXPERIMENTS AND RESULTS

Thin films of YPBCO, YTBCO, and YBCZO were grown by laser ablation, each of average thickness 1.5 mm.[1,2] Since the films were epitaxially deposited on twinned single-crystal $LaAlO_3$ substrates, transport measurements are representative of collective AB-plane behavior. Single crystals of YTbCO were grown by the self-flux growth technique.[2] Resistivity measurements $\rho_{AB}(X,H,T)$ for $0<X<X_C$, 2 K$<T<$300 K and 0 T$<H<$20 T were made using an in-line four-probe method for the thin film samples and the Montgomery technique for the single crystals. In all cases, corrections for thermal EMFs were applied with current densities of 1 A/cm$^2<J<$50 A/cm^2. These measurements allow determination of such physical quantities as the mean-field upper critical field H_{C2} and irreversibility field H_I, and their dependence on temperature T, dopant concentration X and magnetic field H.

This study has revealed that an increase in Tb doping appears to shift the vortex–glass transition line to higher temperatures or "stiffening" as compared to undoped YBCO, while leaving T_C and the slope of the mean-field normal phase-mixed phase boundary line, $dH_{C2}/dT|_{T=T_c}$, relatively unchanged [$\Delta T(H_{C2})$ and $\Delta dH_{C2}/dT|_{T=T_C}$ $<2\%$] as seen in Fig. 1. The absence of change in ξ_{GL}, the Ginzburg–Landau superconducting pair coherence length ($H_{C2}=\phi_0/2\pi\xi_{GL}^2$, ϕ_0 is the flux quanta), implies some possible vortex-impurity interactions causing an enhanced pinning or "stiffening" of the vortex system and bringing about the transition to the vortex–solid phase at higher temperatures. Fitting the power-law temperature dependence of the irreversibility line shows an increase in ν' of 20% with increased Tb doping (Fig. 2). Co-doped $YBa_2(Cu_{1-X}Co_X)_3O_{7-\delta}$ (YBCCO-chain site doping) single crystals at concentrations less than $X=0.025$ show a similar behavior with an increase in ν' ($\nu'=0.55$ at $X=0.01$ to $\nu'=0.66$ at $X=0.02$); but no significant shift in temperature of the irreversibility line as measured by dc magnetization.[9] However, at $X=0.025$ doping this system undergoes an orthorhombic-to-tetragonal phase transition, resulting in behavior similar to the Pr- and Zn-doped systems. Magnetization studies show oxygenation of as-grown polycrystalline $HgBa_2CaCu_2O_{6+\delta}$ introduces small displacements to higher temperatures in the irreversibility line and increases in ν' ($\nu'=1.2$ to $\nu'=1.3$) which are attributed to variations in CuO_2 planar coupling with planar separation distances.[10]

In contrast to the phase diagram of the Tb-doped system, increased Pr and Zn doping of YBCO tends to depress both T_C and dH_{C2}/dT (Fig. 3), but to increase ν' (Fig. 2). The depression of dH_{C2}/dT has been seen in other H_{C2} studies of YPBCO and is attributed to hole filling and/or hybridization.[1,4] The enlargement in the size of ξ_{GL} with increased doping (Fig. 3) redefines the length scales in the vortex system resulting in an inability of the quenched dis-

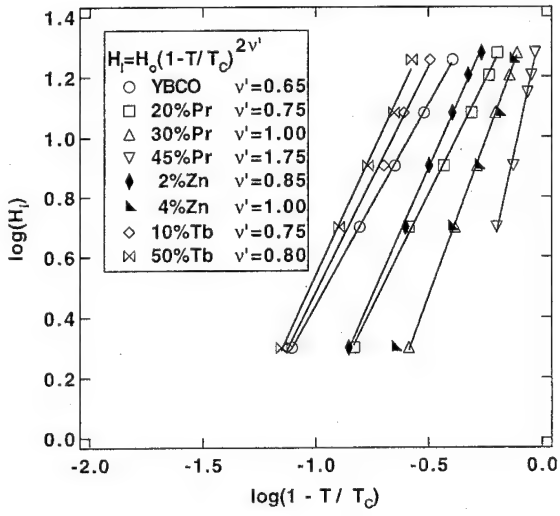

FIG. 2. Log–log plot of H_I vs $1-T/T_C$ for thin film samples of Pr-, Tb-, Zn-doped YBCO. (Solid lines represent power-law fits with given exponents.)

order (twinning and point defects) to reduce thermally activated vortex motion thus "softening" the vortex system. As mentioned above, single crystals of YBCCO at dopant concentrations of greater than $X=0.025$ have a similar behavior with the irreversibility line shifted to lower temperatures and increasing ν' ($\nu'=0.75$ at $X=0.025$ to $\nu'=1.3$ at $X=0.04$ for $H>1$ T) which has been attributed to decoupling of the vortices between CuO_2 planes.[9] Thickness dependence studies of YBCO thin films by ac magnetization show a progressive depression in transition temperature T_I with ν' increasing from $\nu'=0.66$ to $\nu'=0.86$ as film thickness decreased from 1000 to 20 nm, respectively.[11] Although no explanation was afforded, the reduction in the number of possible CuO_2 planes coupled by flux lines from 30 000 to 60, results in similar behavior seen in Pr-, Zn-, and Co-doped YBCO with increased doping. From a magnetoresistivity study of YBCO thin films with decreasing strip width from 5.6 to 0.54 mm, evidence was offered that size effects were responsible for softening of the vortex system elasticity.[12] This evidence took the form of an increase in the dynamical exponent z by some 70% ($z=5.6$ to $z=9.7$) with an associated increase in ν' of 40% ($\nu'=0.75$ to $\nu'=1.07$).

These systems were chosen for study based on the need to understand the effects magnetic and nonmagnetic impurities have on the mechanisms responsible for the depression of superconductivity and on the fundamental phenomena which underlies the vortex state in these unconventional type II superconductors. Within this and similar studies, alterations of the structure in and around the CuO_2 planes have redefined the boundaries of the $H-T$ phase plane. This phenomenon is intimately tied to the manner in which the vortex system detects these changes and adapts its dynamical properties. The questions brought up and left unanswered here will provide an area for more detailed investigation in future work.

Rotational magnetic measurements of vortex pinning in polycrystalline superconductors (abstract)

M. K. Hasan, S. J. Park, and J. S. Kouvel
Department of Physics, University of Illinois, Chicago, Illinois 60607-7059

Magnetization-vector measurements were made at various temperatures on polycrystalline disks of $YBa_2Cu_3O_7$ and $(Ba,K)BiO_3$ as each was rotated about its axis in a fixed field **H** along the disk plane. For hysteretic starting states, the vortex flux density vector **B** is found to bifurcate into a $\mathbf{B}_R$ component that rotates rigidly with the sample and a $\mathbf{B}_F$ component that stays at a fixed angle (θ_F) relative to H, thus turning frictionally relative to the sample, as seen earlier.[1] With increasing H, B_R decreases and B_F increases in size, indicating a distribution in the strength of the vortex pinning torques. After B_R has vanished, the frictional angle θ_F decreases rapidly. Thus, the quantity $H\mu \sin \theta_F$ (μ being the quantized vortex moment), which equals the average pinning torque (τ_p) on each vortex, does not remain constant but diminishes with increasing H. This decrease of τ_p is consistent with the collective pinning phenomenon known as vortex bundling. At fixed H, τ_p diminishes rapidly with increasing temperature, reaching very low values well below T_c. These results are compared with those derived from critical-state model interpretations of conventional hysteresis loop data. © *1996 American Institute of Physics.* [S0021-8979(96)63208-4]

4 Gbit/in.^{2} inductive write heads using high moment FeAlN poles

W. P. Jayasekara, S. Wang,[a] and M. H. Kryder
Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

Thin film inductive write heads incorporating 2-μm-thick single and multilayer FeAlN/SiO_2 poles were fabricated. The poles were trimmed to 1 μm trackwidth using focused ion beam etching from the air bearing surface of the sliders. Tests on 2950 Oe media show satisfactory media saturation. Overwrite in excess of -43 dB and hard transition peak shift <2 nm were measured for wide trackwidth heads with 0.2 μm gap lengths. Tracks written using a 1 μm track width head were imaged using magnetic force microscopy, showing well defined transitions at linear densities up to 6600 flux changes per millimeter. A written track width of approximately 1.1 μm and a side erase band of less than 0.1 μm were observed. Assuming a coding scheme with a density ratio of 1.33, these heads promise a recording density of over 4 Gbit/in.^{2} © *1996 American Institute of Physics.* [S0021-8979(96)12008-1]

I. INTRODUCTION

Achieving high areal density magnetic recording requires writing data at high track density as well as high linear density. The former requires write heads with very narrow track widths, while the latter calls for narrow gap heads capable of both saturating high coercivity media as well as generating a high write field gradient. Recording heads capable of 1–3 Gbit/in.^{2} areal density recording have been discussed in the past.[1–3] In this article we discuss the performance of narrow and wide track width write heads with poles made of FeAlN high moment material. These heads are capable of saturating 2950 Oe media. The narrow track heads are shown to write at an areal density of over 4 Gbit/in.^{2}

II. EXPERIMENT

The write heads were made with poles consisting of 2-μm-thick single and multilayer FeAlN/SiO_2 films. This material was deposited in a Perkin Elmer 2400 system by rf-diode sputtering an FeAl target in an Ar/N_2 ambient. FeAlN films deposited on glass wafers were reported earlier.[4] These showed coercivity $H_c<1$ Oe, anisotropy field H_k of 6 Oe, saturation magnetization of 20 kG (yielding a permeability of 3400), near zero magnetostriction, and, for laminated films, a permeance roll-off frequency of over 200 MHz. Wafer level testing of FeAlN write heads have shown satisfactory magnetic behavior.[5] The poles were defined by ion milling through a photoresist mask. Track widths of 10–24 μm were defined in this manner. The gap consisted of 0.2 μm sputtered Al_2O_3. The heads incorporated 15 turn plated copper coils and hard cured photoresist insulators. The heads were subsequently machined into two rail sliders. The magnetic separations quoted below are based on air bearing simulations, and 38 nm for the sum of carbon overcoat, half media thickness, and pole tip recession. The heads were lapped to a target throat height of 0.5–1.0 μm. The poles of the wide track width heads were trimmed from the air bearing surface (ABS) of the slider using focused ion beam etching (FIBE). A 0.7 μm track width defined by trimming a 12 μm track width head is shown in Fig. 1.

The recording data presented in this article pertain to a 22 μm track width head and a 1 μm track width focused ion beam etched head. For the latter, the etch depth was 1 μm, which previous modeling showed to be adequate to prevent disturbing adjacent data tracks.[6] These heads had poles consisting of two 1-μm-thick laminations. The two cobalt based thin film media used in this experiment had coercivities of 2500 and 2950 Oe. Both had an M_rt of 0.65 memu/cm^2 and a carbon overcoat of 7.5 nm. The written pattern was read back with a separate magnetoresistive sensor with a read trackwidth of 2.8 μm and a shield to shield gap spacing of 0.36 μm.

III. RESULTS AND DISCUSSION

The signal read back using the MR head as a function of the write current for the 22 μm track width and the 1 μm track width write heads on 2950 Oe coercivity media is shown in Fig. 2. Complete media saturation is accomplished for both heads. The media saturation onset currents for both heads are quite similar, indicating that the pole trimming has

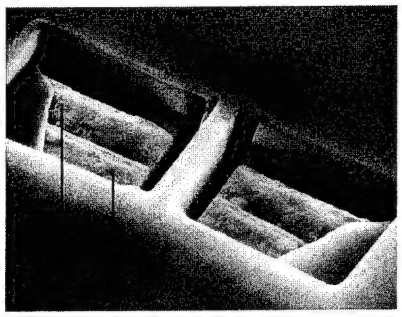

FIG. 1. 0.7 μm track width defined by focused ion beam etching from the ABS.

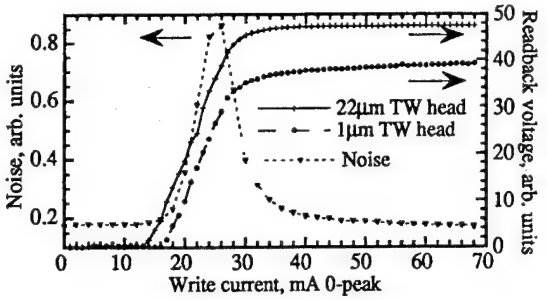

FIG. 2. Readback voltage and reverse dc erase noise as a function of write current, on 2950 Oe media.

had no detrimental effects on head performance. The efficiency of the heads was evaluated using the reverse dc erase noise method.[7] In this measurement the media is dc erased with one polarity, and then the media noise is measured as a function of the dc write current applied to the head with opposite polarity. The reverse dc erase noise exhibits a maximum at the current at which the field in the media equals the remanent coercivity of the media. This is also depicted in Fig. 2, for the 22 μm track width head on 2950 Oe media. The nominal magnetic separation (fly height, overcoat, half media thickness, plus pole tip recession) in this case was 105 nm. Using the Karlqvist relationship between deep gap field and field at the media, a relatively low efficiency of approximately 27% is calculated for this head.

Overwrite results at the same fly height are presented in Fig. 3. In this measurement, a 625 flux changes per millimeter (fc/mm) pattern was overwritten by a 2500 fc/mm pattern, and the reduction in signal amplitude at the fundamental frequency of the overwritten pattern was determined. The wide track width head demonstrates very good overwrite on 2950 Oe coercivity media. However, the overwrite for the 1 μm track width head (not shown) was much lower. This is attributed to the 2.8 μm track width MR read head sensing incompletely overwritten track edges of the 1-μm-wide track. Hard transition peak shift (HPS) was measured using overwrite spectra.[8] An HPS of less than 2 nm is obtained at a write current over 55 mA and a magnetic separation of 80 nm, as shown in Fig. 3. It was observed that at separations over 100 nm an HPS of less than 5 nm could not be achieved, inspite of the good overwrite observed earlier. This is attributed to the lower write field gradient experienced at the larger separations.

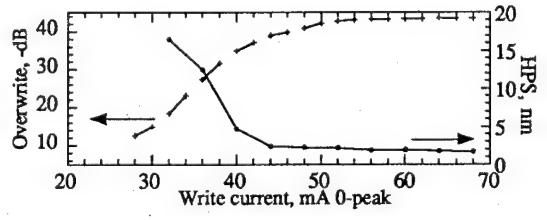

FIG. 3. Overwrite and hard transition peak shift as a function of write current for 22 μm head on 2950 Oe media.

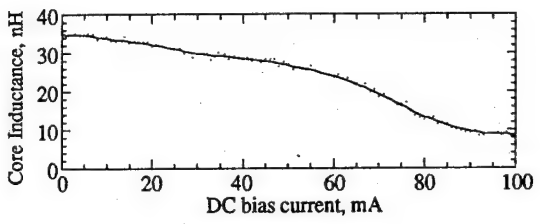

FIG. 4. Core inductance of the write head as a function of applied dc bias current.

Core inductance of the head as a function of applied dc bias current is shown in Fig. 4. Up to a current of approximately 60 mA, the inductance rolls off gradually, indicating that no severe saturation is occurring in this regime. However, a sharper drop in inductance is observed beyond 60 mA, indicative of possible saturation of the neck region. The core inductance at zero bias current is lower than in a conventional NiFe head, indicating lower core permeability. This is consistent with the low efficiencies observed, and has been reported earlier.[9] This low permeability could be due to low substrate temperature when FeAlN was deposited without substrate preheating on Al_2O_3–TiC wafers,[10] and/or due to the high anisotropy of the FeAlN deposited on nonplanar surfaces of the head.[11] Core inductance measured as a function of frequency for heads with poles with 20 laminations does not show any appreciable roll off in the measured range of 1–50 MHz.

Roll-off measurements were done on 2950 Oe media at a magnetic separation of 80 nm. As shown in Fig. 5, D_{50}, the linear density at which the readback amplitude falls to 50% of that at low density, is 5200 fc/mm. The signal from the 1-μm-wide tracks shows slightly different characteristics, possibly due to track edge effects detected by the wider track width read head. Assuming $D_{50} \approx 1.44/\mathrm{PW}_{50}$,[12] where $\mathrm{PW}_{50}=[g^2+4(a_x+d)^2]^{0.5}$ is the width at half maximum amplitude of the readback pulse, $g=0.18$ μm is half the read gap, a_x is the transition parameter of the written pattern, and $d\sim 60$ nm is the magnetic separation during readback, $a_x\sim 40$ nm. This is consistent with calculations based on the Williams–Comstock model. This also predicts a D_{50} of 6200 fc/mm if the read gap is reduced to 0.2 μm.

Tracks written using the 1 μm track width head at a magnetic separation of 94 nm on 2500 Oe coercivity media were imaged using magnetic force microscopy (MFM). The MFM lift height was 25 nm. An all-ones pattern written at a linear density of 6600 fc/mm, shown in Fig. 6, has been

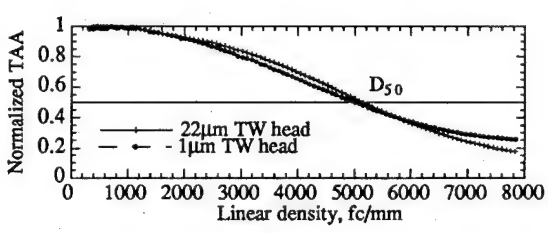

FIG. 5. Roll-off curves for FeAlN write heads on 2950 Oe media.

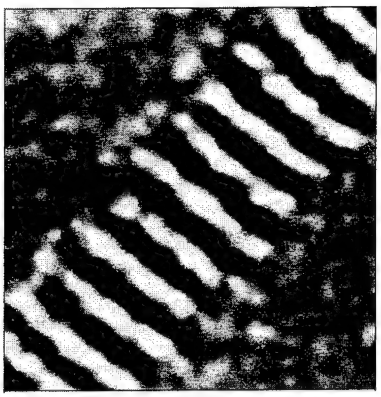

FIG. 6. MFM image of 6600 fc/mm pattern written with 1 μm track width head. Total field width is 2.5 μm.

FIG. 8. MFM image of offtrack overwrite test showing side erase band. Total field width is 5 μm.

defined well. In contrast, a track written at a linear density of 8800 fc/mm, shown in Fig. 7, is showing some transition percolation. The written track width is observed to be approximately 1.1 μm. An off-track overwrite image, where a track was written at a low density and partly overwritten by another track at twice that density after stepping the head half a track width, is shown in Fig. 8. A narrow erase band of <0.1 μm is observed between the tracks. This is consistent with modeling results (cf. 6).

Allowing ± 0.1 μm for track misregistration, these images show that a track pitch of 1.35 μm can be achieved with these heads. Using a coding scheme with a density ratio of 1.25 (bits/fc), the 6600 fc/mm tracks correspond to a user bit density of 8250 bits/mm, while a code with a density ratio of 1.33 would yield 8800 bits/mm. These correspond to areal densities of 6.1 and 6.5 Mbit/mm^2, or 3.95 and 4.2 Gbits/in.^{2}, respectively.

IV. CONCLUSIONS

Write heads using FeAlN high moment pole material were fabricated and tested. These heads are capable of saturating 2950 Oe media. MFM imaging showed clearly defined transitions in tracks written at a linear density of 6600 fc/mm. Wide track width heads demonstrated overwrite of over -43 dB and a hard transition peak shift of <2 nm. Inductance measurements indicate that the heads were not undergoing severe saturation in the operating regime. The heads were observed to have somewhat low efficiencies. This is attributed to low permeability of FeAlN deposited without substrate heating and/or deposited on nonplanar surfaces. Narrow track width heads were defined by pole trimming wide trackwidth heads from the ABS. These were demonstrated to be capable of writing at an areal density of 4 Gbits/in.^{2}

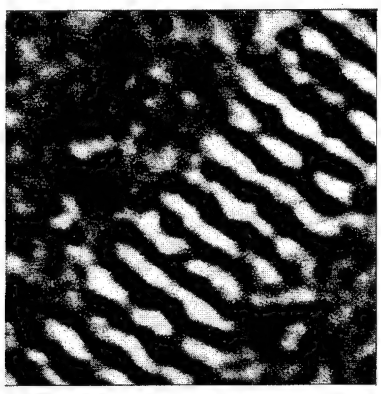

FIG. 7. MFM image of 8800 fc/mm pattern written with 1 μm track width head. Total field width is 2.5 μm.

Experimental studies of nonlinearities in MR heads

Xinzhi Xing and H. Neal Bertram
Center for Magnetic Recording Research, University of California at San Diego, La Jolla, California 92093-0401

Magnetoresistive (MR) heads have been widely developed for high density digital magnetic recording. The nonlinear MR head response causes nonlinear distortion in the playback signals, and this results in a degradation of system performance. In this work, techniques for identifying the nonlinearity due to the playback process have been developed. Different levels of nonlinear distortion in the playback signals were observed for different head/disk combinations. The behavior of the MR nonlinear distortion as a function of flying height and recording density was also examined. © *1996 American Institute of Physics.* [S0021-8979(96)28708-0]

I. INTRODUCTION

In magnetic recording, nonlinear distortions in the playback signals cannot generally be corrected by equalization; therefore it is particularly important to correctly characterize these effects. For rigid disk and magnetoresistive (MR) head combinations, both the write and read process can cause nonlinear distortion in the playback signals. Previous studies[1–4] explored nonlinearities induced by the write process. Few studies have been done on readback induced nonlinearities. This work concentrates on investigating the nonlinear distortion in the playback signals due to the readback process of MR heads. The nonlinear response of an asymmetric MR (AMR) head is due to the fact that the playback output is proportional to $\langle \cos^2 \theta \rangle$,[5] where θ is the angle between the magnetization and the current direction. The average is over the active read region of the head. When the head is properly biased ($\theta \sim 45°$), and the signal field from the medium is small, the head response can be considered approximately linear, and linear analysis applies.[4] However, when this is not the case, the nonlinear terms contribute significantly, the playback wave form will deviate from linearity and eventually saturate. The level of this nonlinear distortion changes with the head and disk parameters, the recording density, and flying height d. In our investigation, the playback nonlinearity was examined in both the time and frequency domain in order to obtain a more complete understanding of the playback distortion.

II. EXPERIMENTAL TECHNIQUES

A. Time domain measurements

For a linear system,

$$V_r(t) = \sum_i a_i V_{\mathrm{is}}(t - iT) \tag{1}$$

where $V_r(t)$ represents the playback signal of the recorded data pattern, $V_{\mathrm{is}}(t)$ is the playback pulse of an isolated transition, and T is the bit separation. a_i, the write sequence, can take three values for each i, 1, 0, -1. From Eq. (1), the playback wave form of the recorded pattern at a given density is predictable once the isolated playback pulse is known. On the other hand, by reversing the linear superposition process, the isolated playback pulse can be determined from the playback wave form of a recorded data pattern.

The area under the recorded playback wave form is simply the weighted sum of the areas of the isolated pulses:

$$A_r = \int V_r(t)dt = \sum a_i \int V_{\mathrm{is}}(t - iT)dt = \sum a_i A_{\mathrm{is}}(i) \tag{2}$$

where $A_{\mathrm{is}}(i)$ is the area of the ith isolated pulse. For a data pattern with an odd number of transitions, A_r is independent of T, and $A_r = A_{\mathrm{is}}$. From an approximate linear analysis,[6] this area is

$$A_{\mathrm{is}} = 4IR \frac{\Delta\rho}{\rho} \langle \sin \theta \rangle E \frac{M_r \delta}{M_s t} (g + t)/v \tag{3}$$

where I is the sense current, R is the resistance of the MR element, $\Delta\rho/\rho$ is the fractional change in the resistivity, E is the efficiency of the MR head, g is the element to shield spacing, t is the thickness of the MR element, and v is the relative velocity between the head and disk. It should be noted that the area under the playback pulse depends only on the head parameters and disk $M_r\delta$, and is totally independent of the flying height d and the recorded transition shape.

In order to identify the nonlinear distortion from the area of playback wave form, an experimental technique based on Eqs. (2) and (3) was developed. In this method, three adjacent transitions (tribit) were recorded at different bit separations. Areas under tribits of two polarities (Fig. 1) versus recording density were determined. The variation of these two areas represents how the total nonlinear distortion in the playback signal changes with the recording density.

Another method of characterizing the nonlinearity is the shape analysis of the playback signal. A data pattern containing two adjacent transitions (dibit) were recorded at different densities. The measured amplitudes of the recorded dibits were compared with two different reference dibits. The first reference was obtained by linearly superimposing the measured isolated pulses. The second reference utilized a linear superposition of theoretically obtained isolated pulses. In this way the nonlinear distortion was identified.

B. Frequency domain measurement

In the frequency domain measurement, square waves were utilized to study the head nonlinearities. In a linear system, the spectrum of the playback signal is

 0021-8979/96/79(8)/5883/3/$10.00

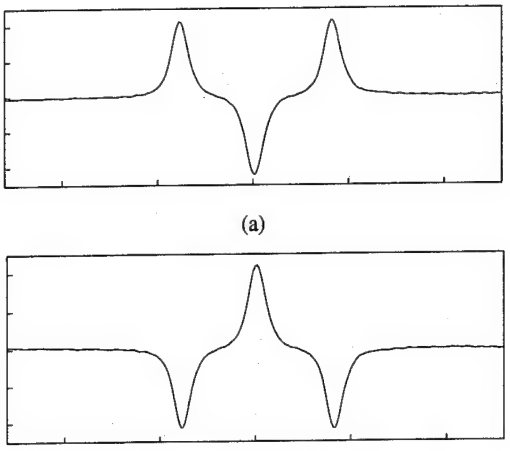

FIG. 1. (a) Positive tribit. (b) Negative tribit.

$$V(k)=2k_0V_{is}(k)\sum_{-\infty}^{\infty}\delta(k-(2m+1)k_0) \tag{4}$$

where $k_0=\pi/B$ and $V_{is}(k)$ is the Fourier transform of the isolated playback signal.[5] Only odd harmonics exist.

Our measurement utilizes a previously developed method for analyzing nonlinearities.[7] Two square waves were recorded, one at a lower frequency f, the other at a higher frequency $(2n+1)f$, where n is an integer. The $(2n+1)$th harmonic of the low frequency signal was compared with the fundamental of the high frequency signal. To maximize the sensitivity of the measurement, $n=1$ was chosen. The ratio

$$R31=\frac{V(3f,1)}{V(f,3)} \tag{5}$$

is defined as the three to one ratio. $V(3f,1)$ represents the fundamental of the high frequency and $V(f,3)$ represents the third harmonic of the low frequency.

From Eq. (4), the $R31$ of a linear system is 3. Nonlinearity in the play back signals results in a deviation of the $R31$ value from 3. Since head nonlinearities occur at low density and medium nonlinearities occur at high density, these two effects can be distinguished by using this method.

III. MEASUREMENTS

The measurements were performed on a Guzik spinstand tester. An MR head with a read track width of 3.75 μm, MR element thickness of 25 nm, and shield to shield spacing of 0.55 μm was used. Two thin film disks with $M_r\delta$ equal 0.9 memu/cm^2 (disk 1) and 0.65 memu/cm^2 (disk 2) were selected for this investigation. Since high coercivity, low moment disks were used, the medium nonlinearities do not appear until the density reaches approximately 100 kfci. Thus, in this density range, we can exclude the medium effects and only consider the head nonlinearities.

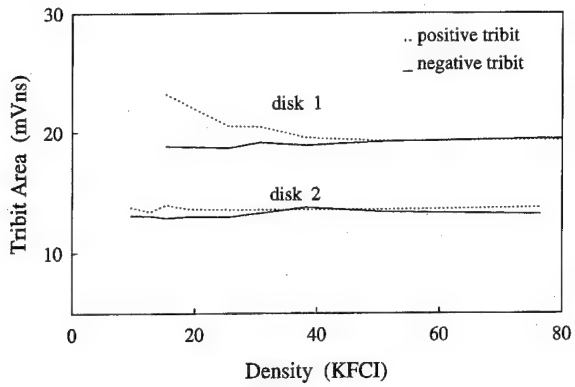

FIG. 2. Tribit areas vs recording density for disk 1 and disk 2.

IV. DISCUSSION AND RESULTS

A. Tribit area measurement

Measured tribit areas of both polarities versus recording density for disk 1 and disk 2 at a 4.5 μ'' flying height are shown in Fig. 2. For disk 1, the areas of the positive tribit and negative tribit are quite different at low recording densities since this is where large head nonlinearities occur. When the bit separation decreases, overlapping of the adjacent transitions causes a smaller signal field. The less distorted MR head response results in a smaller difference between the two polarities at a higher recording density. These two curves converge at 50 kfci and remain constant at higher densities, which suggests that nonlinear head distortion disappears above 50 kfci. In the linear region, the area under the tribit from measurement is 19 mV ns, and from the linear analysis,[6] we expect 20 mV ns. Nonlinearity is not observed for the low moment disk 2. The area under the tribit for disk 2 obtained from measurement is 13.5 mV ns, and agrees well with 14.4 mV ns given by the theory.

The tribit areas vs recording density at different flying heights for disk 1 are shown in Fig. 3. At a low flying height of 3.5 μ'', a larger separation between positive and negative areas was observed, and the convergence occurred at a higher density of 70 kfci. This result is understandable, be-

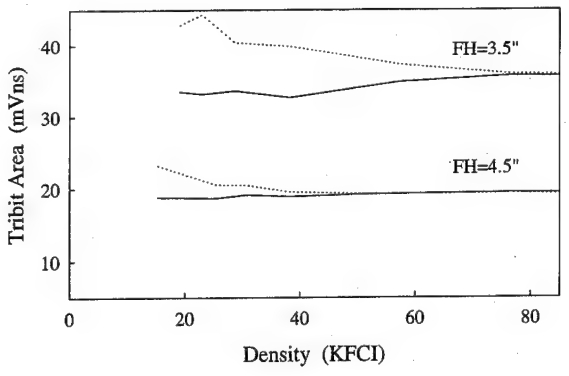

FIG. 3. Tribit areas vs recording density for disk 1. Solid curve and dashed curves correspond respectively to negative and positive tribit.

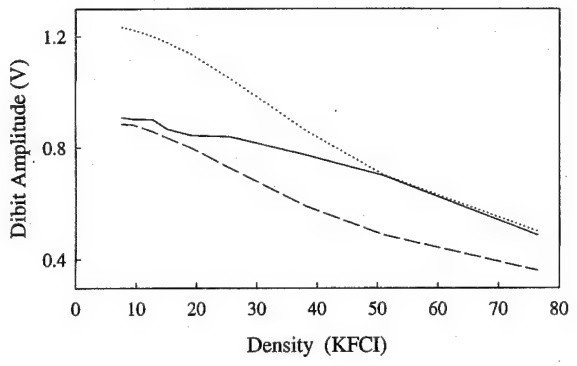

FIG. 4. Dibit amplitude vs recording density. Solid curve (—) shows the experimental results for disk 1; dashed curve (---) is the linear superposition of measured isolated pulses; dotted curve (···) is the linear superposition of calculated pulses.

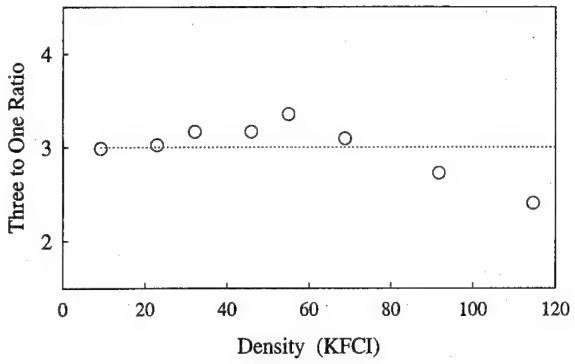

FIG. 5. Three to one ratio vs recording density for disk 1.

cause the head senses a larger signal field at a lower flying height; therefore, the nonlinear distortion in the playback signal is more severe.

B. Dibit measurement

Figure 4 shows the dibit measurement results for disk 1. The solid curve is the amplitude of the measured dibits versus recording density and the dashed curve is the amplitude of dibits from the linear superposition of measured isolated pulses. For comparison, a pulse calculated from the linear analysis theory was used to create linear dibits. The result from this calculation is plotted in Fig. 4 as the dotted curve and represents the behavior of a linear system.

The measured curve is close to the dashed curve at low density, where large nonlinearities exist. With increasing density, the measured curve becomes close to the linear curve as nonlinear distortion decreases. Linear head response is observed when the density is larger than 50 kfci, where the measured curve joins the linear curve.

C. Frequency domain measurement

The three to one ratio versus density for disk 1 is plotted in Fig. 5. The curve increases with density and peaks at 50 kfci. The nonlinear distortion decreases at lower density in the high frequency signal than in the low frequency case. The peak occurs where the nonlinear distortion in the high frequency signal disappears which is 50 kfci in this case. Media nonlinearities enter the results above 80 kfci where $R31$ falls below 3.

V. CONCLUSIONS

In this work, techniques for characterizing the playback process induced nonlinearity in both time and frequency domains have been developed. Various head/disk combinations were examined by using these techniques. For the head 1/disk 1 combination, nonlinearity was observed below 50 kfci at a 4.5 μ'' flying height. A lower flying height will worsen the nonlinear distortion. The linear analysis of MR heads agrees well with the experimental results when the head is operating in the linear region.

Micromagnetic simulations were performed to study the biasing characteristics and playback performance of actual dual spin-valve GMR heads. Both symmetric and asymmetric dual spin valve heads were analyzed. The study shows that the symmetric dual spin-valve head is not properly biased in its patterned form, without any additional transverse biasing schemes. On the other hand, the asymmetric dual spin valve head is self-biased since in this form, the free layer is free from the demagnetizing fields arising from the pinned layers. However, opposite GMR effects with similar magnitudes would be required for the two spin valve structures in the same multilayer film.
 [S0021-8979(96)15908-4]

I. INTRODUCTION

The spin-valve head has emerged as one of the most promising read sensors employing the giant magnetoresistive effect in magnetic recording applications. The dual spin-valve (DSV) structures that further enhance the GMR effect have been proposed and fabricated.[1,2] While the magnetic properties look promising at the sheet film level,[2] the actual device performance of such structures has not been analyzed or demonstrated.

In this work, micromagnetic simulations are performed to address the above issues. The modeling is performed on narrow track dual spin valve heads intended for future high density rigid disk recording applications.

II. MODEL AND SIMULATION

The most basic dual spin valve consists of a five layer GMR film sandwiched by two antiferromagnetic films. The five layer GMR film consists of three ferromagnetic layers separated by two thin conductive metallic layers. The two outer magnetic layers are exchange coupled to the antiferromagnetic films. The center ferromagnetic layer rotates freely, acting as flux sensing layer. Figure 1 shows the schematics of the symmetric dual spin-valve structures. The symmetric DSV head has the magnetizations of the outer magnetic layers pinned in the same direction, vertical to the air bearing surface (ABS), by the antiferromagnetic films. A GMR ratio above 14% has been obtained experimentally at the sheet film level with additional thin ferromagnetic layers added on each side of the each conductive interlayer to enhance the GMR effect.[2]

Here, only the most basic DSV structures were modeled. The three magnetic layers are assumed to be made of Permalloy with $M_s = 800$ emu/cm^3 and unaxial anisotropy field $H_k = 5$ Oe. The thicknesses of the multilayer structure are assumed to be 4(nm)/2(nm)/7(nm)/2(nm)/4(nm) for the NiFe/Cu/NiFe/Cu/NiFe structure respectively, unless mentioned otherwise. The three magnetic layers of the GMR film are discretized into three two dimensional arrays of elements. The thickness of each element is the same as the layer thickness and the size of each element is 5 nm×5 nm. Besides the inclusion of the magnetostatic interaction, ferromagnetic interlayer exchange coupling between the three magnetic layers is assumed. The interlayer exchange field H_{fe} is defined as

$$\mathbf{H}_{1,or3} = H_{fe}\hat{m}_2$$

and

$$\mathbf{H}_2 = H_{fe}(\hat{m}_1 + \hat{m}_3),$$

where $\mathbf{H}$ are the interlayer exchange field acts on one of the layers and $\hat{m}$ is the unit vector of local magnetization. H_{fe} defines the magnitude of the interlayer exchange field. Between each pair of adjacent layers, same magnitude of the exchange field $H_{fe} = 10$ Oe is assumed. The interfacial exchange coupling fields provided by the two antiferromagnetic films on the two outer magnetic layers were modeled by unidirectional fields of a magnitude 500 (Oe) along the pinning direction.

The head transfer curve is calculated with the excitation field calculated from a step transition in the presence of the soft magnetic shields. For all the calculations, the shield-to-shield spacing is $G = 0.2$ μm. The sensor structure has a track width of $W = 0.5$ μm and stripe height of $h = 0.3$ μm, unless mentioned otherwise.

Both types of DSV heads utilize abutted permanent magnet (PM) films as longitudinal domain stabilization. The de-

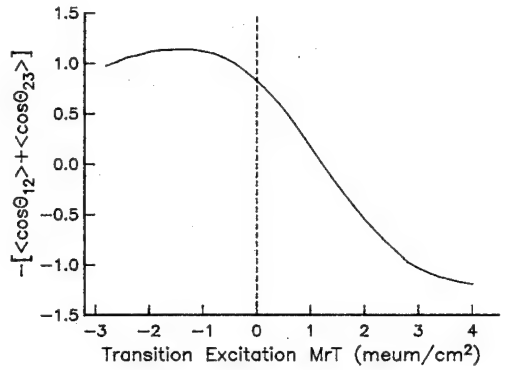

FIG. 2. Calculated transfer curve of the symmetric dual spin-valve head. $\langle\cos\theta_{12}\rangle+\langle\cos\theta_{23}\rangle$ is the GMR output averaged over the entire active region where θ_{12} and θ_{23} denote the angles between the magnetizations in the layers 1 (pinned) and 2 (free) and layers 2 and 3 (pinned), respectively.

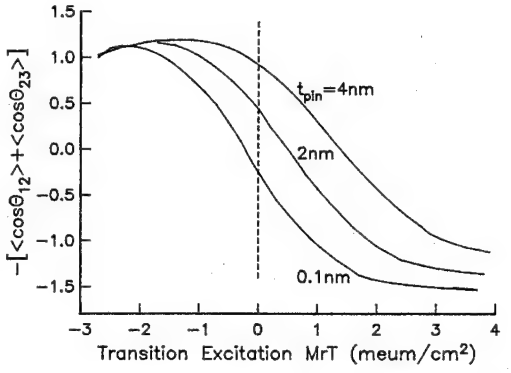

FIG. 4. Transfer curves calculated for different pinned layer thickness. The thickness of the free layer is 7 nm.

tail of the modeling with abutted PM film is described in Ref. 3. The PM moment is optimized for maximum head sensitivity while maintain head stability without any hysteresis and irreversible jumps in the calculated transfer curve.

III. RESULTS AND DISCUSSIONS

A. Symmetric dual spin valve structure

Figure 2 shows the calculated transfer curve for the symmetric DSV. As shown by the curve, the head is not properly biased. This phenomenon is due to the demagnetizing fields arising from the two pinned layers acting on the center free layer. Since the magnetizations of the two outer layers are exchange pinned in the same vertical direction, the demagnetizing field are reinforcing each other and rather strong. Due to this field, at the quiescent state, the magnetization of the free layer is oriented towards the opposite direction of the magnetizations in the pinned layer, as clearly shown in Fig. 3. The properly biased free layer should have the magnetization orient in the horizontal direction.

Reducing pinned layer thickness improves the biasing condition to a certain degree. As shown in Fig. 4, transfer curves were calculated for three different pinned layer thickness, assuming that both pinned layers are equally thick and the free layer thickness remains the same ($\delta_f=7$ nm). However, optimum biasing was obtained only when the pinned layer thickness is nearly zero.

Since the demagnetizing field acting on the free layer is in the opposite direction of the magnetizations of the pinned layers, bias condition can be improved by increasing the interlayer ferromagnetic exchange coupling between the free and pinned layers. Figure 5 shows three transfer curves with different interlayer ferromagnetic exchange field. As the exchange field increases, the bias condition does increase, but not without reducing the linear dynamic range of the output. At $H_{fe}=80$ Oe interlayer exchange coupling field, the head become properly biased, but the linear dynamic range of the output has decreased by near 50%.

The most effective way to bias the symmetric spin valve head is to apply an external field, e.g., by employing a current carrying conducting film near the sensor film which provide a rather uniform external field to the sensor. Here, a

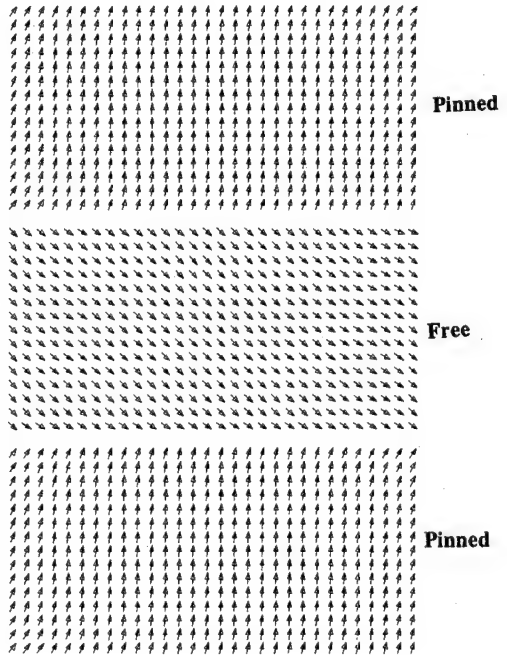

FIG. 3. Magnetization configurations at quiescent state of a symmetric dual spin valve head. Due to the demagnetizing field, the magnetization of the free layer rotates downward away from the horizontal.

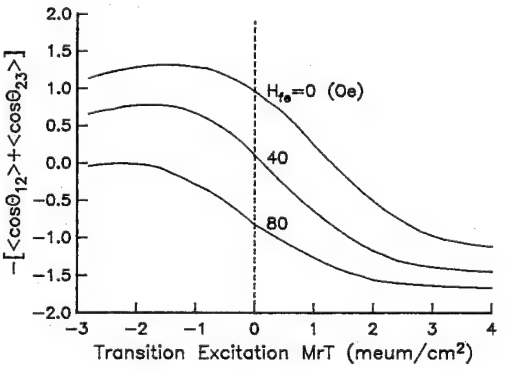

FIG. 5. Transfer curves calculated for three different interlayer ferromagnetic exchange coupling strength. Same coupling field is assumed between the free and the pinned layers across the two conductive interlayers.

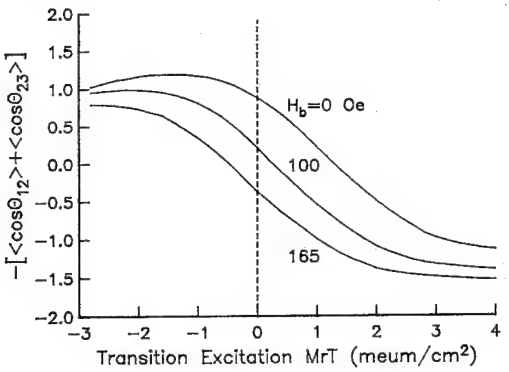

FIG. 6. Transfer curves calculated for three magnitudes of the external transverse bias field: $H_b=0$ Oe, $H_b=100$ Oe, and $H_b=165$ Oe.

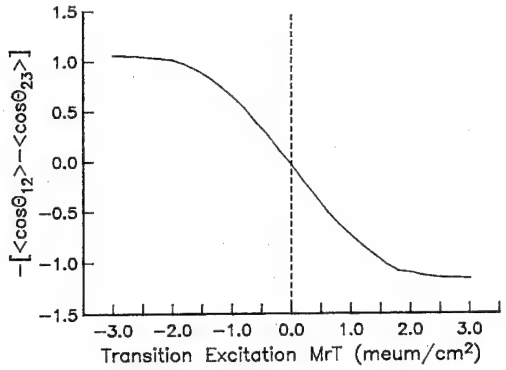

FIG. 8. Calculated transfer curve of the asymmetric dual spin valve head. The output is calculated according to $\langle\cos\theta_{12}\rangle-\langle\cos\theta_{23}\rangle$, assuming the dual spin valve has opposite GMR effect with same magnitude.

series of transfer curves are calculated with different magnitudes of an uniform external field, applied in the upward vertical direction, as shown in Fig. 6. For the head geometry simulated here, an external field magnitude of $H_b=165$ Oe is needed to properly bias the head.

B. Asymmetric dual spin valve structure

Figure 7 shows the schematics of the asymmetric dual spin-valve structures. The asymmetric DSV has the magnetizations of the outer magnetic layers pinned in the opposite vertical direction. For the asymmetric DSV, the GMR effect between the two pairs of magnetic layers is assumed to have opposite sign with exact same magnitude, even though to date, observed inverse GMR effects are significantly smaller than the ordinary GMR effect.[4] The thickness of the free layer is 7 nm and the thicknesses of the pinned layers are 4 nm with same magnetic parameters (used for symmetric DSV calculation). The output is calculated as

$$\mathrm{GMR}_{\mathrm{output}}=-(\langle\cos\theta_{12}\rangle-\langle\cos\theta_{23}\rangle).$$

Figure 8 shows a calculated transfer curve for the asymmetric dual spin-valve head structure. As shown by the transfer curve, the head is self biased, because the demagnetizing fields arising from the oppositely pinned outer magnetic layers cancel each other at the free layer. In another words, the magnetizations of the two outer layers form a flux closure with little impact to the free layer. If the sense current flows in the direction such that it reinforces the flux closure rather than opposing it, the self biasing is stable and efficient.

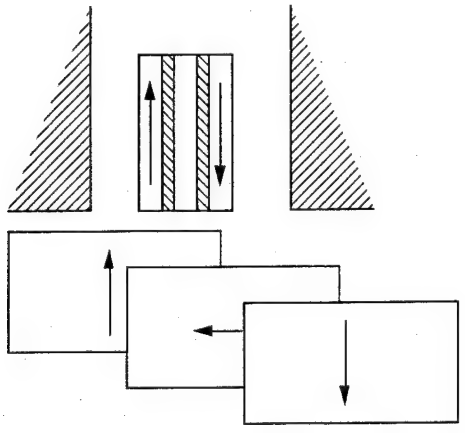

FIG. 7. Schematics of the asymmetric dual spin-valve head structure.

IV. SUMMARY

Micromagnetic simulations were performed to study the biasing characteristics and playback performance of actual dual spin valve GMR heads. Both symmetric and asymmetric dual spin-valve heads were analyzed. The study shows that the symmetric dual spin-valve head is poorly biased in its patterned form, without any additional transverse biasing schemes. This phenomenon is seen on both unshielded and shielded devices and is due to the demagnetizing field acting on the free layer from the pinned layers on both sides. The existing interlayer ferromagnetic exchange coupling is too small to counterbalance the demagnetizing field. On the other hand, the asymmetric dual spin-valve head is self-biased since in this form, the free layer is free from the demagnetizing fields arising from the pinned layers. However, opposite GMR effect with similar magnitudes would be required for the two spin valve structures in the same multilayer film.

Sensing elements which are 0.20 μm wide have been fabricated from giant magnetoresistance material that has four magnetic layers separated by 16–17 Å copper alloy layers. The material has a bulk magnetoresistive coefficient of 12%–15%, and when etched into the 0.2-μm-wide stripes, the stripe material has a shifted linear response range of about 8%, extending from −140 to +140 Oe, for example. Empirical models have been developed for both the bulk material and the stripe material. Using the stripe material model, a numerical analysis was performed for end-on, 0.2-μm-wide, read head sensors in a shielded read head with a 0.25 μm head gap. The analysis shows that with input fields of ±100 Oe from transitions, a peak to peak output of 0.85 mV can be achieved in the assumed read head structure with a 0.20-μm-wide tip. If a 0.25 μm flux gathering tip is used, the peak to peak output can be increased to 1.3 mV. © *1996 American Institute of Physics.* [S0021-8979(96)12108-8]

I. INTRODUCTION

An experimental and analytical investigation has been made on the use of 0.2-μm-wide, four magnetic layer, giant magnetoresistance (GMR) stripes in end-on read head sensors in which the stripes are perpendicular to the recording surface.[1] Figure 1 depicts such a head sensor structure with a flux gathering front tip and contact at the air bearing surface. The figure also illustrates the use of the sense current in a 0.2 μm winding to generate a bias field. The front contact protects the active part of the sensor from abrasion but at the expense of signal attenuation. A numerical analysis was performed for the end-on read head sensors using this material in a shielded read head with a 0.25 μm head gap. A 0.2 μm contact at the air bearing surface and a 1.25 mA sense current also were assumed. The analysis also included the effects of a field dependent permeability. Assuming state of the art lithography and advanced fabrication methods, this work shows that with signal fields of ±100 Oe from recorded transitions, peak to peak signal swings of 1 mV can be achieved for submicron sensors and track widths.

Electron (e) beam lithography was employed to define the 0.2 μm stripes used to perform the experimental measurements. However, the fabrication capability to form the 0.2-μm-wide front contact and the 0.2-μm-wide bias winding was not available. The effects of the front contact and bias winding were treated analytically.

II. EXPERIMENTAL RESULTS

Experimentally, 0.20-μm-wide sensing elements were fabricated from GMR materials that contained four magnetic structures separated by 16–17-Å-thick copper alloy layers (Cu, Ag, Au). The outside magnetic structures were 55 Å thick and had 40-Å-thick ternary layers (65% Ni, 15% Fe, 20% Co) and 15-Å-thick cobalt-rich layers (95% Co, 5% Fe) at the interfaces. The two interior magnetic structures were 50 Å thick with a 20 Å ternary layer sandwiched between two 15-Å-thick cobalt-rich layers. The material has a bulk magnetoresistive coefficient of 12%–15% and a sheet resistance of 12–14 Ω per square.

Figures 2(a) and 2(b) illustrate typical $M-R$ responses for sheet samples using a four-point probe method. The saturation field typically could be varied from 100 to 500 Oe depending on deposition conditions and the nonmagnetic layer thickness. The small switching transitions occurring at field magnitudes of 5–10 Oe correspond with the coercive force of the bulk sample. The measured remnant magnetization was approximately 25% of the saturated value.

Figure 3 shows a scanning electron microscope picture of a section of a nominal 0.2-μm-wide, six-contact, 100-μm-long test structure used for the measurements. Structures varied in width from 0.17 to 0.22 μm. When etched into the 0.2-μm-wide stripes, the material illustrated in Fig. 2(a) had a linear range of about 8% extending from about −140 to +140 Oe, as illustrated in Fig. 4. Note that the switching is very abrupt and occurs at the ±140 Oe values. On other 0.2 μm samples, switching occurred in the 100–150 Oe range.

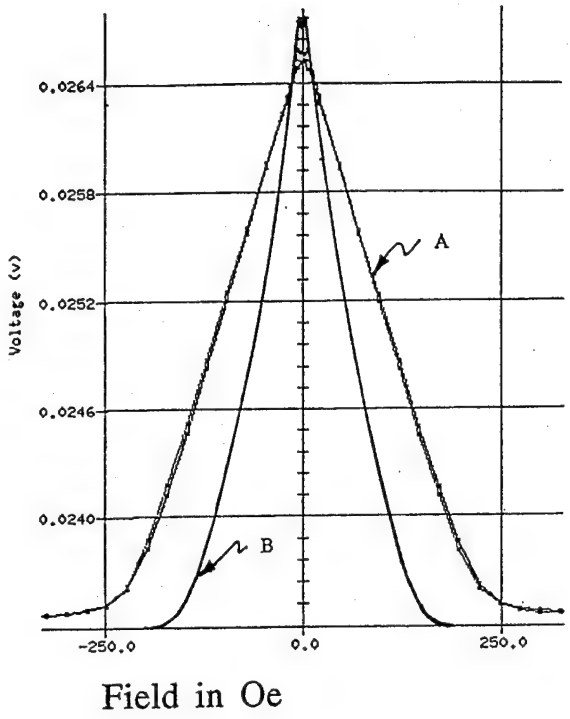

FIG. 2. Bulk sample GMR response.

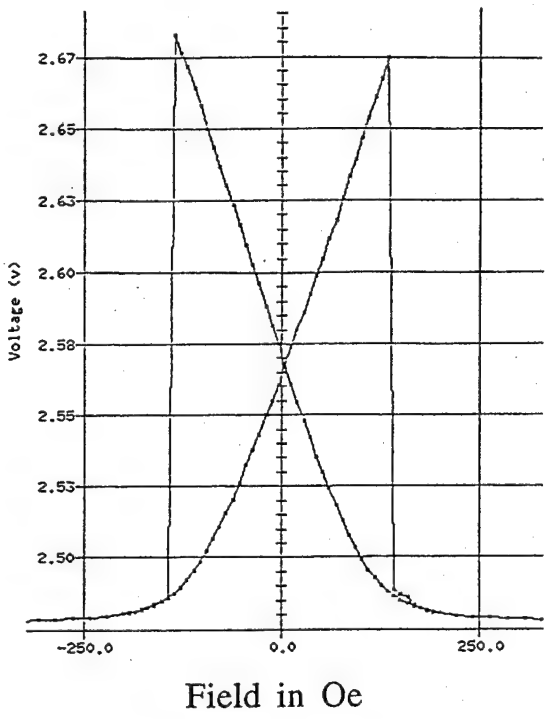

FIG. 4. Stripe $M-R$ response.

III. EMPIRICAL MODELS AND ANALYSIS

A. Bulk model

Generally within a 10% experimental error, the bulk magnetic properties of the GMR material examined could be characterized by assigning to every magnetic layer the same antiparallel coupling field H_3 and the same parallel coupling field H_2 with their axes perpendicular to one another.[2] These two parameters were suffice to characterize the $M-R$ response to the field, the field to saturate the response, the remnant magnetization, the magnetization curve, the rest directions of the magnetization, and the field at which switching occurs. If H_w is the drive field and M is the saturation magnetization, the energy density (E in erg/cm^3) is given by

$$E=H_3M|\sin^3\Theta|/3-H_2M\sin^2\Theta/2-H_wM\sin\Theta,$$

where Θ is the angle of the magnetization with respect to an axis perpendicular to the applied field and the material anisotropy constant is lumped into the H_2 constant. With no field applied, the two rest directions of the magnetization are given by $|\sin\Theta|=H_2/H_3$ and switching occurs when the reversing field is given by $|H_w|=H_2H_2/(4H_3)$. The $\sin^3\Theta$ term was chosen on the basis of a simple fit to the experimental data. The bulk curve of Fig. 5 illustrates the calcu-

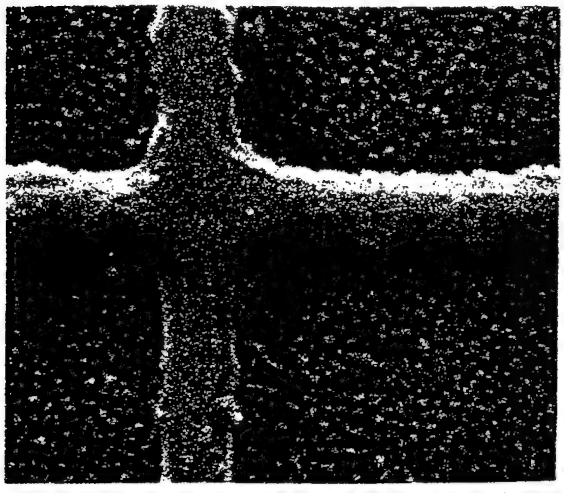

FIG. 3. Scanning electron microscope picture 0.2 μm stripe.

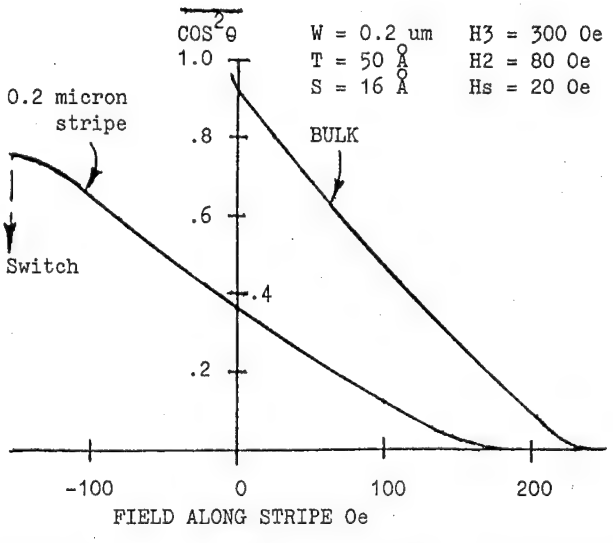

FIG. 5. Calculated stripe response.

lated response for material with parameters close to those measured for the experimental sample indicated in Fig. 2(a).

B. Stripe model

When the material is etched into narrow stripes, exchange energy and demagnetizing effects from the curling of the magnetization at the edges greatly alter the $M-R$ behavior of the material as noted in the experimental results indicated in Fig. 4. The four magnetic layer stripe structure was modeled as two identical, paired, magnetic layers coupled by a common demagnetizing field arising at the edges. It was also assumed that alternate magnetic layers rotated with equal magnitude but in opposite directions. Because the equivalent magnetic poles at the layer edges are of alternate polarity, the demagnetizing field diminishes rapidly with distance into the material; the effective range of the field is less than 50 Å. The same, average, short range, field value was used for all layers in the analysis. Also, the net field from the sense current (H_s) assumed a uniform current density.

The maximum torque which can be sustained from the edge demagnetizing field occurs when the edge magnetization makes a 45° angle with the edge. If this value is exceeded, the edge magnetization flips. The 0.2 μm stripe curve of Fig. 5 shows the calculated response and switching behavior for the parameters given. Stripe response was calculated from the torque equation[3] for the magnetization with the constraint that the torque from the edge demagnetizing field be sufficient for equilibrium. At the end of a stripe, the edge magnetization tips out and the magnetization in the center of the stripe tips back in response to the end demagnetizing field. For the 0.2-μm-wide tip with pinned edges, the equilibrium end demagnetizing field is 50–75 Oe and for the 0.25 μm tip it is 25–50 Oe.

Because of the effects of exchange and the edge demagnetizing fields, the average permeability of the stripe material in response to a field along the stripe is a nonlinear function of the applied field. Figure 6 depicts the calculated average permeability of a 0.2-μm-wide stripe with unpinned edges and a 0.25-μm-wide stripe with pinned edges. To prevent switching, the edges must be pinned in the sensor contact area (a proprietary process).

C. Head sensor response

To calculate the response of a 0.2-μm-wide sensor, a 0.25 μm gap between shields was assumed with the shield separation distance increasing to 0.50 μm immediately after the front contact in an arrangement where the front contact is integral with the top pole piece.[4] A nonuniform transmission line model was used which took into account the pinned edges in the contact area, the increased gap beyond the contact area, and the field dependent permeability. Calculations were performed for tip widths of 0.2 and 0.25 μm. The 0.2-μm-wide bias winding was assumed to be located 0.2 μm behind the front contact midway between the $M-R$ stripe and the shield. The method of images was used to calculate the field from the bias winding.

For the 0.25-μm-wide flux gathering tip with pinned edges, an average permeability of 60 and a decay length of

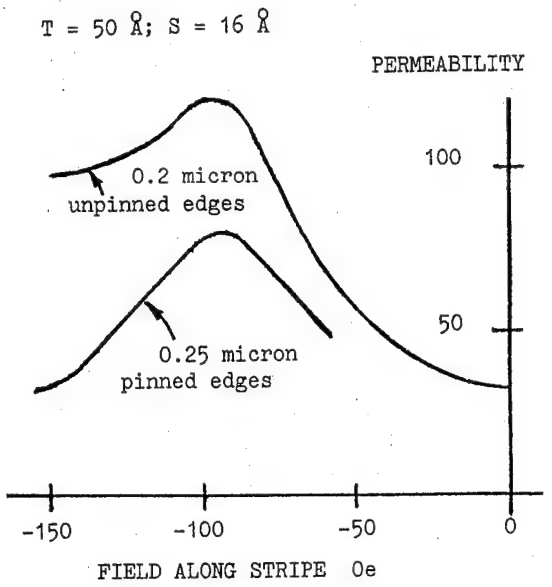

FIG. 6. Stripe average permeability.

0.28 μm was used in the simulation. For the case of the 0.20-μm-wide pinned tip, an average permeability of 45 and a decay length of 0.25 μm were assumed. Beyond the contact area, the 0.2-μm-wide stripe with unpinned edges was assumed to have a permeability of 80 for fields above 50 Oe and a permeability of 40 for fields below 50 Oe. The corresponding decay lengths were 0.45 and 0.32 μm. These average values were calculated for materials with $H_3=200$ Oe and $H_2=75$ Oe, values similar to those of the material indicated in Fig. 2(b). The analysis showed that with input fields of ± 100 Oe from transitions and a sense current of 1.25 mA, the calculated peak to peak output for the 0.20-μm-wide tip is 0.85 mV. If a 0.25 μm flux gathering tip is used, the peak to peak output is 1.3 mV.

IV. SUMMARY

The experimental and analytical results obtained in this work show that with advanced fabrication methods and existing four magnetic layer GMR materials with 12%–15% $M-R$ coefficients, shielded, end-on read head sensors with tip widths of 0.2 and 0.25 μm can be made to yield peak to peak outputs of approximately 1 mV for an input field of ± 100 Oe when operating at a 1.25 mA sense current.

Magnetization reversal processes of NiFe elements exchange coupled by NiO antiferromagnetic films

Juren Ding and Jian-Gang Zhu
MINT, Department of Electrical Engineering, University of Minnesota, Minneapolis, Minnesota 55455

The magnetic domain structures and their switching processes of small peamalloy (NiFe) elements exchange coupled by antiferromagnetic (NiO) thin films were studied using magnetic force microscopy. A uniform external magnetic field generated by an electromagnet was applied to the magnetic force microscopy so that the domain switching processes could be observed *in situ*. The effects of NiFe film thickness, element size, and aspect ratio on domain behavior were investigated. It was found that the unidirectional exchange coupling field of small elements was much greater than that measured on the sheet bilayer films. The results of this study showed little indication of the existence of domain structure in NiO antiferromagnetic film. © *1996 American Institute of Physics.* [S0021-8979(96)12208-4]

I. INTRODUCTION

Antiferromagnetic films are used in variety of applications. One of their main applications is to generate an unidirectional exchange anisotropy within adjacent soft magnetic films, either stacked on top or underneath, through the interfacial exchange coupling, i.e., to maintain the magnetization configuration of a soft film in a single domain state, such as used for domain stabilization in a magnetoresistive head for magnetic recording a pplications.[1] However, the interfacial exchange coupling is usually two to three orders of magnitude smaller than the interatomic spin-to-spin exchange coupling. The interfacial exchange coupling field is only at the order of tens to hundreds of oersteds. The properties of the exchange coupling have been studied extensively and various mechanisms have been proposed.[2,3] Some antiferromagnetic films not only yield pure shifts of the easy axis hysteresis loops, but also expansion of the hysteresis loop; i.e., the coercivity of the adjacent soft film is increased. A NiO antiferromagnetic film is one such example. Whether the interfacial exchange coupling affects the magnetization switching processes of the adjacent soft magnetic film in addition to the shift due to the ideal unidirectional exchange anisotropy has remained unclear.

In attempting to address these issues, we investigated the magnetization switching processes of NiFe/NiO bilayer films which were patterned to micronscale rectangular elements via the magnetic force microscopy (MFM) technique. The focus was to understand the domain reversal processes of various NiFe elements in the presence of interfacial exchange coupling under an uniform external field.

II. EXPERIMENT

Thin films were deposited on Si substrates using rf sputtering. The base pressure before sputtering was about 4×10^{-7} Torr. All films were deposited at room temperature. The Ar pressure was 10 mTorr for all film depositions except NiO. During the deposition of the NiFe thin film, a magnetic field (about 20 Oe) was applied to the sample by using two permanent magnets resulting in an unidirectional anisotropy along the field direction.

NiO antiferromagnetic thin films were deposited using reactive sputtering. The deposited NiO thin films were measured using a vibrating-sample magnetometer (VSM) and the presence of the antiferromagnetic phase was confirmed. In this study, all NiO thin films were prepared under the same conditions and the thicknesses of all NiO films were 80 nm. The grain size of the NiO thin film was about 20 nm measured by atomic force microscopy. It was found that the NiO grains were elongated.

After the deposition, small elements with varying sizes ranging from 2 μm to 200 μm and varying aspect ratios were fabricated using photolithography and ion milling. In the photolithographic process, the samples were heated at 90 °C for 30 min.

All domain structures were imaged using a Digital Instrument Nanoscope III. An electromagnet was designed to attach to the MFM to apply an uniform magnetic field to the samples so that domain switching processes could be observed *in situ*. Magnetic fields as high as 500 Oe could be obtained by controlling an applied current. The lift height of the MFM tip was 100 nm for all images shown in this paper. The tips were magnetized in a large field in the direction parallel to the film plane and perpendicular to the cantilever.

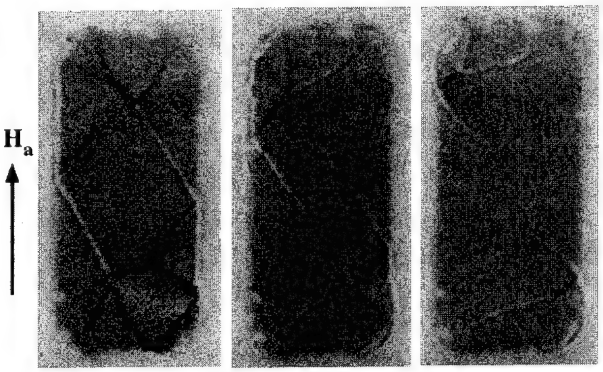

FIG. 1. Domain structures of NiFe single layer (20 nm thick) element (10 μm×20 μm) under external magnetic field. The arrow shows positive external field direction and also corresponds to the magnetic easy axis of the element (likewise in the following figures).

 0021-8979/96/79(8)/5892/3/$10.00

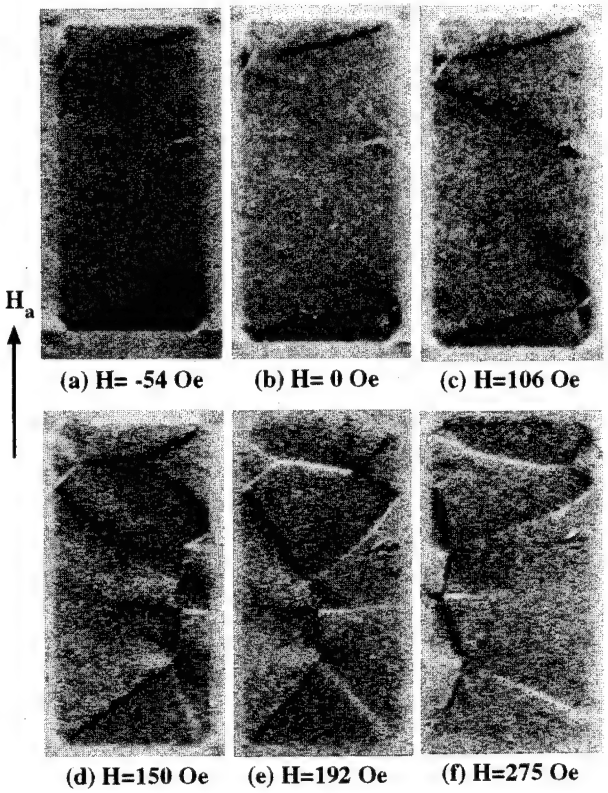

FIG. 2. Magnetization switching process of 20 nm thick NiFe element (10 μm×20 μm) exchange-coupled with a 80 nm NiO antiferromagnetic layer. The unidirectional exchange coupling field was antiparallel to the arrow direction (likewise in the following figures). The exchange coupling field of the sheet film was about 14 Oe.

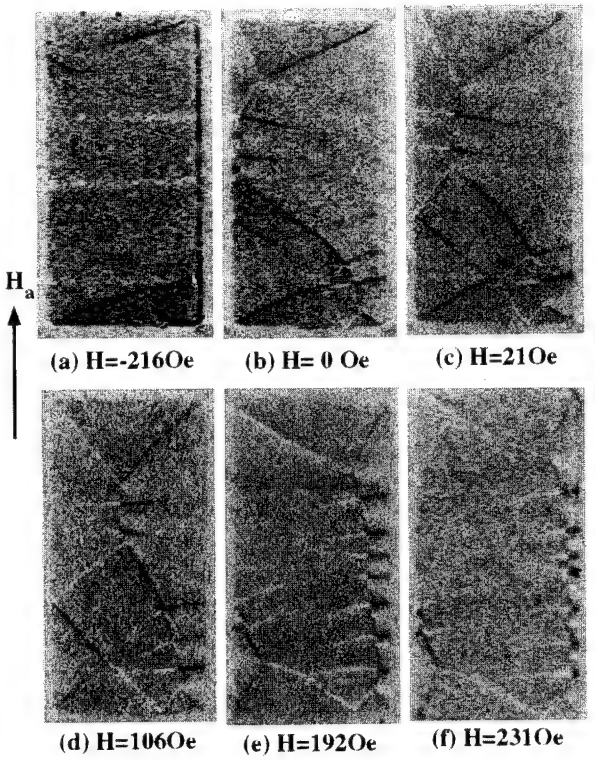

FIG. 3. Magnetization switching process of a 30 nm thick NiFe element (10 μm×20 μm) exchange coupled with a 80 nm NiO antiferromagnetic layer. The exchange coupling field of the sheet film was about 9 Oe.

III. MAGNETIZATION REVERSAL OF NiFe SINGLE LAYER FILM

Figure 1 shows three MFM images of the magnetic domain configurations for a patterned NiFe single layer film element (10 μm×20 μm). The three images correspond to three different magnitudes of the external field, which was applied along the film easy axis direction. At zero external field [Fig. 1(a)], a typical closure domain configuration is observed and the film is in a self-demagnetized state. As the external field increases, the domains with magnetization parallel to the field expand [Fig. 1(b)]. At $H=106$ Oe [Fig. 1(c)], a quasisingle domain state is reached with only edge domains remaining at both ends of the element.

IV. MAGNETIZATION REVERSAL OF NiFe/NiO BILAYER FILM

Three different NiFe/NiO bilayer films were deposited, with thickness of the NiFe layer 10 nm, 20 nm, and 30 nm respectively while keeping the NiO layer the same thickness. The exchange fields, measured by the shift of the easy axis hysteresis loop with a VSM, are 24, 14, and 9 Oe, respectively for the three sheet films before patterning. The coercivities of the NiFe films expanded a little (by about 5 Oe).

A. Comparison with NiFe single layer film

Figure 2 shows a series of MFM images of the bilayer film element. The thickness of the NiFe film was 20 nm same as that in the single layer film with the same element size (10 μm×20 μm). The interfacial exchange field was in the opposite direction of the positive external field. At zero external field [Fig. 2(b)], a quasisingle domain configuration with edge domains remaining at the ends was observed. This indicates that the magnitude of the interfacial exchange field is greater than 106 Oe which kept the single layer element in a similar single domain state. The complete demagnetized state with closure domains is formed at a field magnitude of 192 Oe [Fig. 2(e)]. It is interesting to note that the interfacial exchange field in the patterned elements is nearly one order of magnitude greater than that measured on the sheet films. Two other elements of the same size on the same bilayer film were examined and similar results were obtained. This surprising difference between the interfacial exchange field of the sheet film and the small element was not caused by the patterning process. The exchange field of a sheet film subjected to a the heating procedure similar to that in the patterning process did not exhibit any significant change.

B. Effect of NiFe film thickness

Figure 3 shows the domain configurations in a bilayer film element with a NiFe film thickness of 30 nm. In this case, at zero external field, the quasisingle domain state could no longer be achieved [Fig. 3(b)]. This is due to the combined factors of stronger demagnetizing field in the single domain state and an effective reduction of the interfacial exchange coupling field due to the thicker NiFe film

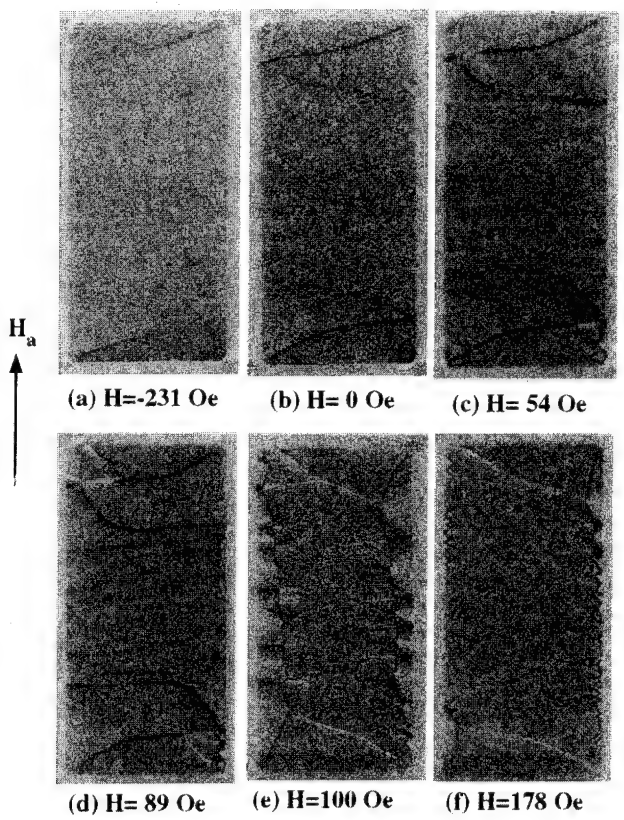

FIG. 4. Magnetization switching process of a 30 nm thick NiFe element (20μm×40 μm) exchange coupled with a 80 nm NiO antiferromagnetic layer.

since the exchange coupling field arises only from interfacial energy. The coercive state [Fig. 3(e)] occurs at an external field of 106 Oe which is smaller than that for 20 nm thick NiFe film with same element size (192 Oe) mainly due to the smaller exchange coupling field.

For the 10 nm thick NiFe film, the domain switching process was very difficult to observe because of the large exchange coupling field. The single domain state was broken at about 400 Oe applied external field.

C. Effect of element size

Figure 4 shows the magnetization switching process of a bilayer film element with a size of 20 μm×40 μm. The thickness of NiFe layer was 30 nm. In contrast to the 10 μm×20 μm element (Fig. 3), the quasisingle domain is formed in the 20 μm×40 μm element at zero external field due to a smaller demagnetization field in the middle of the element. It should be noticed that a central domain is formed at coercive state in the big element while the closure domain structure is formed in the small element. Cross-tie structures are almost evenly distributed.

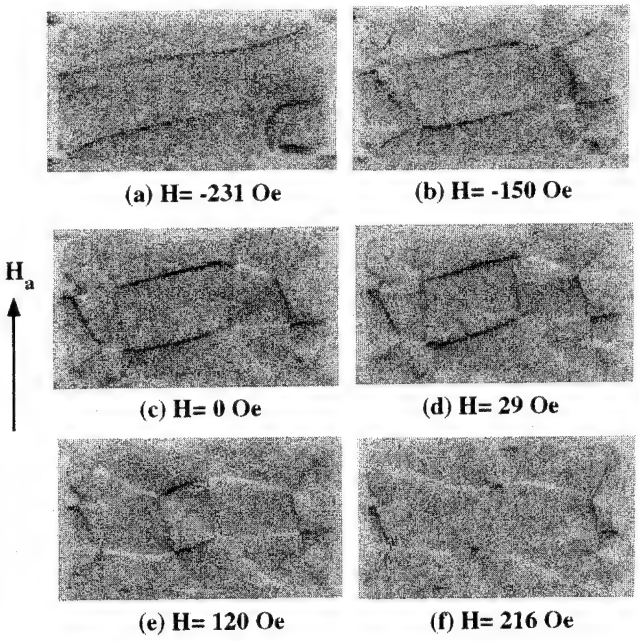

FIG. 5. Magnetization switching process of a 30 nm thick NiFe element (20 μm×10 μm) exchange coupled with a 80 nm NiO antiferromagnetic layer.

D. Effect of aspect ratio

Figure 5 shows the magnetization reversal process of a 20 μm×10 μm element with 30 nm thick NiFe layer. At zero external field, a multidomain structure is formed due to the large demagnetization field. In order to achieve a single domain state, an external field of about 200 Oe needs to be applied in the exchange coupling field direction.

V. CONCLUSIONS

Magnetic domain reversal processes in patterned exchange coupled NiFe/NiO bilayer film elements have been investigated via *in situ* magnetic force microscopy. It was found that the unidirectional exchange anisotropy field of the patterned small elements, arising from the interfacial exchange coupling, is significantly greater than that measured on the sheet bilayer films. For multidomain states, cross-tie structures were particularly prominent in the NiFe layer of the NiFe/NiO bilayer film elements while they were rarely observed in the NiFe single-layer film for identical film thicknesses. The "well-behaved" domain configurations in the NiFe layer of the exchange-coupled bilayer film elements gave little indication of the existence of antiferromagnetic domains in the NiO film.

Domain structures at the cross sections of thin film inductive recording heads

Francis H. Liu, Hua-Ching Tong, and Lena Milosvlasky
Read-Rite Corporation, Fremont, California 94539

Using a scanning Kerr effect microscope with external ac-tickle field excitation, zigzagged and slanted intersections of domain walls were observed at the symmetry-axis cross sections of thin film inductive heads. These domain walls are believed to be the intersections of edge-closure domain walls, with the magnetization on the two sides of the walls (or lines) oriented in "head-to-head" or "tail-to-tail" configurations. They are thus slanted or zigzagged in order to spread the charges along the walls over a larger region, thereby reducing magnetostatic energy. This interpretation is further evident by the observation that upon applying a small dc bias field in the symmetry-axis direction, the slanted or zigzagged intersections of domain walls were observed to displace according to the field direction, and sometimes deformed to different configurations. Upon lapping the heads from their air-bearing surfaces, slanted domain walls at the sloped backgap cross sections were occasionally observed. © *1996 American Institute of Physics.* [S0021-8979(96)12308-0]

INTRODUCTION

The readback noise in thin film inductive recording heads, such as popcorn and wiggle noise, has been correlated with magnetic domains and their dynamic behavior.[1,2] However, only the dynamic response of domain walls at the top-yoke surfaces, sloped pole-tip surfaces and air-bearing surfaces (ABS) were typically observed. Domain walls at various depth of thin film heads have been observed by using an electron microscope;[3] complete depth profiles of domain walls in thin film heads, however, have yet to be reported. In this report, for the first time, we report the domain wall depth profiles observed directly, by using scanning Kerr effect microscopy (SKEM), at the symmetry-axis cross sections of top (P2) and bottom (P1) permalloy yokes, as well as at the ABS-side cross sections of sloped backgap region.

EXPERIMENTAL METHODS

A SKEM was used to image the dynamic domain structures in thin film heads. A ferrite-core electromagnet, attached to the objective, was used to generate uniform external magnetic tickle field of 50 Oe peak to peak at 0.5 MHz, which in turn modulate the magnetization in thin film heads. Using longitudinal Kerr effect, average magnetization dynamics in response to the high frequency tickle field was thus mapped out. A lapping and polishing process similar to that in throat height definition was typically used to obtain the cross sections at symmetry axis and that lapped from ABS. With external field excitation and the plane of laser beam incidence both in the direction of symmetry axis, dynamic domain wall structures observed at the symmetry-axis cross section can thus be obtained.

RESULTS

The symmetry-axis cross section of head A and its corresponding domain configuration are shown in Figs. 1(a) and 1(b), respectively. In head A, domain walls were observed to be slanted all in the same orientation (yet with slightly different angles), as shown in Fig. 1(b). The corresponding domain structures of Fig. 1(b) imaged from the deposition side, both before and after lapping, are shown in Figs. 2(a) and 2(b), respectively. Closure domain structures were observed before and after cross sectioning. Based on the domain images observed in Figs. 1(b) and 2(b), a schematic interpretation of a section of the P2 domain structure is shown in Fig. 3.

The domain configuration of the symmetry-axis cross section of head B is shown in Fig. 4(a). As opposed to the domain configuration of head A, as shown in Fig. 1(b), domain walls were observed to be slanted in the alternating orientations in the top pole of head B, as shown in Fig. 4(a). Upon +15 Oe of dc bias field applied to head B, the slanted walls were observed to displace according to the field direction, in that one domain wall was displaced in one direction and the adjacent walls were observed to displace in the opposite direction, as shown in Fig. 4(b). Upon −15 Oe of dc bias field applied to head B, however, a new wall with a kink in the middle was observed to form, in addition to the displacements of slanted domain walls, as shown in Fig. 4(c).

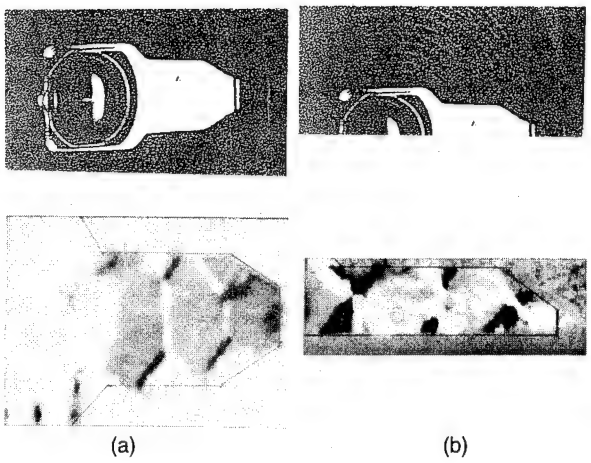

FIG. 2. Top-view (P2 deposition-side) domain structure of head A (a) before cross section and (b) after cross section.

The domain configuration of the symmetry-axis cross section of head C is shown in Fig. 5(a). In this case, both zigzagged and slanted domain walls were observed. Even more complicated domain wall deformations were observed with a small dc bias field applied to head C, as shown in Figs. 5(b), 5(c), and 5(d). In addition to the slanted domain walls connecting the top and bottom surfaces of P2, V-shaped and upside down V-shaped domain walls were observed in head C upon a small dc bias field, as shown in Figs. 5(b)–5(d). In particular, the two ends of V-shaped walls were observed to terminate only at the top surface of P2, whereas the two ends of upside down V-shaped walls were observed to terminate only at the bottom surface of P2. Upon removing the small dc bias field, the remanent domain structure of head C is shown in Fig. 5(e). Comparing with the domain structure as shown in Fig. 5(a), the remanent domain structure in head C is now completely different from that before applying dc bias field.

It is interesting to note that very few or no domain walls were observed at the sloped backgap regions of symmetry-axis cross sections of heads A, B, and C, as shown in Figs. 1, 4, and 5, respectively. In an attempt to observe the domain configurations at the sloped backgap region directly, head D was lapped from its ABS and toward its backgap. In this case, slanted domain walls were observed at the sloped backgap region, as shown in Fig. 6(b). The corresponding P2 domain structure before cross sectioning and its schematic interpretation is depicted in Fig. 6(a) and 6(c), respectively.

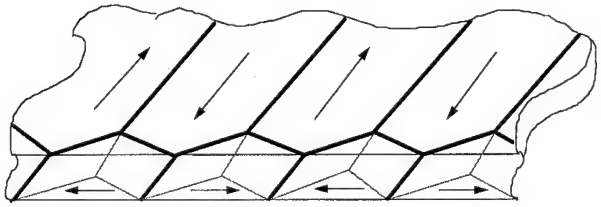

FIG. 3. Schematic interpretation of the P2 domain structure observed in head A.

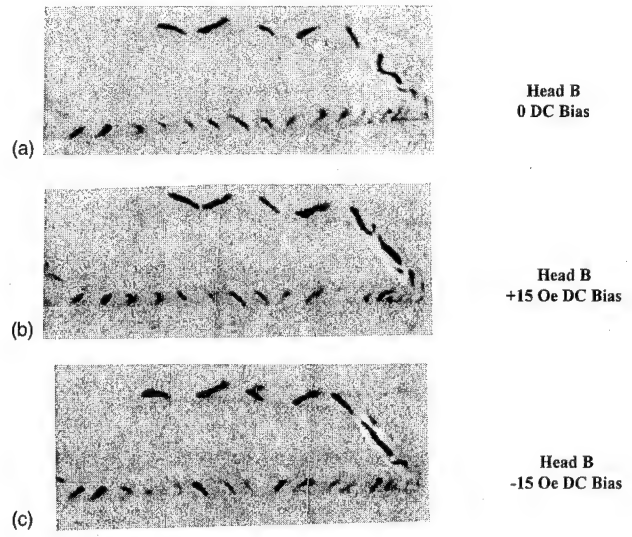

FIG. 4. Domain structure at the symmetry-axis cross section of head B, with (a) 0 Oe, (b) +15 Oe, and (c) −15 Oe of dc bias field.

DISCUSSION

Based on the domain images observed at the symmetry-axis cross section, as shown in Fig. 1(b), and at the P2 deposition side after cross sectioning, as shown in Fig. 2(b), it is clear that the domain walls observed at the symmetry-axis

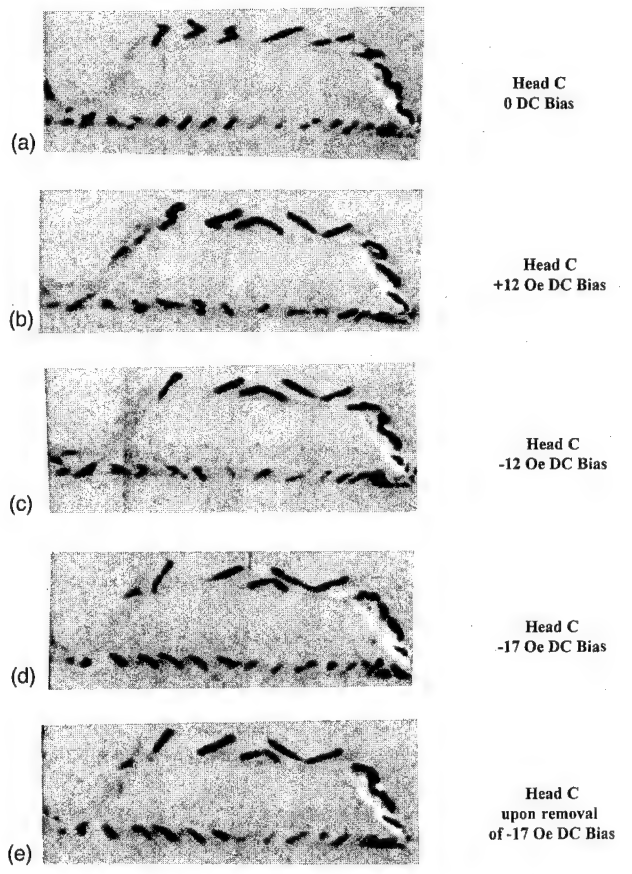

FIG. 5. Domain structure at the symmetry-axis cross section of head C, with (a) 0 Oe, (b) +12 Oe, and (c) −12 Oe, (d) −17 Oe of dc bias field, and (e) upon removal of −17 Oe of dc bias field.

cross section are the intersections of edge-closure domain walls, as schematically illustrated in Fig. 3. This observation is expected since soft ferromagnetic material, such as permalloy, usually form flux closure domain structures in a specific geometry to minimize its total energy. This interpretation is further evident by the observation that these walls were typically observed to displace according to a small external dc bias field in the symmetry-axis direction, as shown in Figs. 4 and 5. Here, when one wall was observed to displace in one direction, the adjacent walls were typically observed to displace in the opposite direction, as one edge-closure domain expands and the adjacent edge closure domains shrink in response to a dc bias field.

The intersections of closure domain walls are believed to be charged domain walls (or lines, strictly speaking), with the magnetization on the two sides of the domain walls oriented either "head-to-head" or "tail-to-tail," as shown schematically in Fig. 3. These domain walls are thus slanted or zigzagged in order to spread the charges along the walls over a larger region, thereby reducing magnetostatic energy.[2] Furthermore, it has been theoretically predicted[4] and experimentally inferred[5] that 90° walls in Fe films of up to 0.7 μm thick are slanted at their cross sections. It is thus plausible to observe the intersections of two 90° walls to be slanted as well. In consistence with the above observation and interpretation, slanted domain walls were also observed at the air-bearing surfaces of some thin film inductive heads.[2]

Various angles, length, and structures of domain walls, however, have been observed at the symmetry-axis cross sections, as shown in Figs. 4 and 5. It is believed that the exact angles, length, and structures of domain walls are the results of total energy minimization, which includes wall energy and the associated magnetostatic energy. The wall energy in turn depends on the distribution of stress and magnetostriction products in the permalloy yokes. It is thus reasonable to expect the domain walls at the specific locations of symmetry-axis cross sections to reflect the local distribution of stress and magnetostriction products, not only in the symmetry-axis direction, but also in the film thickness direction. Upon small dc bias field, the charge distributions along the walls may alter, resulting in deformation to again minimize the total energies, as shown in Figs. 4 and 5. Deformations and instabilities of domain walls in the thickness direction, as shown in Figs. 5(a) and 5(e), can thus be another sources of wiggle or popcorn noise in thin film inductive recording heads. The effective anisotropy of sloped backgap region was also observed, in some cases, to be transverse to that of other regions of the heads. They may thus also be a source of readback noise.[1]

CONCLUSIONS

Using SKEM, domain structures of thin film inductive recording heads were observed from three principal perspectives: the deposition side, the symmetry-axis cross section and the ABS-side cross section. Thus, domain structures at the bottom poles (P1) and backgap closures, which previously cannot be observed at finished head form, can now be observed directly. Various slanted and zigzagged intersections of domain walls were observed at the symmetry-axis cross sections of thin film heads. Upon small dc bias field, even more complicated domain wall deformations in the thickness direction were observed. It is thus speculated that deformations and instabilities of domain walls in the film thickness direction can be another sources of readback noise, such as popcorn and wiggle noise. Domain walls at the sloped backgap regions that are longitudinal to the flux conduction direction were also observed occasionally. They may thus also cause readback noise.[1]

Picosecond time-resolved magnetization dynamics of thin-film heads

M. R. Freeman

J. F. Smyth
IBM Storage Systems Division, 5600 Cottle Road, San Jose, California 95123

The application of picosecond magneto-optic sampling techniques to studies of the magnetization dynamics of thin-film recording heads is described. Time-resolved magnetization measurements are performed using picosecond stroboscopic scanning Kerr microscopy. A Faraday probe is used to monitor the coil excitation current with the same optical setup, yielding a direct measure of the magnetic propagation delay through the head. This delay is found to have a marked spatial dependence across the face of the pole tips. As an aid to visualization of the spatial dependence, scanned images of the polar Kerr rotation at fixed time delays are acquired. © *1996 American Institute of Physics.* [S0021-8979(96)16008-9]

I. INTRODUCTION

The dynamical properties of small magnetic structures represent problems of great current interest, both because of the implications for magnetic recording and due to the rapid improvements in experimental and computational attacks on the fundamental issues.[1–5] Just as there has been continual focus on the intrinsic limitations that size may impose on the recording process,[6] fundamental speed limitations are of concern as well.[7] In this paper we report novel measurements of the fast (subnanosecond regime) time response of the complex micromagnetic circuit which makes up a thin-film inductive write head. Picosecond magneto-optic sampling measurements[8] have been performed which yield a direct time-domain comparison of the excitation current in the coil with the magnetization response anywhere across the pole tips (P1 and P2) on the air-bearing surface.

II. THE EXPERIMENTS

Details of the experimental setup are shown schematically in Fig. 1. The optical measurements are performed with picosecond pulses delivered by a synchronously pumped, cavity dumped dye laser. A polarizing beamsplitter and differential diode detection scheme is used to monitor the polar Kerr rotation. Ordinary low-speed signal diodes can be used as the picosecond-scale information is all obtained via the timing of the optical probe pulses relative to the excitation of the head. The heads are driven by electronically generated and time-delayed current pulses, synchronized to the cavity dumper. Two pulses of opposite polarity are superposed to create a bipolar waveform to simulate actual write conditions (albeit with much shorter transition times). The typical "pulse sequence" consists of a 5-ns duration positive pulse placed in the center of a 75-ns-width negative pulse of half the amplitude, repeated at 631.7 kHz. The time resolution in this configuration is limited to 50 ps by trigger jitter of the electronic pulsing circuit. The electronic pulse risetime at the head itself is still significantly larger than this in these measurements, limited by the coil inductance. To minimize this risetime, the head is mounted on a circuit board with the twisted pair leads normally running to the harness truncated to a few millimeters in length, and connected to a coplanar transmission line which delivers the current pulses. In practice, the current waveform is toggled on and off at 2 kHz such that the actual Kerr signal measured arises from the difference in the perpendicular magnetization under drive to that in the remanent state (where the magnetization is almost entirely in-plane.)

The current waveform is monitored by a small sample of thin-film bismuth-doped yttrium–iron–garnet, placed next to one of the coplanar lines. The garnet, with low perpendicular anisotropy and magnetization lying in the plane of the film in zero applied field, is situated such that the stray magnetic field from the lead is perpendicular to the film. The perpendicular component of magnetization is then proportional to the coil current (provided the transition times are within the bandwidth established by the ferromagnetic resonance of the garnet.) The perpendicular magnetization is measured "instantaneously" by sampling with a picosecond probe pulse at normal incidence to the film. A local in-plane field of 0.1 T, created by a small NdFeB permanent magnet, stiffens the

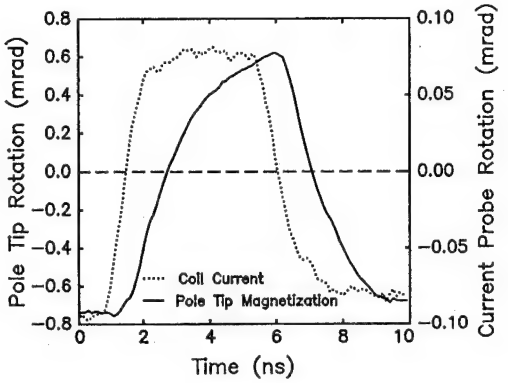

FIG. 2. A time-resolved optical measurement of the perpendicular magnetization at P2 on a 10-turn recording head, with the corresponding optical measurement of the coil current for absolute timing comparisons.

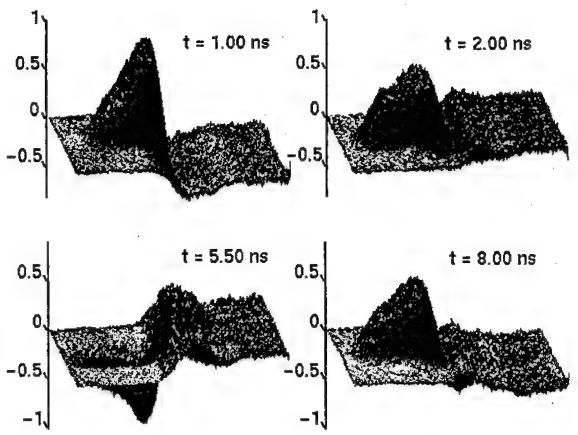

FIG. 3. A collection of stroboscopic scanned images of the perpendicular magnetization in a 12-μm-square region centered on the gap, with P2 to the left and P1 on the right. The labels correspond to time positions during a write cycle as shown in Fig. 2.

restoring force on the garnet magnetization to raise the ferromagnetic resonance frequency. This resulting Faraday current probe has a bandwidth of almost 5 GHz, corresponding to a risetime of 65 ps. The electrical pulse propagation delay along the line separating the Faraday probe and the head itself is approximately 80 ps.

III. RESULTS

An example of the time-domain measurements is shown in Fig. 2. Here, a bipolar current waveform of nominal operating amplitude, ± 61 mA, has been applied to a permalloy head having a 10-turn input coil. The dotted line illustrates the time dependence of the actual write current as sampled by the Faraday probe. The corresponding response of the perpendicular magnetization recorded by the polar Kerr effect is shown by the solid line, measured here for the bottom of the pole tip P2. The 80-ps time shift from the line length between the garnet and the head has been removed in this plot. The data indicate a 1.6-ns time constant for the magnetization change, combined with an apparent 0.7-ns magnetic propagation delay between the arrival of current at the coil and the onset of magnetization change at the pole tip.

The instantaneous spatial dependence of the perpendicular magnetization during the write cycle is acquired by scanning the sample under a laser spot produced by focussing the 585-nm wavelength beam using a 0.6 numerical aperture microscope objective. The resulting spatial resolution is close to the diffraction-limited value of 0.8 μm. This spatial resolution is sufficient to allow us to resolve many interesting position-dependent features in the magnetization, although it is clearly insufficient to resolve all of the detail in the magnetization near the gap. Representative images from a permalloy head taken at four different instants along a time-span similar to that of Fig. 2 are shown in Fig. 3. The shape of the current waveform in this case is the same as in Fig. 2, but the amplitude is now ± 94 mA. The images are three-dimensional renderings in which the topography corresponds to the local perpendicular magnetization. The spatial window is 12 μm on a side, approximately centered on the write gap between P1 and P2. Of particular note is the fact that under these extreme drive conditions, significant differences in the response time at different spatial locations arise, to the extent that there exist instants at which the net perpendicular magnetization has the same phase on both pole tips. A sequence of such images has been stitched together into a "slow-motion" video[9] having an effective frame rate of 20 billion per second. Our interest in strong drive conditions also stems from a desire to use the heads as high-speed field transducers in research applications.

The spatial dependence is further highlighted by the spot measurements of the time dependence of the magnetization at different locations compared in Fig. 4. Very dramatic differences can be observed, for example, by comparing the responses on P2 (solid curve) to those near the far edges of P1 (dot–dashed curve). Even at the nominal drive current of 61 mA one observes very rapid time response on P1 far from P2, approaching the rise time of the current pulse at the coil as determined by the current probe. To some degree this is understandable in that the extremal regions of P1 remain everywhere well below saturation, hence a continuous high permeability path for rapid flux transport is assured. However, by simply reducing the amplitude of the drive current, comparably fast response is not achieved at P2, suggest-

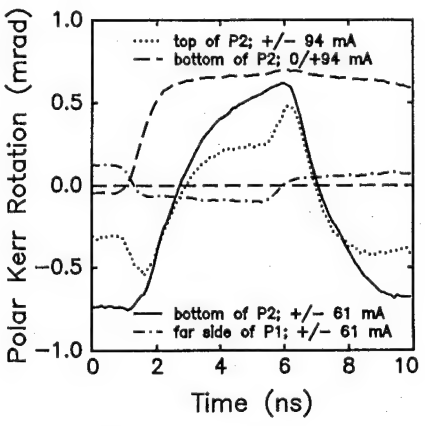

FIG. 4. Time-resolved magnetization measurements at different spatial locations on the pole tips, and for different current pulsing conditions.

ing that eddy currents (perhaps screening currents induced in P1) play a more important role there. Illustrative time-domain observations made using larger drive currents are also shown in Fig. 4. The dashed curve indicates that P2 can be forced from the remanent state to saturation very quickly at a 94-mA drive level with unipolar current pulses. The onset of slow decays of the magnetization from the saturated to remanent states is also made visible by our method in this case. Finally, an apparent nonmonotonic response of the perpendicular magnetization has been observed at the top of P2 (away from the gap; dotted curve in Fig. 4.) The equilibrium magnetization under drive this far from the gap includes a substantial in-plane component, however, and this observation should be complemented with a transverse Kerr measurement. Diffraction effects can also affect the purity of the polar Kerr measurement near the edges of the pole tips, and it would be desirable to repeat these measurements with higher spatial resolution.

IV. SUMMARY

In summary, a picosecond time-domain technique has been described which enables very high-speed measurements of the magnetic dynamics underlying the thin-film inductive write process. A key feature of the technique is the ability to monitor the coil current on precisely the same time axis, yielding direct measurements of magnetic propagation delays in the head. The data therefore contain all of the information that could be obtained in frequency-dependent phase sensitive measurements of the same response.[1,2] The measurements can easily be extended to much shorter time scales through the use of photoconductive switches to generate the current waveforms[8] (producing faster risetimes and eliminating jitter); this will be done as the speed of the technology increases to demand it. In addition, transverse Kerr measurements can be performed to probe the other components of the pole tip magnetization, and external ("media-like") sensors could be incorporated to monitor components of the magnetic field external to the poles themselves.

Stress and magnetic properties in high moment FeN thin films

Kyusik Sin
Center for Research on Information Storage Materials (CRISM), Dept. of Materials Science and Engineering, Stanford University, Stanford, California 94305

Shan X. Wang
Dept. of Electrical Engineering, Stanford University, Stanford, California 94305

Single layer FeN films with low coercivity and low residual stress were prepared on Corning 0211 glass and Si substrates using rf diode sputtering without postannealing. Substrates and a small amount of nitrogen in the film had a significant effect on the magnetic properties and residual stress of FeN films. The residual stress in the pure Fe films showed tensile characteristics due to thermal stress. The stress decreased with increasing N_2/Ar flow ratio and passed a zero point at a flow rate ratio of ~3.5%, accompanied with a low coercivity. The stress changed to compressive with further increasing nitrogen in the lattice. The tensile-to-compressive transition in residual stress can be explained by the increase in lattice constant in FeN films. The lattice constant increased with increasing nitrogen flow during deposition, which was probably due to more nitrogen incorporation in the bcc Fe lattice. © *1996 American Institute of Physics.* [S0021-8979(96)06508-7]

I. INTRODUCTION

In recent years there has been significant interest in ferromagnetic FeN films for head core materials because of their high saturation magnetization which is necessary for writing on media possessing very high coercivity (2500–4500 Oe).[1] It has been reported that high saturation magnetization ($4\pi M_s$=18–22 kG), low coercivity (<1.5 Oe), and low saturation magnetostriction ($<2\times10^{-6}$) can be obtained by the addition of a few percent of N into bcc Fe.[2] However, as-deposited FeN films often possess a large residual stress which causes low adhesion and makes head fabrication process very difficult. The residual stress also produces additional magnetic anisotropy other than induced magnetic anisotropy in the film head structures. The purpose of this article is to report the influence of substrates and N_2/Ar flow rate ratio on the coercivity and residual stress of single layer FeN films prepared using rf reactive sputtering without postannealing.

II. EXPERIMENTAL PROCEDURES

Single layer FeN films, 6000 Å in thickness, were prepared on Corning 0211 glass, (111) Si, and Al_2O_3–TiC substrates using a Perkin–Elmer 4400 rf diode sputtering system. The base pressure of the system was below 3×10^{-7} Torr. The FeN films were prepared from an 8 in. diam Fe target in Ar+N_2 plasma. A total gas pressure of 3 m Torr was used. The N_2/Ar flow rate ratio was varied to control the nitrogen content in the FeN films and to obtain optimum coercivity of the films. A magnetic field of about 50 Oe was applied parallel to the film plane during sputter deposition.

The microstructure of the films was determined using an x-ray diffractometer (θ–2θ scan). The magnetic properties of the films were determined using a magneto-optic Kerr effect M-H loop tracer. The saturation magnetostriction constant (λ_s) was measured using an ac magnetostriction tester. The residual stress in the films was determined from curvature measurements using the laser scanning technique[3] on (111) Si wafers and glass plates before and after film deposition.

III. RESULTS AND DISCUSSION

X-ray diffraction results on 6000 Å thick FeN films on Corning 0211 glass with various N_2/Ar flow ratios are shown in Fig. 1. The films exhibit strong (110) texture of α-Fe when the N_2/Ar flow rate ratio is small. As the N_2/Ar flow ratio increases, γ'-Fe_4N phase is formed and the intensity of γ'-Fe_4N peak increases. One of the interesting results is that the (200) γ'-Fe_4N peak is dominant whereas Wang *et al.* reported that the (111) γ'-Fe_4N peak was dominant in FeN films. The full width at half maximum (FWHM) of the (110) α-Fe peak increases with increasing N_2/Ar flow ratio, indicating a probable decrease in grain size. The decrease in grain size is attributed to the existence of γ'-Fe_4N at the grain boundaries inhibiting grain growth during sputtering.[4]

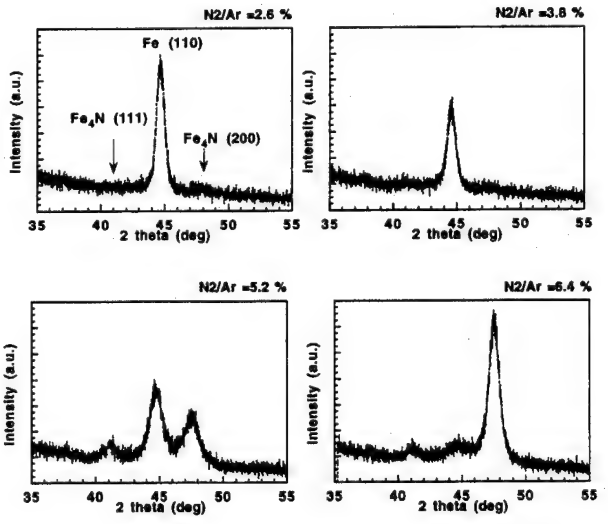

FIG. 1. X-ray diffraction spectra of 6000 Å FeN/glass films sputtered at various N_2/Ar flow rate ratios (input power: 0.64 kW, gas pressure: 3 m Torr).

 0021-8979/96/79(8)/5901/3/$10.00

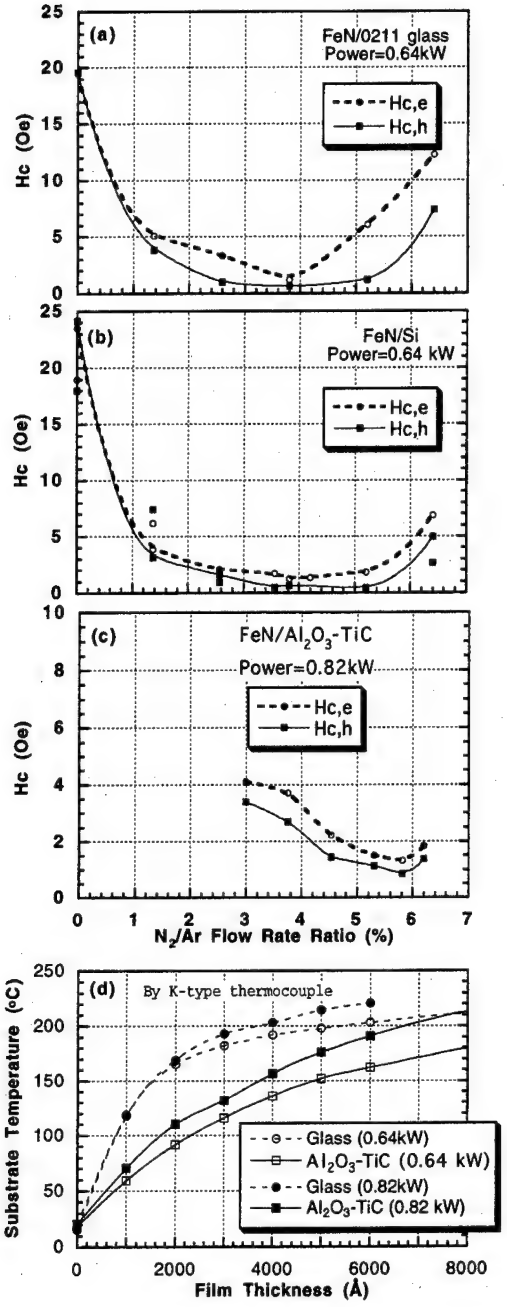

FIG. 2. Effect of N_2/Ar flow rate ratio on the coercivity of 6000 Å FeN films on (a) 0211 glass, (b) (111) Si, and (c) Al_2O_3–TiC substrates. (d) The changes in surface temperature of glass and Al_2O_3–TiC substrates during sputtering.

The coercivity of pure Fe films on glass in Fig. 2(a) is about 20 Oe. As N_2 is introduced, both easy axis coercivity ($H_{c,e}$) and hard axis coercivity ($H_{c,h}$) decrease significantly. At a N_2/Ar flow ratio of 3.8% and an input power of 0.64 kW, the easy axis and hard axis coercivities are 1.2 and 0.6 Oe, respectively. The x-ray intensity of γ'-Fe_4N at the minimum coercivity is very small indicating an optimum amount of γ'-Fe_4N phase for the minimum H_c. Further increases in N_2/Ar flow ratio increase coercivity. The increase in coercivity beyond the optimum N_2/Ar flow ratio might be related to the increase in grain size. The transmission electron microscopy study showed that the average grain size of FeN/glass at 3.8% N_2/Ar flow ratio was about 90 Å. The average grain size increased to about 320 Å at 6.4% due to the formation of a large amount of γ'-Fe_4N.

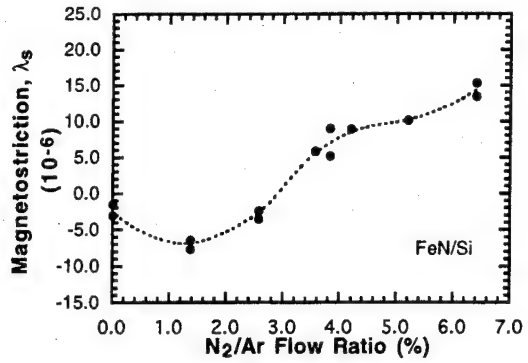

FIG. 3. Effect of N_2/Ar flow rate ratio on the saturation magnetostriction (λ_s) of FeN films on Si substrates.

As shown in Figs. 2(a) and 2(b), both FeN films on 0211 glass and Si substrates show similar coercivities at the N_2/Ar flow ratio of 3.8% and the input power of 0.64 kW. However, FeN/Si have a broader range of low coercivity. In the case of Al_2O_3–TiC substrates [see Fig. 2(c)], the input power was optimized to be 0.82 kW due to the larger thermal mass of Al_2O_3–TiC substrates. Figure 2(d) is the actual surface temperature during sputtering measured using a *K*-type thermocouple attached to the surface of the substrate. The surface temperature of the Al_2O_3–TiC substrate rises very slowly compared with that of glass substrate. The final surface temperature of Al_2O_3–TiC substrate at 0.82 kW becomes close to that of glass substrate at 0.64 kW. The optimum N_2/Ar flow ratio was also shifted from 3.8% to 5.8% due to a larger sputtering rate of Fe at 0.82 kW.

The saturation magnetostriction (λ_s) of the FeN on Si substrates is shown in Fig. 3. The λ_s is negative for pure Fe films as expected.[5] An increase in N_2/Ar flow rate ratio increases λ_s and there is a transition from negative to positive at a flow rate ratio of 2.8%. This behavior is consistent with other results and can be attributed to the increase in the amount of Fe_4N phase in the films[2,6] or incorporation of nitrogen atom in α-Fe lattice.[7] The N_2/Ar flow rate ratio at the zero magnetostriction point was lower than that at the minimum coercivity.

The residual stress in the films on Si substrate is tensile (240–450 M Pa) when the N_2/Ar flow ratio is 0, as shown in Fig. 4(a). It decreases as N_2/Ar flow ratio increases and reaches a zero point at a N_2/Ar flow ratio of ~3.8%, which corresponds to the minimum coercivity. It has a broad range of low stress (<100 M Pa). The sign of residual stress changes to compressive with further increasing nitrogen flow (−330 to −450 M Pa at N_2/Ar of 6.4%). The residual stress of FeN/glass in Fig. 4(b) shows similar profile but with steeper transition from tensile to compressive stress. The profiles of residual stress are well correlated with those of coercivity shown in Figs. 2(a) and 2(b). The residual stress (σ_{total}) is composed of thermal stress (σ_{th}) and internal stress (σ_{int}). The thermal stress is due to the difference in thermal

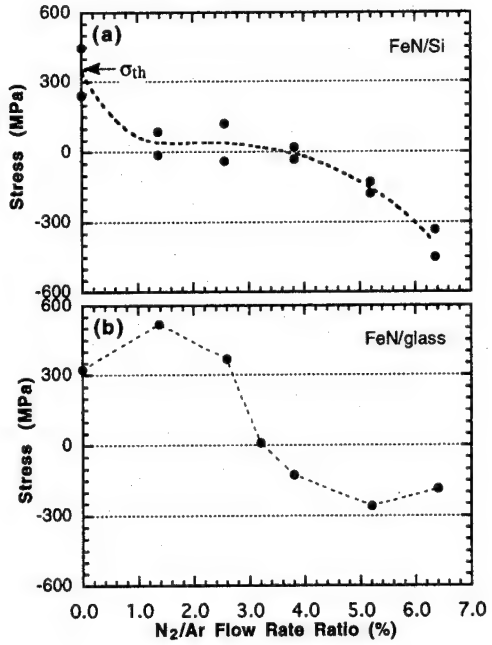

FIG. 4. Effect of N_2/Ar flow rate ratio on the residual stress of 6000 Å FeN films on (a) Si and (b) glass substrates.

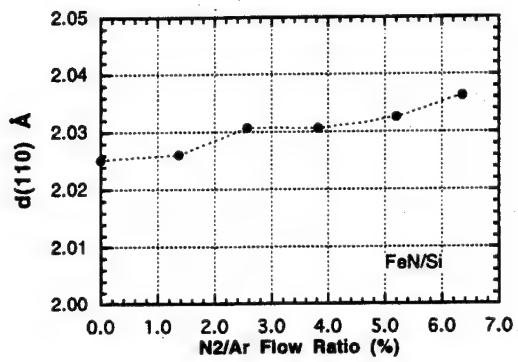

FIG. 5. Effect of N_2/Ar flow rate ratio on the $d(110)$ of bcc Fe in FeN films on Si substrates.

expansion coefficient between the film and the substrate: $\sigma_{th}=E_f(\alpha_f-\alpha_s)\Delta T/(1-\nu_f)$, where E_f is the Young's modulus of the film, α_f and α_s are the thermal expansion coefficient of the film and the substrate, respectively, and ΔT is the temperature difference between the sputtering and room temperature. Assuming that the Young's modulus and the thermal expansion coefficient of Fe do not change significantly with the addition of a few percent of N into Fe, the thermal stress is calculated to be ~360 M Pa (tensile) using $E_{f(Fe)} = 205$ G Pa, $\alpha_{f(Fe)} = 11.7 \times 10^{-6}$ °C^{-1}, $\alpha_{s(Si)} = 2.6 \times 10^{-6}$ °C^{-1}, $\Delta T=135$ °C, $\nu_f=0.3$. Thus, the residual stress at zero N_2/Ar flow rate is caused mostly by thermal stress. The decrease in tensile stress and the transition from tensile to compressive stress are explained by an increase in the lattice spacing of (110) α-Fe planes [$d(110)$]. The peak position of (110) α-Fe was calibrated by the (111) peak of Si. As shown in Fig. 5, the values of $d(110)$ increase with increasing nitrogen flow rate during deposition which results in more nitrogen being incorporated in the interstitial sites of bcc Fe lattice.[8,9] It is to be noted that $d(110)$ still increases even though γ'-Fe_4N is formed in the film. This result suggests that N atoms are still incorporated in α-Fe lattice during the formation of γ'-Fe_4N, resulting in a monotonic increase in residual stress.

IV. CONCLUSIONS

Single layer FeN films with low coercivity ($H_{c,e}=1.2$ Oe, $H_{c,h}=0.6$ Oe) and low residual stress (<100 M Pa) were prepared using a rf diode sputtering without postannealing. Substrate and a small amount of nitrogen in the film had a significant effect on the magnetic and mechanical properties of FeN films. The stress in the films was tensile when N_2/Ar flow ratio was 0. It decreased as the ratio increased and passed a zero point at a N_2/Ar flow rate of ~3.5%. The stress changed to compressive with further increasing nitrogen in the lattice. The tensile-to-compressive transition in residual stress can be explained by the change in lattice constant in FeN films. The lattice constant increased with increasing nitrogen flow during deposition, probably due to more nitrogen incorporated in the lattice.

Effect of base layers on the soft magnetic properties of FeTaN films

V. R. Inturi and J. A. Barnard
Department of Metallurgical and Materials Engineering and Center for Materials for Information Technology, The University of Alabama, Tuscaloosa, Alabama 35487-0202

The effects of base layers with different crystal structures and well defined growth textures on the soft magnetic properties of FeTaN films have been studied. Broadly speaking, base layers with fcc or hcp crystal structures and having predominantly (111) and (0002) growth textures, respectively, significantly improve the soft magnetic properties of the subsequently deposited (110) textured bcc FeTaN films. Base layers with bcc crystal structures and (110) growth textures either degrade the soft magnetic properties or have little effect. © *1996 American Institute of Physics.* [S0021-8979(96)12408-7]

I. INTRODUCTION

In our continuing efforts to improve the soft magnetic properties of high moment (~20 kG) FeTaN films, we have noticed that certain base layers can have substantial beneficial effects. To determine the origin of these effects (assumed to be crystallographic), identically processed FeTaN films of varying thickness have been prepared with and without selected base layers.

In previous work,[1] the effect of N content on the soft magnetic properties of FeTaN films (no base layers) has been systematically documented. λ_s was found to vary linearly with N (negative for zero N but crossing zero and becoming increasingly positive with increasing N). The initial permeability also increased linearly with N up to the onset of stripe domains. H_{ce} varied in a more complex manner, decreasing strongly on initial incorporation of N, then remaining constant over a broad range of N content, finally increasing dramatically as stripe domains appeared. For FeTaN grown without a base layer, processing conditions which produce acceptably small λ_s often do not coincide with those yielding a small enough coercivity and sufficient permeability.

FeTaN films were deposited reactively by dc magnetron sputtering using an Ar and N_2 gas mixture and a 4 in diam Fe—10 w/o Ta target. The base vacuum was $\sim 3.6\times10^{-7}$, the Ar+N_2 total pressure was 3 mTorr, and the power was 220 W. The sputtering rate was ~12 Å/s. All the films were grown in an aligning field of 80 Oe to induce uniaxial in-plane magnetic anisotropy. The substrate materials used were 7059 Corning glass, oxidized Si (111), and oxidized Si (100). Thicknesses were measured by DekTak IIA surface profilometer, coercivity with a SHB 10 Hz loop tracer, saturation magnetostriction with an high precision optical magnetostriction unit, growth texture with a Rigaku D/max-B x-ray diffractometer, and initial permeability with a permeameter. All the base layers were deposited by dc magnetron sputtering using 3 mTorr Ar pressure and 220 W power. All the measurements reported were made on as-deposited films. The saturation magnetization, M_s, for all the films, independent of base layer, was found to be ~1650 emu/cc.

II. RESULTS AND DISCUSSION

Preliminary measurements of the effect of Cr and Ta (bcc), Cu (fcc), and Hf (hcp) base layers on the magnetostriction of FeTaN films are summarized in Fig. 1. The FeTaN films were grown with a fixed Ar+N_2 gas mixture (known to produce good soft magnetic properties in thicker films) and with varying thickness. The base layer thicknesses are fixed at ~1000 Å for this set of films. It is very clear that the base layers having fcc (Cu) and hcp (Hf) crystal structures and close packed plane growth textures [i.e., (111) and (0002)] significantly improve the magnetostriction. Of the two bcc base layers examined Cr, with a (110) texture, clearly increases λ_s while Ta with a complex texture (and a mixture of bct β-Ta and bcc α-Ta phases), has a beneficial effect on thin FeTaN films which does not persist to large thicknesses. The general decrease of λ_s with increasing FeTaN thickness is attributed to a decrease in average N content with increasing thickness as monitored by lattice parameter measurements.[2] Films with lower N content (i.e., smaller d spacing) should have lower λ_s as noted previously.[1]

Based on the clear effects illustrated in Fig. 1, a more systematic study was undertaken using Ti (hcp) and Ag (fcc) base layers (both ~600 Å thick) with well defined growth textures. Figures 2(a)–(c) illustrates the effect of these base layers on λ_s, H_{ce}, and μ_i, all of which are clearly and sig-

nificantly improved (the λ_s values for the no base layer films are slightly lower than those plotted in Fig. 1 because the sputtering conditions were slightly different). Figure 2(a) shows the effects of Ti and Ag base layers on λ_s. Both Ti and Ag substantially reduce λ_s and the beneficial effect persists to 5000 Å films where almost a 50% reduction is observed. The effect of Ti and Ag base layers on coercivity is plotted in Fig. 2(b). Generally, the coercivity decreases with increasing FeTaN thickness. Both base layers improve coercivity but Ti is more effective, reducing the coercivity at 5000 Å by ~50%. Figure 2(c) shows the dependence of initial permeability on FeTaN thickness and the presence of Ti and Ag base layers. μ_i improvement with the base layers is quite remarkable, particularly for Ti, where μ_i is doubled for the 5000 Å films. In summary, by using a 600 Å Ti base layer with strong (0002) growth texture, 5000 Å thick FeTaN films with extremely good soft magnetic properties ($\lambda_s = 0.5 \times 10^{-6}$, $H_{ce} = 0.6$ Oe, $\mu_i = 2000$) can be grown.

Some of these results can be explained by the dramatic effects that the base layers have on the growth texture of FeTaN films. These effects are summarized in Fig. 3 for the case of Ti (similar results were found for Ag but we focus on Ti for clarity). In Fig. 3, θ-2θ x-ray diffraction (XRD) scans (Bragg–Brentano mode[3]) of FeTaN films of varying thicknesses grown using identical sputtering conditions with and without a Ti base layer are plotted along with the XRD scan of the bare Ti base layer. A remarkable improvement in the FeTaN (110) texture which persists up to 5000 Å thickness is caused by the Ti base layer. This can be observed by comparing the FeTaN (110) intensities with and without the Ti base layer. The XRD scan of the bare Ti base layer clearly shows a very strong (0002) growth texture. The effect of Ti on the FeTaN crystallography can be quantitatively described by plotting the FeTaN (110) peak intensity measured in both θ–2θ and fixed incidence (Seemann–Bohlin) modes[3] vs FeTaN thickness [Fig. 4(a) and 4(b)]. In the θ–2θ mode, the (110) intensity is proportional to the fraction of (110) planes parallel to the substrate (the textured portion of the film), while in fixed incidence mode, the (110) intensity is due to those (110) planes not parallel to the substrate. From Fig. 4(a), it is clear that the FeTaN (110) peak intensity with a Ti base layer is several times greater than the FeTaN (110) peak intensity without a base layer. Furthermore, from the intensities obtained in the fixed incidence XRD mode [Fig. 4(b)], one sees that the number of FeTaN (110) planes nonparallel to the surface of the film is significantly reduced by the Ti base layer. Taken together, this is strong evidence that Ti

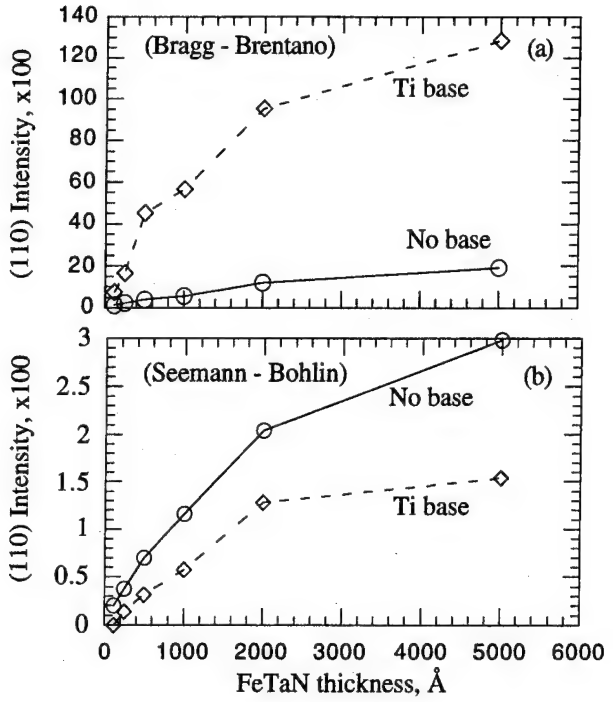

FIG. 4. (110) peak intensity of FeTaN films with and without a Ti base layer in two XRD modes.

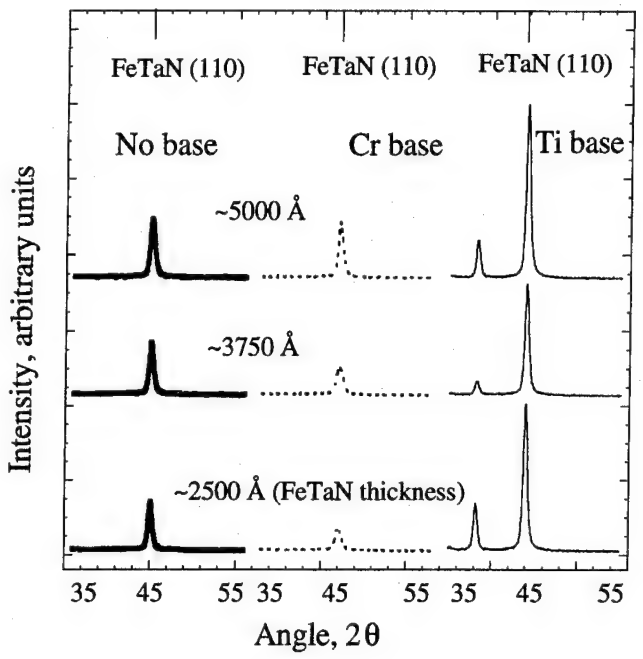

FIG. 5. Comparison plot of θ–2θ XRD scans of FeTaN films with no base layer and with Cr and Ti base layers.

(and Ag base layers, not shown here) strongly enhance the (110) texture of FeTaN films.

Ti base layers do cause an increase of ~25% in FeTaN grain size as determined by full width half maximum (FWHM) measurements of the FeTaN (110) peak. However, the contribution of this grain size increase (which decrease the amount of disordered material having positive magnetostriction[4]) to the change in λ_s is only ~6%.[1] The enhancement of (110) growth texture in FeTaN films may be understood on the basis of standard metallurgical arguments. At interfaces between two crystal structures, orientation relationships are often formed which have the closest packed planes in each structure parallel to the another. For bcc:fcc and bcc:hcp orientation relationships two classical variants are known, Nishiyama–Wasserman (NW) and Kurdjumow–Sachs (KS) which predict (110) bcc‖ (111) fcc [or (0002) hcp].[5,6]

At this point, it is useful to recall that Cr base layers had a deleterious effect on λ_s in FeTaN. This result requires an explanation as there is good lattice matching between Cr and FeTaN and a Cr (110) base layer might be expected to promote FeTaN (110) growth texture. In fact, the opposite is true. In Fig. 5, a series of XRD scans are plotted which clearly demonstrate that the Cr (110) base layer actually inhibits FeTaN (110) texture. Note that the Cr (110) peak overlaps the FeTaN (110) peak and contribute to the observed intensity further demonstrating the deleterious effect of Cr (110) base layer on FeTaN (110) growth texture. The reasons for this phenomenon are not clear at this time.

The improvement of λ_s can be directly attributed to the enhancement of the (110) texture. As calculated earlier,[1,7] (110) textured polycrystalline Fe-based films should have lower λ_s than randomly oriented Fe-based films and the stronger the texture the lower the λ_s. Crystallographic texture may also be at the root of the permeability increase. For Fe–Si alloy films multilayered with permalloy spacers, a strong correlation between improved (110) texture and increased μ_i has been reported.[8] Although it is not surprising that H_c should decrease as the other soft magnetic properties improve, there is no obvious crystallographic origin to this effect.

The Hf-added FeRuGaSi alloy film has an amorphous structure in the as-deposited state and becomes nanocrystalline after annealing. Due to this structure change from crystalline to amorphous by the addition of Hf, soft magnetic degradation of the film deposited on the slant grooved substrate, which is necessary for the sophisticated embedded thin film (ETF) head structure, is greatly suppressed and the undesirable film stress is relieved. The FeRuGaSi-Hf alloy film has higher resistivity and permeability at high frequencies than those of sendust film, and the read/write characteristics of this alloy film show better performance than sendust film. © *1996 American Institute of Physics.* [S0021-8979(96)12508-3]

I. INTRODUCTION

The embedded thin film (ETF) head with a rubbing surface similar to a TSS (tilted sputtered sendust) head and an embedded thin film coil in between the gap, has potential characteristics for high frequency tape recording systems because of its small magnetic core size.[1] The read/write characteristics of this head reflect directly film core permeability. The FeRuGaSi alloy, which has high permeability, high wear resistivity, and high magnetization, is a very attractive candidate for the core material of this head.[2] The thick film deposited on the slant groove substrate, however, gives rise to film cracking/peeling due to the large internal stress accompanied with undesirable growth anisotropy.[3] To overcome these problems, we introduce an additive element to the FeRuGaSi alloy system with the aim of inhibiting the grain growth by annealing. Among the elements studied, we found Hf is the most effective one to reduce film stress as well as to improve high frequency permeability.

II. EXPERIMENT

Thin films were prepared by dc magnetron sputtering method using alloy sputtering target of 100 mm in diameter. The sputtering conditions are 0.5 Pa in Ar gas pressure and 400 W of incident power. The thermal treatment was performed in vacuum without a magnetic field for one hour at a fixed temperature. Coercivity and magnetostriction are measured by a $B-H$ loop tracer. Permeability was measured by a figure-eight-coil permeance tester. The magnetic induction was measured by a vibration sample magnetometer. The x-ray diffractions are measured by θ–2θ method using Co–$K\alpha$ radiation. The transmission electron microscope (TEM) observation was also performed to clarify the film microstructure. The embedded thin film (ETF) head with a FeRuGaSi-Hf film core was fabricated by the same process as the prior study[1] except for thermal treatment at 700 °C before glass molding. Read/write characteristics were measured with a conventional drum tester.

III. RESULTS AND DISCUSSION

A. Magnetic properties

Figure 1 shows the effects of Hf content on the coercivities of $Fe_{74.5-x}Ru_{4.5}Ga_3Si_{18}Hf_x$ alloy films for the annealing temperatures of 600 °C, 700 °C, and 800 °C. All the films were deposited on flat substrates. Coercivities increase with Hf additions up to 3 at. %, while in the region from 3.5 at. % to 5.5 at. %-Hf very small coercivities are observed. Coercivities minima are obtained for the 700 °C annealing. With the fixed contents of 3.5 at. %-Hf and 4.5 at. %-Ru, the compositional contours of coercivity, magnetic induction, permeability, and zero magnetostrictive lines are shown in Fig. 2. All the specimens were annealed at 700 °C. There was no film crack/peeling for all the specimens. Eventually, a coercivity of 16 A/m, permeability of 1700, and magnetic induction of 1.1 T are obtained for the $Fe_{71}Ru_{4.5}Ga_3Si_{18}Hf_{3.5}$ alloy film with a 10 μm thickness.

B. Microstructure

In order to observe the microscopic structure of the FeRuGaSi-Hf alloy film, x-ray diffraction and TEM observation were performed. Figure 3 shows the x-ray diffraction patterns of the various Hf content films for the as deposited state and after annealing ones at 700 °C. The structure of the as deposited films changes from crystalline to amorphous

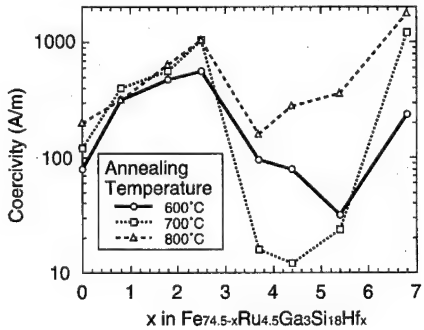

FIG. 1. Hf composition dependence of coercivity for various annealing temperatures.

 0021-8979/96/79(8)/5907/3/$10.00

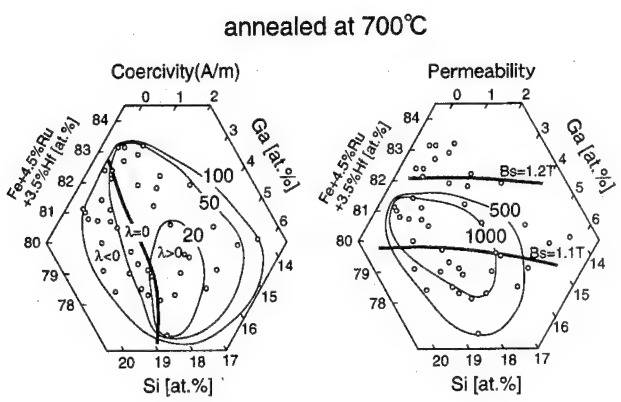

FIG. 2. Compositional contours of coercivities, permeability, magnetic induction, and zero magnetostrictive line.

with increasing Hf content. The annealed film structure becomes nanocrystalline with increasing Hf composition, and crystalline orientation of (110) is remarkably suppressed due to random orientation of the crystallites. In the system with a small Hf content, diffraction peaks of ordered DO_3 phase such as (111) are not observed because of preferred orientation of (110), while in Hf-rich film the DO_3 peaks are recognized.

Figure 4 shows bright field TEM images in the as-deposited film (a) and the annealed ones at 600 °C (b) and 700 °C (c).[4] Hf-free FeRuGaSi film shows enormous crystal growth by annealing, and crystal structure changes from B2 to DO_3 with increasing annealing temperature. For the Hf-added film, on the other hand, only slight crystal growth is observed and the average crystal sizes are 12 and 24 nm for 600 and 700 °C annealing, respectively. The crystal structure of the FeRuGaSi-Hf film changes from B2 to DO_3, which is the same character as in the FeRuGaSi alloy film. Thus, major reasons for the soft magnetic character in the Hf added system are (a) because of the DO_3 ordered phase and (b) due to the nanocrystalline structure.[5]

C. Head characteristics

FeRuGaSi-Hf film is suitable for a magnetic recording head with a slant groove such as an embedded thin film

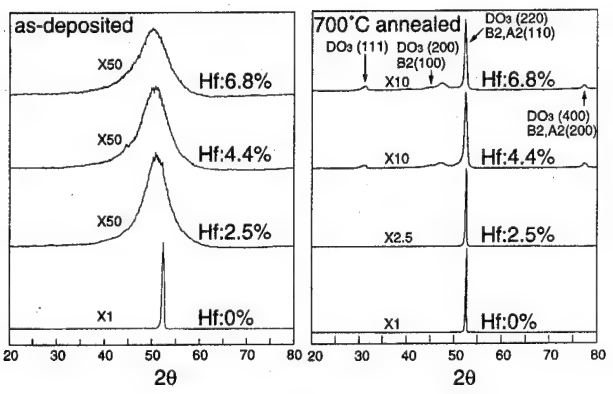

FIG. 3. X-ray diffraction patterns of the as-deposited and annealed films for various Hf contents.

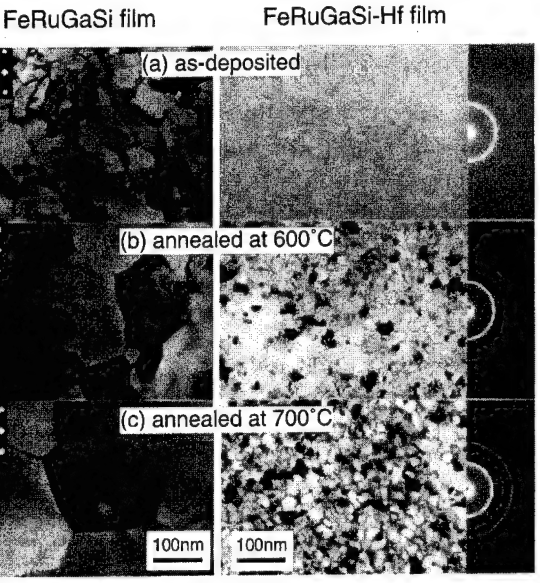

FIG. 4. TEM images for the films of as-deposited (a) and annealed at 600 °C (b), 700 °C (c).

(ETF) head, because the amorphous structure of the as-deposited film can reduce anisotropy by diminishing columnar structure and crystal orientation. A schematic view of the embedded thin film head and its abbreviated manufacturing process is shown in Fig. 5. The permeability of thin film *on the slant grooved part* is measured after glass molding. Figure 6(a) shows frequency dependence of permeability in the Hf-FeRuGaSi film and sendust film with the thickness of 15 μm. FeRuGaSi-Hf film has higher permeability compared with that of sendust film, especially in high frequencies.

Frequency dependence of the reproducing voltage by the read/write measurement is shown in Fig. 6(b) for the ETF head utilizing the sendust film and FeRuGaSi-Hf film. Experimental specifications of the recording measurements are 14 μm in track width, 18 μm in gap depth, 0.2 μm in gap length, 16 turns in coil turns, commercial metal particle (MP)

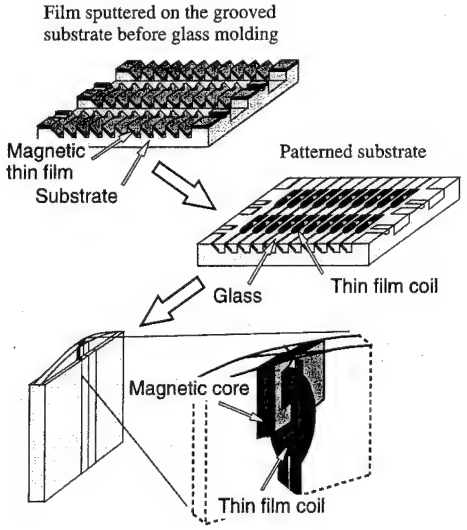

FIG. 5. Schematic view of the embedded thin film head.

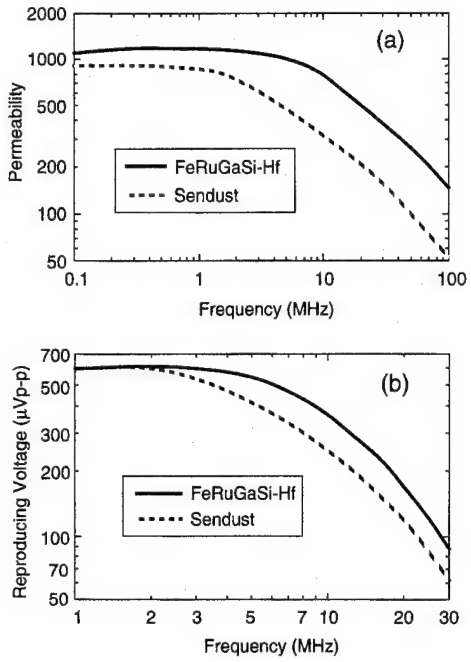

FIG. 6. (a) Frequency dependence of permeability in the FeRuGaSi-Hf and sendust films. (b) Frequency dependence of reproducing voltage in the ETF heads with FeRuGaSi-Hf and sendust films.

tape for a Hi-8 VCR (video cassette recorder), and 10 m/s head-tape speed. Although both the heads have almost the same reproducing voltage at low frequencies, the FeRuGaSi-Hf head show higher output than that of the sendust head at high frequencies. These results correspond to the permeabilities differences of the films.

One of the possibilities for the FeRuGaSi-Hf film having high permeability at high frequencies is considered to be the high resistivity of the film. Film resistivities are shown in Fig. 7 for the as deposited and 700 °C annealed films with various Hf contents. Hf-rich films show higher resistivities of 130–140 $\mu\Omega$ cm after annealing at 700 °C, which is about 40% higher than that of sendust film annealed at the optimum temperature of 600 °C. Improvement of the high frequency permeability, however, cannot be well-explained solely from the resistivity increase. The magnetic flux mostly concentrates on the thin skin depth of the film in high frequencies. The magnetic uniformity of the soft magnetic character of the FeRuGaSi-Hf alloy film, without any initial and surface degraded layer, is better than that of sendust film, because the as-deposited FeRuGaSi-Hf film is amorphous and then crystallized. The flux path, therefore, may be better for the FeRuGaSi-Hf alloy film. The detailed analysis of the high frequency character, including magnetic domain structure, should be subjects for future research.

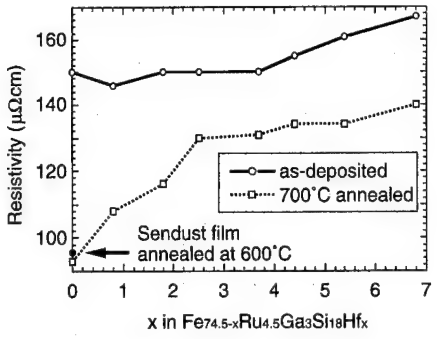

FIG. 7. Hf composition dependence of resistivity.

IV. CONCLUSION

The FeRuGaSi-Hf alloy film shows good soft magnetic properties with a Hf content of 3.5–4.5 at. %. The as-deposited FeRuGaSi-Hf film is amorphous and becomes nanocrystalline after annealing. The origin of magnetic softness is considered due to the nanocrystalline structure as well as the DO_3 ordered structure. The ETF head with this film realized better high frequency recording performance.

Theory, fabrication and testing of dual track complimentary type of thin-film recording heads for perpendicular magnetic recording system

T. Ichihara, S. Nakagawa, N. Matsushita, and M. Naoe
Department of Physical Electronics, Tokyo Institute of Technology, 2-12-1, O-okayama, Meguro, Tokyo 152, Japan

A new type of recording head for a perpendicular magnetic recording system, a dual track complimentary (DTC) type of thin-film head, was proposed in this study. The magnetic core of the head has a "*U*" character shape which is provided with "a pair of" recording tracks and the efficiency to detect flux reversal in the media will become high enough to achieve high linear density. The two-dimensional analysis of DTC heads implied that the perpendicular component of the head field should become larger by using the double-layered media under a narrower spacing condition. Recording characteristics using conventional ring head were evaluated in order to determine the principle of DTC configuration. Several DTC heads were prepared using photolithography technique and their performances were examined. A typical DTC head has inductance of about 500 nH, which is relatively low, and constant up to 10 MHz. DTC heads seems to be one of the most hopeful candidates as the heads useful for perpendicular magnetic recording systems. © *1996 American Institute of Physics.* [S0021-8979(96)06608-3]

I. INTRODUCTION

A perpendicular magnetic recording system with a single pole-type (SPT) head and double-layered thin-film media has a high potential which exceeds the longitudinal magnetic recording systems in both linear and track recording densities.[1] However, the reproducing efficiency is still insufficient because of the relatively opened magnetic circuit system, as shown in Fig. 1(a). We have proposed a new type of recording head for perpendicular magnetic recording system, named as a dual track complimentary (DTC)-type of head,[2] as illustrated schematically in Figs. 1(b) and 1(c). In this system, the magnetic core in the head (the head core) has a "*U*" character shape and it is provided with "a pair of"recording tracks. As shown in Fig. 1(c), the reproducing flux from one pole returns to another pole in the head through the perpendicularly magnetized recording layer and the soft magnetic backlayer of the medium. So the closed short magnetic circuit is formed and the efficiency to detect flux reversal in the media will become high enough to achieve high linear density. Furthermore, both of the poles of the magnetic core are always contacted with the recorded bits, so the head is free from interference of external field. It seems that the track density advantage of perpendicular recording is reduced by a factor of 2. However, if the reproducing output becomes much higher, the total track width will become narrower than the SPT head configuration.

In this study, first a theoretical consideration based on a two-dimensional model was performed to determine the efficiency of DTC head. Secondly, using a conventional ring type of thin-film head, the read/write characteristics in the DTC head-media system were evaluated in order to recognize the recording mechanism of this system. Then, a DTC-type of several thin-film heads were prepared using photolithography techniques and their performances were evaluated.

II. THEORETICAL ANALYSIS OF DTC HEAD CONFIGURATION

It is important to calculate the magnetic field originating from recording heads in order to determine the efficiency of the writing and reading process. Although the magnetic fields of the DTC head should be calculated in three-dimensional analysis, especially in a thin-film-type of DTC head configuration, two-dimensional analysis is convenient to calculate the field more easily. Four assumptions were made for the calculation: (1) the head field can be calculated from magnetic scalar potential V, (2) the head core and the backlayer are perfectly soft magnetic materials with infinite permeability, (3) the thickness of the backlayers is infinite, and (4) the relative permeability of the recording layer is unity. Then, the magnetic potential caused by the head field can be expressed as a two-dimensional Laplace equation. However, this kind of two-dimensional analysis is valid only when there is no change in the field in the third dimension, i.e., the direction along the recording track. The solution, therefore, is only approximation for a thin-film head with DTC con-

figuration. Then, the magnetic force line can be calculated analytically by using a conformal mapping with Schwarz–Christoffel transformation.

Figure 2 shows the magnetic force line distribution around the poles in a conventional ring-type of head derived by Westmijze.[3]

The transformation from w-plane to a z one in the gap region of the DTC head was expressed as follows, using the coordinate as illustrated in Fig. 3(a):

$$z = i\frac{g}{\pi}\log\left(\frac{i\sqrt{P}+t}{i\sqrt{P}-t}\right) - \frac{g}{\sqrt{P}\pi}\log\left(\frac{1+t}{1-t}\right) - g + ih \qquad (1)$$

$$t = \sqrt{\frac{\zeta - P}{\zeta + 1}},\quad \zeta = -\exp\left(-\frac{\pi}{V_0}w\right), \qquad (2)$$

where P is determined by boundary condition. Figures 3(b) and 3(c) show the magnetic force line distribution around the head poles of a DTC head. The pole gap of 20 in Figs. 3(b) and 3(c) was the same with that of the ring head in Fig. 2 and the head-backlayer spacing corresponded to 1 and 0.5, respectively. It has been recognized that the field beneath the poles of the DTC head should be stronger than that of the ring head, as shown in Fig. 2. In addition, the perpendicular component of the magnetic field around the tips of the head is very large and dominant. The perpendicular component of the head field seems to be so appropriate to enhance the writing and reproducing efficiency. Consequently, it was concluded that the DTC head configuration may be very applicable for the perpendicular magnetic recording system using the double-layered media.

III. RECORDING CHARACTERISTICS OF DTC SYSTEM USING CONVENTIONAL THIN-FILM HEAD

A conventional ring-type of head was used to detect written magnetic transitions from the DTC head structure. The moving direction of the head was rotated through 90° from the conventional moving direction, as shown in the insets in Fig. 4. Ba–ferrite floppy disks (type ED) and Co–Cr–Ta/Ni–Fe double-layered thin-film media for perpendicular recording were used for evaluating the recording characteristics. Several parameters of the Co–Cr–Ta media were listed in Table I.

Figure 4 shows the dependence of the reproduced voltage on the motive force of the DTC head configuration at linear recording density of 400 frpi using a conventional

ring-type of thin-film head and Ba–ferrite floppy disk or Co–Cr–Ta/Ni–Fe double-layered media. In both cases, the output voltages were not so high because the conditions of spacing between head and media and the measurement apparatus could not be optimized. Furthermore, it was considered that the perpendicular component of recording field was relatively weak because 0.35 μm of the gap of two poles was too short. However, it was confirmed that saturation recording could be performed using the DTC head configuration and the perpendicular media such as Co–Cr–Ta/Ni–Fe thin-film media.

IV. PREPARATION OF DTC THIN-FILM HEADS

Figures 5(a) and 5(b) show the typical configuration of the DTC head and Fig. 5(c) shows the scanning electron micrograph (SEM) images of the head, respectively, prepared in this study.

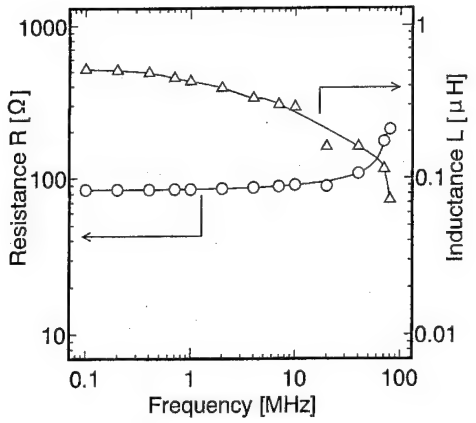

FIG. 6. Change of impedance of head as a function of frequency of 100 kHz–80 MHz.

Ni–Fe thin films for magnetic core layers and Al layers for electric coils were deposited by using the facing target sputtering (FTS) apparatus. Insulating layers were made of photoresist. The fabrication procedure is similar to one for a conventional ring-type of thin film head. However, the upper magnetic pole was not put above the lower pole in order to construct a pair of recording tracks, and then they performed totally as a DTC head.

Figure 6 shows the change of the head impedance as a function of frequency in the range from 0.1 to 80 MHz. The head inductance is relatively low and almost constant up to 10 MHz. These results insist that the heads of DTC configuration can be applicable at relatively high frequency.

V. CONCLUSION

A dual track complimentary (DTC)-type of thin-film recording heads was proposed in this study.

Theoretical calculation implied that the perpendicular component of the head field becomes larger by using the double-layered media under narrower spacing condition. These results suggested that the heads of DTC configuration are suitable to apply for the perpendicular magnetic recording system.

Read/write characteristics using a conventional ring-type of thin-film head and the Ba–ferrite or Co–Cr–Ta/Ni–Fe media implied that the DTC head should be applicable to the perpendicular recording system.

The head composed of Ni–Fe core layers and Al spiral coils has relatively low and constant inductance up to 10 MHz. These results insist that the DTC heads can be applicable at high frequency, which is required for higher recording density and higher transfer rate of data.

In conclusion, the DTC-type of recording heads may be one of the candidates for use in perpendicular magnetic recording systems in the near future.

Shun-ichi Iwasaki
Tohoku Institute of Technology, Sendai 982, Japan

Soft magnetic bilayered microstrip films have been studied for various materials such as Ni–Fe–Mo–Cu, Co–Zr–Mo–Ni, Fe–Si–N, and Ni–Fe in terms of their magnetization dynamics. Effects of the strip width and the interlayer thickness on permeability were investigated. An optimum interlayer thickness was found for obtaining the maximum permeability for those films except Fe–Si–N, but the optimum value differs in magnetic film material. A scanning Kerr effect microscope observation reveals that permeability variations with strip width related to changes of the dynamic domain configurations of the strips. All magnetic film materials except Fe–Si–N show a high permeability of more than 1000 at 2 μm strip width at each optimum interlayer thickness. When the film width is reduced to 1 μm, however, the permeability decreases significantly regardless of the interlayer thickness and kinds of the film materials. For such narrow strip film, a higher permeability is obtained for higher anisotropy field. It is concluded that the shape anisotropy of the micropatterned films must be controlled for achieving a higher permeability. © *1996 American Institute of Physics.* [S0021-8979(96)12608-X]

I. INTRODUCTION

Sliding contact recording is attractive for high density recording because of the minimum spacing loss. A contact recording head such as a single pole head for perpendicular recording or a MR head with a recessed MR sensor is inevitable to have a flux conducting yoke. To improve recording performances, especially, reproducing sensitivity, a very narrow strip-shaped thin film with a high permeability is required for such the yoke. We have recently reported that permeability variation with respect to the strip width is affected by the interlayer thickness for Ni–Fe bilayered strip films.[1] In this paper, microstrip soft magnetic films of various materials of Ni–Fe–Cu–Mo, Co–Zr–Mo–Ni (Ref. 2) and Fe–Si–N have been studied in terms of their permeability and domain magnetization behavior. Such magnetic behaviors of microrectangular films with various aspect ratios are also discussed from the view point-of-head yoke application.

II. EXPERIMENTS

The films were deposited using an rf sputtering method onto Si substrates with an applied magnetic field. The sputtering conditions are listed in detail in Table I along with those for Ni–Fe films[3] deposited by ion-beam sputtering (IBS). The bilayered film was composed of two magnetic layers of 20 nm thick and a nonmagnetic interlayer. The interlayer thickness was varied from 2 to 5 nm, where the bilayered sheet films exhibited no changes in coercivity or anisotropy field, representing no exchange coupling between magnetic layers. A 5 nm thick underlayer and overlayer of the same material as interlayer shown in the table were formed. The sheet film of about 9 mm square was etched by ion milling into an array of strips with different widths keeping a constant strip packing density of 50%. The anisotropy field *Hk* of the film was in the range from 2.5 to 4 Oe.

Permeability in the strip length direction, namely, the hard axis of magnetization in the original sheet film, was measured by an eight-figured coil method with a driving magnetic field of 5 mOe at 10 MHz. Dynamic domain behavior was observed by a scanning Kerr effect microscope (SEKM) with a driving field frequency of 0.5 MHz.

III. RESULTS AND DISCUSSIONS

A. Bilayered strips of moderate width

The strip width dependence of the permeability for the bilayered film is shown in Fig. 1 along with the previous

FIG. 1. Dependence of permeability of bilayered strip films on strip width as a parameter of interlayer thickness.

results in Fig. 1(d) for the Ni–Fe bilayered film. For any of the materials, the permeability decreased as the strip width W decreased from 9000 μm (sheet state) to around 100 μm. For further reduction of the strip width, the permeability undulated and the manner depends on the interlayer thickness b. It is noted that the permeability variation with respect to

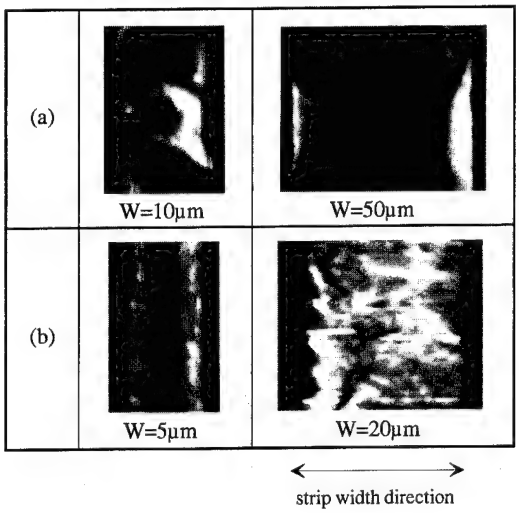

FIG. 2. Scanning Kerr effect microscope images of Co–Zr–Mo–Ni bilayered strip films of width for (a) minimum and (b) maximum permeability.

the interlayer thickness in the region below 100 μm is quite different in the magnetic materials as seen between Fig. 1(a) and Fig. 1(d).

For the Ni–Fe–Mo–Cu bilayered film with Ti interlayer, the permeability changes with the strip width, in the same manner as NiFe film, exhibiting a peak value as shown in Fig. 1(a). However, the strip width for the maximum permeability decreases with increasing interlayer thickness in Fig. 1(a), while it increases in Fig. 1(d). The tendency in Fig. 1(a) was similarly observed for the Ni–Fe–Mo–Cu bilayered films deposited on glass substrates by either ion-beam sputtering or rf sputtering. As reported by the authors,[4] the increase in permeability with decreasing strip width can be explained by the domain configuration transition from the multidomain state to the single-domain-like state, namely the easy-axis state.[5]

On the other hand, the Co–Zr–Mo–Ni bilayered film showed a complicated tendency as shown in Fig. 1(b), where the SiO_2 interlayer was used. For the 2 nm thick interlayer, the permeability change displayed a oscillatory curve according to the strip width exhibiting the minima and the maxima. In order to investigate this phenomenon, Scanning Kerr images of the strips were observed at a driving field of 1 Oe. The results are shown in Fig. 2. The films with minimum permeability exhibited a multidomain configuration accompanied by large domains insensitive to the applied field. To the contrary, although small variation of contrast was observed, the strip films for the maximum permeability responded uniformly throughout the whole strip, similarily to the Ni–Fe–Mo–Cu films and the Ni–Fe films of strip width for the maximum permeability. Therefore, the oscillatory change of the permeability for the Co–Zr–Mo–Ni film is attributed to the domain structure, though the mechanism of change in domain configuration is not clear.

As for the Fe–Si–N films, the permeability decreased monotonically with decreasing the strip width regardless of the interlayer thickness. This may be due to the fact that magnetic interaction between the layers is rather weak owing

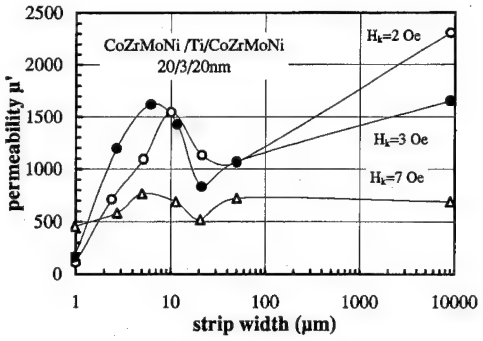

FIG. 3. Effect of anisotropy field on permeability of Co–Zr–Mo–Ni bilayered strip films.

to a relatively high *Hc* of around 0.5 Oe and generally seen large dispersion of anisotropy of the intrinsic sheet film.

B. Very narrow bilayered strips

When a proper interlayer thickness is chosen, the permeability more than 2000 as the same value of the original sheet film could be obtained for the 10 μm width in any film material except Fe–Si–N. However, as the strips become narrower than 10 μm, the permeability rapidly decreases and finally drops to the value as low as few hundred at 1 μm width. According to the edge-curling wall theory by Slonczwski *et al.*[5] and by Ruhrig *et al.*,[6] the easy-axis state changes into the hard-axis state at the critical strip width *Wc*. The calculated values of *Wc* range between 1.4 and 2.1 μm for our experimental *Hk*'s. Therefore, it is easily understood that the lowest permeability was obtained at 1 μm strip width for every kinds of materials. On the other hand, when the anisotropy field *Hk* is increased, the *Wc* should decrease, then, permeability would be improved even for 1 μm strips. Figure 3 shows the effect of the *Hk* on the permeability for the Co–Zr–Mo–Ni bilayered strip films. A Ti interlayer and glass substrates are used in this case. The permeability changes differently from that in Fig. 1(b). As the *Hk* is increased up to 7 Oe, a higher permeability than the previously mentioned strips is obtained for the very narrow strip width of 1 μm. Besides edge-curling wall, other possible origins of the low permeability for 1 μm strip are the increase in coercivity and the localized insensitive domains.[4] For example, the coercivity reaches to about 10 Oe at around 1 μm of the strip width. Therefore, it seems difficult to further improve the permeability for such very narrow long strips by adjusting the material parameters.

C. Aspect ratio of strip

Figure 4 shows the scanning Kerr images for the Ni–Fe–Mo–Cu bilayered strip film which were measured before and after forming the array of rectangular-shaped patterns

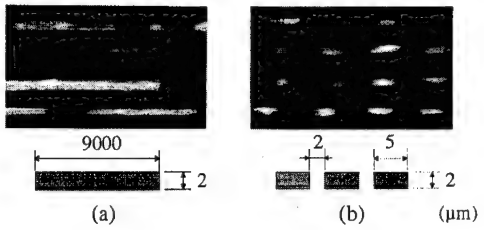

FIG. 4. Scanning Kerr effect microscope images of (a) long strip-shaped and (b) microrectangular Ni–Fe–Mo–Cu bilayered films.

whose size is 2 μm in width and 5 μm in length. It was found that the microrectangular shape films with a small shape anisotropy, whose size is the same order as actual head elements, respond more uniformly to the driving field, comparing with the continuously long strip-shaped films. This has been prospected by the partial response of magnetization for a narrowest film.[4] Therefore, the shape anisotropy of the strip is one of the factors to define the magnetization configurations. It is safe to say that the optimization of the shape anisotropy of the patterned film could give rise to a high effective permeability.

IV. CONCLUSIONS

The permeability of the microstrip bilayered films of Ni–Fe–Cu–Mo, Co–Zr–Mo–Ni, and Fe–Si–N was investigated. An optimum interlayer thickness was found for obtaining the maximum permeability and is determined by the film material itself. When the interlayer thickness was kept at the optimum, similar value of permeability to that for the original sheet film could be obtained except for a Fe–Si–N film. For very narrow and long strips of 1 μm width, it is necessary to increase the *Hk* for a high permeability. Further investigations regarding multilayered strip films with thinner magnetic layers is also necessary. As a highly homogeneous response was obtained for a small aspect ratio pattern, the shape anisotropy has a key effect to improve magnetic sensitivity of the micropatterned film.

Pole tip recession studies of hard carbon-coated thin-film tape heads

Bharat Bhushan and Steven T. Patton
Department of Mechanical Engineering, The Ohio State University, Columbus, Ohio 43210-1107

Ramesh Sundaram and Subrata Dey
Storage Technology Corporation Louisville, Colorado 80028-8110

Hard carbon coatings were deposited by cathodic arc and direct ion beam deposition techniques on thin-film Al_2O_3–TiC heads and by the latter technique on thin-film Ni–Zn ferrite heads. Functional accelerated tests were conducted against metal particle tapes in a linear tape drive. Ion beam carbon coatings on Ni–Zn ferrite and Al_2O_3–TiC heads substantially reduced the pole tip recession observed with uncoated heads. Cathodic arc carbon coated Al_2O_3–TiC heads performed better than uncoated heads, but were less effective than the ion beam coating. Pole tip recession increased only if carbon was removed from the pole tip. This suggests that coating effectiveness is determined by its adherence to the pole tip. In two-wide pole tip heads, wear of the pole adjacent to the substrate was less than that of the other pole. Coatings withstood accelerated tests and may meet life time requirements of future heads. © *1996 American Institute of Physics.* [S0021-8979(96)12708-6]

A major problem in thin-film recording heads is pole tip/gap recession in inductive heads.[1] Pole tip recession (relative wear of the pole tip with respect to the air bearing surface or ABS) and other damage to the head structure, which may result in signal degradation, can be minimized by depositing a thin (~5 to 20 nm) hard carbon coating over the entire ABS, including the head structure.[2–4] Sputter deposited carbon coatings are currently used in MR heads.[3,4] Cathodic arc and direct ion beam deposition techniques are highly energetic processes which are known to produce a dense and hard coating with good adhesion to the substrate.[5,6] Recent screening studies[5,6] have shown that cathodic arc and ion beam carbon coatings are superior in mechanical properties and scratch and wear resistance to sputtered and plasma-enhanced chemical vapor deposition (PECVD) carbon coatings. The objective of this research was to conduct functional tape drive tests with coated dummy Al_2O_3–TiC and Ni–Zn ferrite heads with thin-film head structure.

Al_2O_3–TiC and Ni–Zn ferrite heads (rms=1.5 nm) with IBM 3480/3490 type of construction were selected for this study, Fig. 1. One of the two modules (19 mm×3.8 mm) had the thin-film construction of an inductive write head, whereas the second module was a dummy module. The radius of the modules was 20 mm. Thick films of NiFe were electroplated and Al_2O_3 and thin films of NiFe were rf sput-

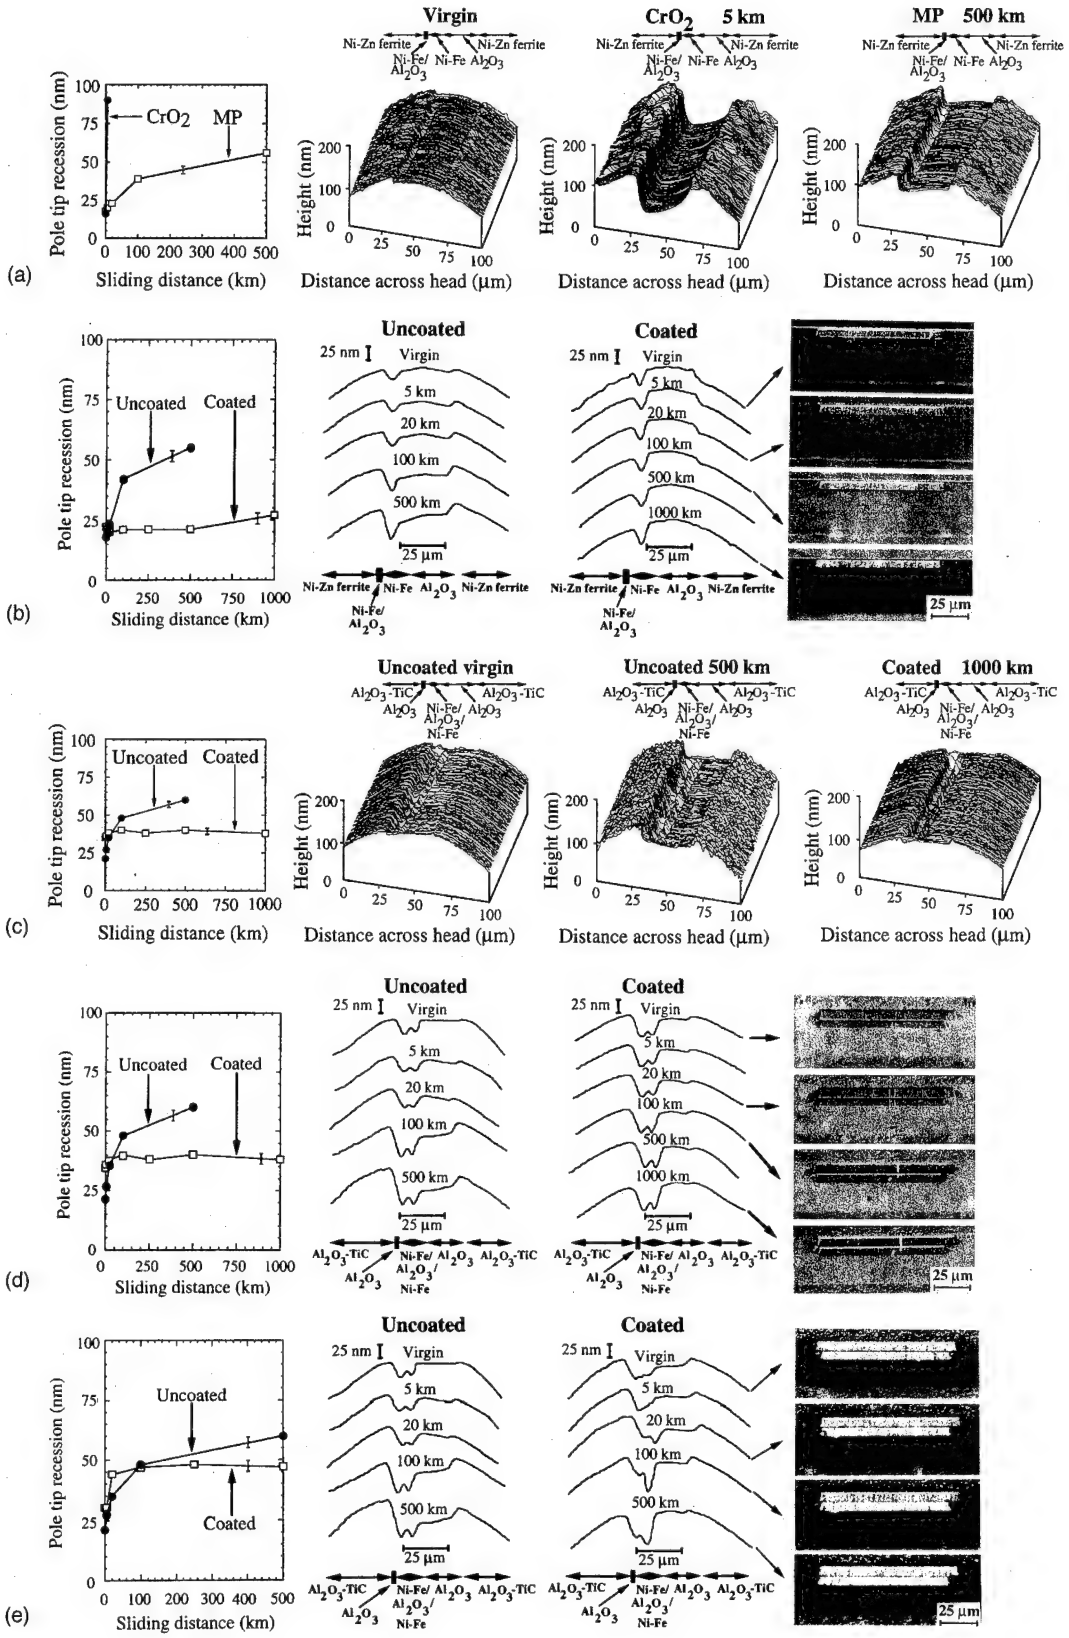

FIG. 3. Pole tip recession vs sliding distance as measured with an AFM. AFM scans across the thin-film structure at various sliding distances and optical micrographs [except (a) and (c)] of the coated thin-film structure at various sliding distances for (a) uncoated Ni–Zn ferrite heads before and after being run against CrO_2 and MP tapes, (b) uncoated and ion beam carbon coated Ni–Zn ferrite heads run against MP tape, (c) and (d) uncoated and ion beam carbon coated Al_2O_3–TiC heads run against MP tape, and (e) uncoated and cathodic arc carbon coated Al_2O_3–TiC heads run against MP tape.

tered. Al_2O_3–TiC heads have two poles with thin-film structure, and Ni–Zn ferrite heads utilize a single pole tip (Fig. 1). The hard amorphous carbon (a–C) (also referred to as diamondlike carbon) coatings with 20 nm thickness were deposited by cathodic arc and ion beam deposition techniques.[5,6] Nanoindentation hardness values of cathodic arc and ion beam carbon coatings are 38 and 19 GPa, respectively, whereas, hardness of commonly used sputtered carbon is about 15 GPa.[5] The critical load required to damage cathodic arc and ion beam coatings in microscratch experiments is more than a factor of two higher than that of the sputtered coatings.[5] The sliding tests on coated heads run against Fuji Atomm double layer video grade (substrate/total thickness $=9.8/13.2$ μm) metal particle (MP) magnetic tapes (rms=4 nm, $P-V=37$ nm)[7] were carried out using a linear tape drive (Honeywell 96) at 1.7 N of tape tension and 3 m/s sliding velocity in an ambient environment (22 ± 1 °C and 45 ± 5% RH) to sliding distances of 500–1000 km.[7] In normal drive operation, the tape wraps 17° over the head and engages one half of the outer bleed slots (Fig. 1), which results in a flying height of less than 100 nm. In these experiments, about 90% of the outer bleed slots were engaged by wrapping the head to increase the minimum film thickness region (which may accelerate wear by particle entrapment) and to increase the friction force (which may accelerate wear). Data in Fig. 2(a) shows an increase in both the friction force and coefficient of friction at large wrap angles. Since at low sliding velocity and high tape tension, the coefficient of friction is higher than that under the condition of entire slot engagement as shown in Figs. 2(b) and 2(c), it appears that air bearing effect is still present at the test conditions.

The pole tip recession was measured by atomic force microscope (AFM) imaging before and after the sliding tests. For recession measurements, the head was placed on a linear stage. A pole on one end was first located in an optical microscope, and then the others were located with respect to that pole. Typically, poles numbered 3, 7, 11, and 15 (out of 1 to 18) were imaged and photographed in this study to account for any variability across the tape width (Fig. 1). Pole tip recession was referenced to the substrate nearest to the pole, and the average was taken over each pole. Pole tip recession for a given condition is the average over the four chosen poles.

Figure 3(a) shows a comparison of the results obtained by running CrO_2 (rms=17.1 nm, $P-V=161$ nm) and MP tapes against uncoated Ni–Zn ferrite heads.[7] CrO_2 tape caused a large pole tip recession and catastrophic wear of the thin-film region after only 5 km of sliding distance, whereas MP tape produced smaller pole tip recession and relatively minor damage primarily in the form of scratching to the thin-film region after 500 km of sliding distance. MP tape was selected since this tape is considered for advanced thin-film head applications.

Figure 3(b) shows a comparison of the performance of uncoated and ion beam carbon coated Ni–Zn ferrite heads during sliding experiments. The pole tip recession increased with sliding distance for the uncoated head, but remained essentially constant over a larger sliding distance for the coated head (error bars in the left block represent the variability in the average pole tip recession over the four chosen poles). The 2D AFM line scans of the uncoated head show that the entire thin-film region recessed from the ABS with increased sliding distance. Optical micrographs of the coated head show that the coating remained on the pole tips through 1000 km of sliding distance which prevented growth of pole tip recession.

Figures 3(c) and 3(d) show a comparison of the performance of uncoated and ion beam carbon coated Al_2O_3–TiC heads during sliding experiments. The pole tip recession increased with sliding distance for the uncoated head, but remained essentially constant over a larger sliding distance for the coated head. The 3D [Fig. 3(c)] and 2D [Fig. 3(d)] AFM line scans show that the coating reduced the growth of recession of the entire thin-film region from the ABS with increased sliding distance as compared to that observed with the uncoated head. Optical micrographs in Fig. 3(d) show that the coating remained on the pole tips through 1000 km of sliding.

Figure 3(e) shows a comparison of the performance of uncoated and cathodic arc carbon coated Al_2O_3–TiC heads during sliding experiments. The performance of the cathodic arc carbon coated head in preventing pole tip recession was better than the uncoated head, but was less effective than the ion beam carbon coating. The 2D AFM line scans and optical micrographs of the coated head show that the coating was removed from the pole farthest from the substrate (bottom pole in optical micrographs) after sliding between 5 and 100 km. Further growth in recession of this pole tip after 100 km observed with the uncoated head did not occur. Further note that wear of carbon coating, when it occurred, was initiated at the pole tips which is related to the adhesion of carbon to various layers present on the substrate. Finally, no loose debris was found on the thin-film region near the pole tips in tests with uncoated and coated heads.

We thank Paul D. Reader of Ion Tech Inc. and S. Anders of Lawrence Berkeley Laboratory for coating of the heads.

Heat capacity measurements of NiO/CoO superlattices (invited) (abstract)

E. N. Abarra, K. Takano,[a] F. Hellman, and A. E. Berkowitz[a]
Department of Physics, University of California at San Diego, La Jolla, California 92093-0319

We present heat capacity measurements of NiO/CoO superlattices grown by reactive sputtering. Neutron diffraction studies of similar superlattices have shown antiferromagnetic ordering through several bilayers despite the short-range nature of the spin interaction in the constituent materials.[1] Specific heat measurements were made using a unique thin film microcalorimeter capable of measuring the heat capacity of thin films from 1.5 K to well above room temperature.[2] We examine the effect of exchange coupling at the interfaces by varying the thickness of the bilayers. For thin bilayers (26 Å), we observe a single broad heat capacity peak similar to a $Ni_{0.5}Co_{0.5}O$ alloy. This peak is at a temperature which corresponds to the superlattice magnetic blocking temperature. For thicker bilayers (>50 Å), two broad maxima occur which approach the individual Néel temperatures of CoO and NiO with increasing bilayer thickness. The ordering temperature of the NiO layers is more suppressed than expected, indicating a more pronounced size effect compared to the CoO layers. The magnetic entropy $S=R(\ln 3+\ln 2)/2$ for the superlattices, within the uncertainties of the measurement, is conserved. We compare the temperature dependences of the specific heats to various models. [S0021-8979(96)43608-2]

Finite-size scaling in thin antiferromagnetic CoO layers

T. Ambrose and C. L. Chien
Department of Physics and Astronomy, The Johns Hopkins University, Baltimore, Maryland 21218

Finite-size scaling effects in CoO, an antiferromagnetic insulator with localized moments, have been observed in CoO/SiO_2 multilayers. The Néel temperatures of the CoO layers, as determined by susceptibility measurements, shows a finite-size scaling relation with a shift exponent of $\lambda=1.6\pm0.1$. © *1996 American Institute of Physics.* [S0021-8979(96)22008-5]

Thin films are suitable media for studying finite-size effects, where the correlation length in the lateral dimensions are not limited but clamped in the direction of the layer thickness. Near the bulk ordering temperature $T_0(\infty)$, the temperature dependence of the correlation length has a power-law dependence of

$$\xi(T)=\xi_0\left[1-\frac{T}{T_0(\infty)}\right]^{-\nu}, \tag{1}$$

where ξ_0 is the correlation length at $T=0$ K, and ν is the critical exponent for the correlation length ξ.[1] From Eq. (1), the ordering temperature $[T_0(t)]$ of a thin layer of thickness t varies as

$$\frac{T_0(\infty)-T_0(t)}{T_0(\infty)}=\left(\frac{\xi_0}{t}\right)^{\lambda}, \tag{2}$$

where λ is the shift exponent for finite-size scaling, $\lambda=1/\nu$, and $T_0(t)$ is less than $T_0(\infty)$.

In a low T_c superconductor where the coherence length is hundred of Å long, a reduction in T_c can be more easily observed in superconducting thin films a few hundred of Å in thickness.[2] For strongly correlated systems, such as ferromagnets, where the correlation length is of the order of atomic spacing, only when the thickness is a few times of ξ_0 would $T_C(t)$ be significantly lower than $T_C(\infty)$. Because of the high Curie temperature (T_C) of common ferromagnets (e.g., Co and Fe with $T_C>1000$ K) and the inability to measure $T_C(t)$ at high temperatures without destroying thin films, $T_C(t)$ can only be measured in ultrathin films only a few atomic layers thick.[3,4] Consequently, there are few such studies reported.

Conspicuously lacking is the studies of finite-size effects of antiferromagnetic (AF) materials, despite the promise of more interesting features because the AF order is realized by compensation of two or more sublattice magnetizations. The studies of AF layer is even more challenging because the AF order with no net magnetization responds only very weakly to the external magnetic field. The only reports of finite-size scaling effects in AF materials have been by indirect determination of the Neel temperature in the FeF_2/ZnF_2 system by thermal expansion measurements[5] and most recently in the Fe/Cr system using transport measurements.[6] In this work, we report the first observation of finite-size effects in CoO, an AF insulator with localized moments, using dc susceptibility measurements.

We have chosen CoO because it is a well-known AF insulator with conveniently accessible $T_N(\infty)$ near room temperature. It has a simple fcc NaCl-type crystal structure with a lattice parameter of $a_0=4.26$ Å. The Co^{2+} moments, with 3.8 μ_B in magnitude, form a fcc lattice.[7] The intrinsically weak response to an external magnetic field requires multilayer samples of CoO with an inert spacer layer. After exploring various materials, SiO_2 was chosen as a space layer, resulting in multilayers with oriented CoO layers. The SiO_2 layers, being insulting, nonmagnetic, and thick (50 or 75 Å), have the added benefit of completely confining the magnetic interactions within the CoO layer. Multilayers of CoO/SiO_2 have been fabricated by multi-source magnetron sputtering using a computer-controlled substrate platform. The CoO layer thickness has been varied from 5 to 125 Å, while keeping the total CoO thickness in the multilayers to be 5000 Å by appropriately controlling the total number of bilayers.

X-ray diffraction data of a representative CoO/SiO_2 sample are shown in Fig. 1. The low-angle data [see Fig. 1(a)] shows many orders of diffraction peaks indicating a good quality multilayer. In the high-angle diffraction, a predominantly oriented film of (100)CoO is observed. The SiO_2 layers are amorphous, with a very broad peak near $2\theta=25°$.

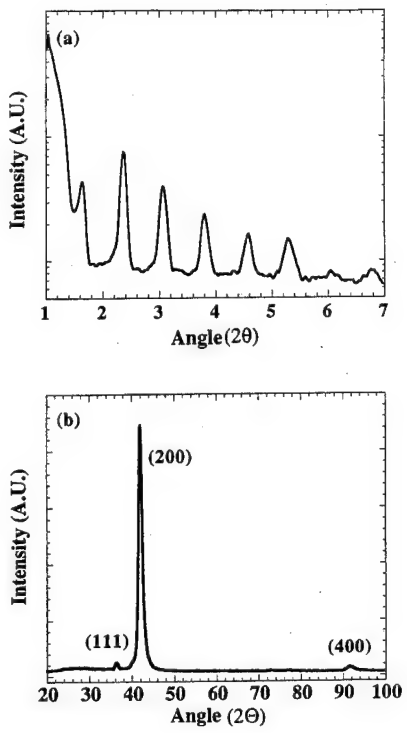

FIG. 1. (a) small-angle and (b) large-angle x-ray diffraction results of a $CoO(65\ Å)/SiO_2(50\ Å)]_{77}$ multilayer.

 0021-8979/96/79(8)/5920/3/$10.00

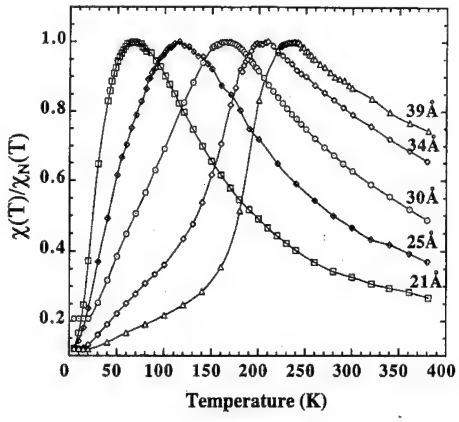

FIG. 2. Temperature dependence of dc susceptibility at $H=100$ Oe of representative multilayer samples of CoO/SiO_2 with a fixed SiO_2 thickness of 75 Å. For clarity, the results are normalized to the susceptibility at the Néel temperature.

Magnetic susceptibility under an external field of $H=100$ Oe has been used to measure the Néel temperature. Although a larger external field would increase the signal, it tends to distort the susceptibility peak, especially for thin CoO layers. Representative results of susceptibility data, normalized to $\chi(T_N)$ for clarity, are shown in Fig. 2. The susceptibility data clearly show that as the CoO thickness (t) is reduced, the susceptibility peak, at which the Neel temperature $[T_N(t)]$ is located, progressively shifts to lower temperatures.

The results of $T_N(t)$ for CoO layer thickness (t) are shown in Fig. 3(a). The values of $T_N(t)$ deviate appreciably from $T_N(\infty)$ for thicknesses $t<80$ Å. The solid curve in Fig. 3(a) is the best-fit results of the finite-size scaling relation[8]

$$\frac{T_N(\infty)-T_N(t)}{T_N(\infty)}=\left(\frac{\xi_0}{t}\right)^{\lambda}, \tag{3}$$

with $\lambda=1.6\pm0.1$, $\xi_0=18\pm2$ Å and $T_N(\infty)=315\pm5$ K. The scaling relation of Eq. (3), as described previously, comes from the critical behavior of the correlation length. It is strictly valid for $T_N(t)$ less than, but close to, $T_N(\infty)$.[8] Nevertheless, Eq. (3) adequately describes the results of a wide range of thicknesses. Only for $t<22$ Å do the values of $T_N(t)$ clearly deviate from the scaling relation. To further illustrate the scaling relation, in Fig. 3(b), a log–log plot of the reduced temperature versus CoO thickness is shown. A straight line with a slope of 1.6 fits the data for $t>22$ Å. Our results also show that AF ordering with $T_N(t)\geqslant5$ K persists down to a thickness of at least 10 Å.

Theoretical studies indicate that the shift exponent has a value of $\lambda=1.5587$ for Ising systems,[9] and $\lambda=1.419$ for Heisenberg systems.[10] Apparently, the value of λ is not sensitive to the types of interactions. Our determined values of $\lambda=1.6\pm0.1$ are in good agreement with these theoretical values.

It should be mentioned that, although there are not many studies of finite-size scaling in magnetic systems, considerable confusion already exists in the scaling relation with which to analyze the data. While many have used Eq. (2), some, unfortunately, have used

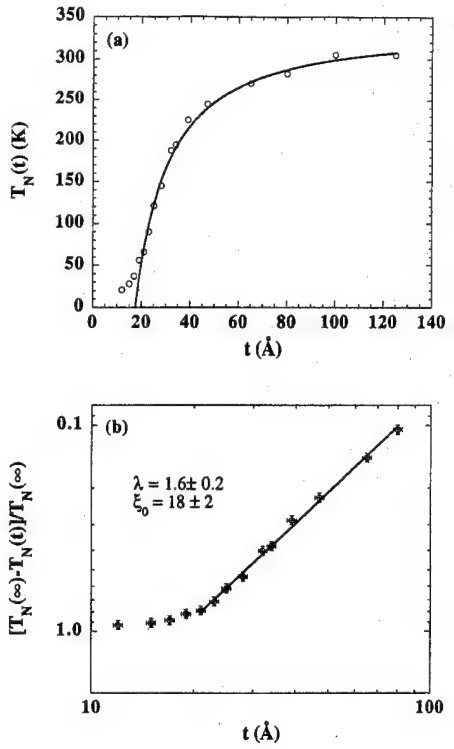

FIG. 3. (a) Néel temperature $T_N(t)$ of CoO/SiO_2 multilayers vs CoO thickness (t). The solid curve is the result of finite-size scaling relation Eq. (3) with $\lambda=1.6$, $\xi_0=18$ Å and $T_N(\infty)=315$ K. (b) Log–log plot of $[T_N(\infty)-T_N(t)]/T_N(\infty)$ vs CoO layer thickness t, where the straight line has a slope of 1.6.

$$\frac{T_0(\infty)-T_0(t)}{T_0(t)}=\left(\frac{\xi_0'}{t}\right)^{\lambda'}. \tag{4}$$

The difference between Eq. (3) and Eq. (4) lies in the denominator on the left-hand side being $T_0(\infty)$ or $T_0(t)$. In Eq. (4), ξ_0' is not the correlation length at $T=0$ K, but the thickness at which $T_N(\xi_0')=T_N(\infty)/2$, and furthermore, one obtains $T_N(t)=0$ *only* for $t=0$. As pointed out previously, data in some thickness range can be reasonably described by *either* Eq. (3) *or* Eq. (4).[11] But the resultant values of λ' and ξ_0' using Eq. (4) are very different from λ and ξ_0 using Eq. (3). This led to the unfortunate confusion of claiming the experimentally determined value of λ' using Eq. (4) to be in agreement, or disagreement, with the theoretical value of λ using Eq. (3). We illustrate this point by fitting the same data in Fig. 3(a) to Eq. (4), and the results are shown in Fig. 4(a). A reasonable fit can *also* be obtained for $t\geqslant15$ Å, as shown by the solid line in Fig. 4(a), although the fit in Fig. 3(a) is clearly better. A comparison of Figs. 3(a) and 4(a) shows that a power-law dependence exists in Fig. 3(b), but less so in Fig. 4(b). However, most importantly, the best-fit values of $\lambda'=3.4\pm0.3$ is very different from $\lambda=1.6\pm0.1$, which is close to the theoretical value. The value of $\xi_0'=30\pm3$ Å is also different from $\xi_0=18\pm2$ Å.

Originally, Eq. (4) was suggested to improve the description of the scaling relationship which showed deviation at smaller thickness range due to nonasymptotic character in the Monte Carlo studies of finite Ising films.[12] It was also found that Eq. (4) can extend the thickness range in which a

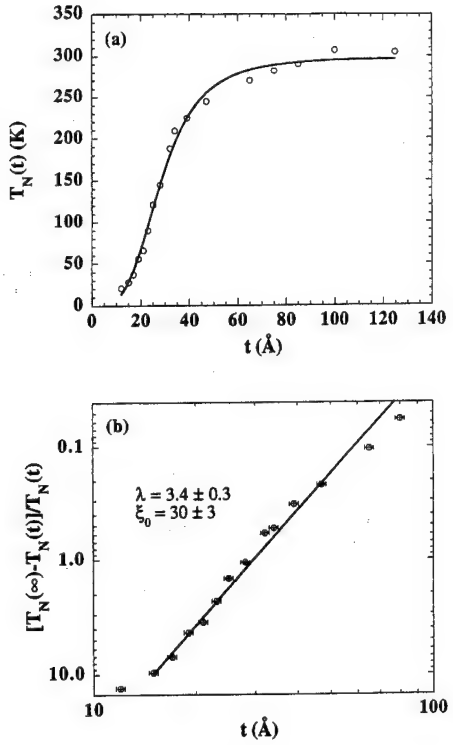

FIG. 4. (a) Néel temperature $T_N(t)$ of CoO/SiO_2 multilayers vs CoO thickness (t). The solid curve is the result of finite-size scaling relation Eq. (4) with $\lambda'=3.4$, ξ_0' = 30 Å and $T_N(\infty)=300$ K. (b) Log–log plot of $[T_N(\infty)-T_N(t)]/T_N(t)$ vs CoO layer thickness t, where the straight line has a slope of 3.4.

single scaling relation can adequately describe the data.[13] This point can be illustrated in the present data. As shown in Fig. 3(a), the data points with $t \leqslant 20$ Å clearly deviate from Eq. (3), whereas practically all data points in the low thickness range can be described by Eq. (4), as shown in Fig. 4(a). However, as mentioned earlier, finite-size scaling is the result of the critical behavior of the correlation length near bulk $T_N(\infty)$. The actual data of $T_N(t)$ in very thin films, much smaller than $T_N(\infty)$, are expected to deviate from the scaling relation.

Finally, we comment on the value of ξ_0. For ferromagnets, ξ_0 is quite small. Observation of finite-size effects are difficult except in ultrathin ferromagnetic films. For spin glasses, ξ_0 is much longer at about 20 Å. Together with a shift exponent of $\lambda=0.64\pm0.07$, finite-size scaling effects can be observed in layers a few hundred Å thick.[14,15] Antiferromagnetic CoO has an intermediate $\xi_0 \approx 18$ Å, exhibiting finite-size effects in CoO films of the order of 50 Å.

In conclusion, we have made, to the best of our knowledge, the first observation of finite-size scaling in CoO, an insulating antiferromagnet with localized moment, using CoO/SiO_2 multilayers. A shift exponent of $\lambda=1.6\pm0.1$, in good agreement with theoretical calculations, has been determined.

We have fabricated and studied the structure and magnetic properties of high quality single crystalline (Mn,Zn)Fe_2O_4, $NiFe_2O_4$, and $CoFe_2O_4$ films. Although (Mn,Zn)Fe_2O_4 and $NiFe_2O_4$ films grown directly on $SrTiO_3$ and $MgAl_2O_4$ show mediocre structural and magnetic properties, these same films grown on $SrTiO_3$ and $MgAl_2O_4$ buffered with $CoCr_2O_4$ or $NiMn_2O_4$ exhibit excellent crystallinity and bulk saturation magnetization values, thus indicating the importance of lattice match and structural similarity between the film and the underlying layer. X ray, Rutherford backscattering spectroscopy, atomic force microscopy, and transmission electron microscopy analysis provide a consistent picture of the structural properties of these ferrite films. © *1996 American Institute of Physics.* [S0021-8979(96)22108-1]

I. INTRODUCTION

There has been much investigation of exchange-coupled biasing as an alternative to the application of a small external field to magnetically saturate thin films. For magnetoresistive sensor or read head applications, a bias field due to an antiferromagnetic layer or a magnetically hard ferromagnetic layer will suppress Barkhausen noise induced by domain wall motion in the adjacent magnetically soft layer. To obtain strong exchange coupling across the interface, one needs a clean interface with minimal strain and roughness. Most magnetic data storage studies of exchange-coupling biasing involve a magnetically soft metallic ferromagnet such as permalloy (Ni–Fe alloy) biased by an antiferromagnet such as a Mn–Fe alloy.[1] The values of the exchange constant deduced from this and similar polycrystalline systems are much smaller than expected, thus suggesting the nonoptimal quality of the interface.

For the fabrication of thin-film inductors, however, metallic ferromagnets such as permalloy are not suitable due to eddy current losses. Low conductivity exchange-coupled magnetic oxide layers are promising for this purpose. There are, however, very few studies of exchange coupling in oxide systems. Notably Wolf *et al.* have investigated CoO/Fe_3O_4 bilayers where CoO is an antiferromagnet with $T_N \sim 295$ K and Fe_3O_4 is a relatively soft ferrimagnet.[2] Exchange biasing in this system is obviously possible only below room temperature. We have studied spinel structure ferrites of $CoFe_2O_4$(CF), (Mn,Zn)Fe_2O_4(MZF) and $NiFe_2O_4$(NF) films, all of which have Curie temperatures well above room temperature. We have optimized growth of single-crystal ferrite films to avoid the high temperatures of 800–1000 °C required in previous work.[3,4] Here we report on the growth of single-crystal MZF, NF, and CF films on CCO($CoCr_2O_4$) and $NiMn_2O_4$(NMO) buffered (100)$SrTiO_3$(STO) as well as (110)STO and (110)$MgAl_2O_4$(MAO) at low temperatures with good crystallinity and magnetic properties approaching bulk values.[5]

II. EXPERIMENTAL PROCEDURE

All films except NF were deposited in a pulsed laser deposition (PLD) system with a KrF excimer laser (248 nm) operating at 10 Hz with an energy density of ~3 J/cm^2 for CCO and NMO and ~4 J/cm^2 for MZF and CF. The CCO films were deposited at 600 °C in 1 mTorr atmosphere of 1% O_2 and 99% N_2. The NMO films were deposited at 600 °C in 1 mTorr of O_2. The MZF and CF films were deposited at 400 °C in a 1 mTorr O_2 atmosphere. The NF films were grown in an off-axis sputtering chamber in a 100 mTorr Ar atmosphere and at 400 °C. The two buffer materials with thicknesses varying from 500–1500 Å promote good crystalline growth of a subsequent ferrite film. We grew ferrite films with thicknesses varying from 700–3000 Å and found no degradation of ferrite crystal quality in this range. The ferrite films discussed in this article are all ~2000 Å thick with buffer layers ~1000 Å thick. Crystal orientation and rocking curve widths were determined by a four-circle x-ray diffractometer with a monochromatic beam and a resolution of ~0.3°. In Rutherford backscattering spectroscopy (RBS), the ratio of backscattering signal of 1.8 MeV $^4He^+$ ions aligned with the [100] direction and along a random direction gives a figure of merit χ_{min} for the crystallinity. Magnetization data were taken on a Lake Shore vibrating-sample magnetometer (VSM) at fields of up to 1.4 kOe at room temperature and on a Quantum Design superconducting quantum interference device (SQUID) magnetometer at fields of up to 5.5 T at room temperature and at 10 K.

III. STRUCTURAL CHARACTERIZATION

Structural characterization of CCO and NMO buffer films on (100)STO reveal the (100) plane to be parallel to the plane of substrate and in-plane alignment of the [001] directions of the buffer and substrate. RBS channeling yields a χ_{min} of 25%–30% for these films. Films grown on (110) STO have a (110) orientation and have the [$\bar{1}$10] direction aligned with that of STO in the plane of the substrate. The full widths at half maximum (FWHM) of the ω rocking curves of the (400) and (440) buffer peaks in the respective films show moderately good crystallinity of $\Delta\omega \sim 1.0°$. Since the spinel lattice constant of the buffer is twice that of the STO substrate, coalescence of neighboring nucleation sites of the

TABLE I. The crystalline quality of three types of (100) oriented ferrite films on (100) $SrTiO_3$ and $CoCr_2O_4$ buffered (100) $SrTiO_3$ as described by the FWHM $\Delta\omega$ of the (400) rocking curve from x-ray analysis and χ_{min} from Rutherford backscattering analysis.

	$(Mn,Zn)Fe_2O_4$		$CoFe_2O_4$		$NiFe_2O_4$	
	Buffered	No buffer	Buffered	No buffer	Buffered	No buffer
$\Delta\omega$	0.9°	2.5°	0.6°	1.3°	0.7°	1.0°
χ_{min}	21%	30%	···	···	18%	35%

buffer on the STO results in antiphase boundaries.[6] These antiphase boundaries give rise to grains on the order of a few hundred Å on a side. To improve the crystalline quality of the buffer, we subsequently annealed CCO and NMO on STO at 1000 °C in air for 30 min. Such an anneal not only oxidizes the sample but also promotes grain growth. Atomic force microscopy (AFM) imaging of annealed CCO on STO reveals typical grains on the scale of 5000 Å. After annealing, rocking curves of the (400) buffer peaks have a much sharper FWHM of $\Delta\omega$=0.5–0.7°. RBS channeling analysis of the buffer layers show a decrease of χ_{min} to 10%–14%, indicating excellent crystallinity. Similarly (110) oriented buffer layers on (110) oriented substrates have improved crystallinity after annealing ($\Delta\omega$~0.7°). A way of avoiding antiphase boundaries is to use spinel structure MAO substrates.

These annealed buffered substrates served as templates to grow spinel structure MZF, NF, and CF ($CoFe_2O_4$) single-crystal films. The buffered substrates gives rise to high quality ferrite films at 400 °C. MZF, NF, and CF grow with the (100) and (110) orientation on (100) and (110) STO substrates, respectively. All three types of ferrite films show excellent crystalline quality as seen from x-ray and RBS analysis. In Table I, the crystallinity of the ferrites buffered with CCO is compared with that of unbuffered ferrites. The buffered ferrites have far better crystallinity than the corresponding unbuffered ferrites as measured by the FWHM of the rocking curves ($\Delta\omega$) from x-ray analysis and χ_{min} from RBS analysis. The similarity of the $\Delta\omega$ and χ_{min} values of the buffered ferrites and underlying buffer indicates excellent epitaxial growth of the ferrites on the buffers. Since MZF films are better lattice matched to NMO than to CCO, the $\Delta\omega$ and χ_{min} values of MZF/NMO/STO ($\Delta\omega$=0.5° and a χ_{min}~16%) are consistently smaller than those of MZF/CCO/STO. However, this difference does not affect any magnetic properties, as shown later. Growth of NF films in a reducing argon atmosphere at 400 °C is incompatible with highly crystalline NMO.

Ferrite films grown on top of buffered substrates have grain sizes on the order of 5000 Å similar to those of the buffer layers. For comparison, we have also deposited MZF, CF, and NF films directly on (100) STO under the same conditions as the above samples. AFM images indicate that grains are less than 100 Å on a side and are consistent with plan view transmission electron microscopy (TEM) images.

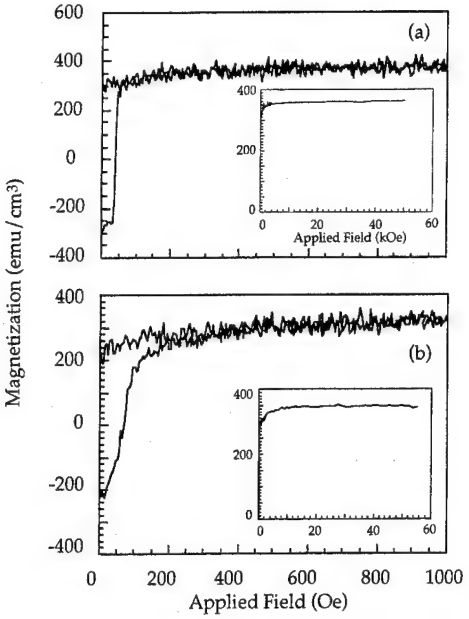

FIG. 1. Magnetization vs field of (100) $(Mn,Zn)Fe_2O_4$ films measured on a VSM up to 1 kOe and on a SQUID magnetometer up to 5.5 T (insets) at room temperature with the field applied parallel to the film surface: (a) on $CoCr_2O_4$ buffered (100) $SrTiO_3$ and (b) on $NiMn_2O_4$ buffered (100) $SrTiO_3$.

IV. MAGNETIC PROPERTIES

Magnetic properties of MZF, CF, and NF films grown on buffered substrates are comparable to those of bulk MZF, CF, and NF. The magnetization loops of (100) and (110) MZF films have saturation magnetizations (M_s) of approximately 320 emu/cm^3 at room temperature. The magnetization of (100) MZF films on CCO and NMO buffered STO was measured on a VSM up to fields of 1 kOe applied in the plane of the substrate [see Figs. 1(a) and 1(b)]. The insets of Fig. 1 are magnetization curves of the same samples measured in the same field configuration on a SQUID magnetometer. The similarity of the magnetization loops of the two films indicates that slight differences in the crystallinity of the films due to buffer layer choice do not affect the magnetization properties. Magnetization loops of (100) MZF films mea-

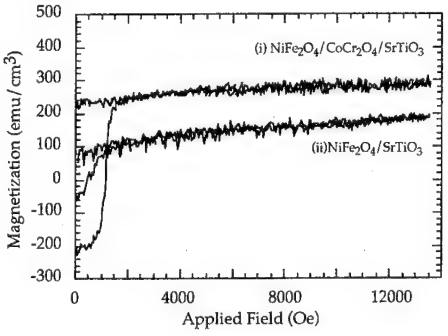

FIG. 2. Magnetization vs field of a (100) $NiFe_2O_4$ film on $CoCr_2O_4$ buffered and unbuffered (100) $SrTiO_3$ with the field applied parallel to the film surface as measured on a VSM. While buffered $NiFe_2O_4$ films reach saturation by ~1 kOe, unbuffered films do not reach saturation even at 5.5 T.

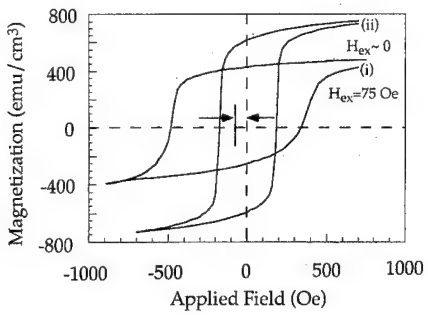

FIG. 3. Magnetization loops of (i) a MZF film on (100) $SrTiO_3$ field cooled in 10 kOe–10 K and (ii) a MZF film on $CoCr_2O_4$ buffered (100) $SrTiO_3$ field cooled in 10 kOe–10 K. The unbuffered MZF film shows an exchange bias field of 75 Oe, thus indicating the presence of regions with antiferromagnetic or glassy properties and exchange coupling across boundaries between ordered and disordered regions.

sured with the field applied parallel to the film surface and in various directions in the plane of the film reveal no easy axes.

NF films on CCO buffered STO show M_s values of 300 emu/cm^3 as compared to bulk values of 270 emu/cm^3 (see Fig. 2). Such a high moment may be attributed to nonequilibrium site occupation quenched into the film. Venzke *et al.* have also observed M_s values greater than that of bulk in NF films homoepitaxially grown on annealed NF films.[7] NF films grown at 600 °C on CCO buffered STO exhibit similar saturation magnetization values; however, their coercive fields are consistently smaller and range from 300–400 Oe. Fewer microstructural defects in the 600 °C samples may present fewer pinning defects and therefore lower coercive field.

Magnetization loops of (100) and (110) CF films on buffered STO and MAO reach bulk M_s values of 400 emu/cm^3. Coercive fields range from 3800–4400 Oe for films grown at 400 °C. Loops of CF on CCO buffered (110) STO and (110) MAO with the field applied in the plane of the substrate reveal an easy axis along the [001] direction. From torque magnetometer measurements, the anisotropy constant of (110) CF films is $K_1 \sim 4.3 \times 10^6$ ergs/cm^3 with the field rotating in the plane of the film. This value is in good agreement with $K_1 \sim 3 \times 10^6$ ergs/cm^3 for bulk CF.[8]

MZF and NF films grown directly on STO and MAO never reach bulk M_s values (see Fig. 2). While buffered NF films reach saturation by ~1 kOe, unbuffered films do not reach saturation even at 5.5 T. In MZF films, x-ray fluorescence spectroscopy indicates similar Zn fractions for MZF films grown with and without a buffer layer. Therefore variations in Zn fractions cannot account for the differences in M_s values of buffered and unbuffered MZF films. MZF films grown on STO and MAO have lattice mismatches of 8% and 4%, respectively. Therefore lattice mismatch and thermally induced strain may give rise to disordered regions in MZF films during low-temperature growth, thus resulting in a reduced M_s. When these MZF films are field cooled in 10 kOe–10 K, magnetization loops show an offset of 75 Oe [see Fig. 3, curve (i)]. This offset is indicative of disordered regions with antiferromagnetic or glassy magnetic behavior and exchange coupling between these structurally and/or chemically disordered regions and crystalline regions of MZF.[7,8] For MZF films grown on buffered substrates, similar field cooled magnetization loops show no offset, indicating a negligible amount of disordered material in buffered MZF films [see Fig. 3, curve (ii)]. In NF films grown directly on STO, a similar effect is seen.[7] Thus we correlate the presence of the offset in field cooled magnetization loops with regions with antiferromagnetic or glassy magnetic properties and with exchange coupling across boundaries between ordered and disordered regions.

We are able to grow CF films on STO with M_s values approaching the bulk values whether or not there is a buffer on the substrate and in spite of measurable differences in the structural quality in the two cases. However, the magnetic properties of MZF grown on top of CF are sensitive to whether the structure is buffered or not and hence to the microstructure. MZF/CF bilayers grown directly on STO have reduced magnetization compared to their buffered counterparts, but nevertheless exhibit exchange coupling.

V. CONCLUSION

In conclusion, we have fabricated high quality single crystalline ferrite thin films of MZF, NF, and CF by using CCO and NMO buffered STO and MAO. The nonmagnetic spinel structure buffer layers are essential in the low-temperature growth of ferrite thin films with magnetic properties approaching the bulk because they take up the strain at the buffer/substrate interface and provide an improved coincidence site in the case of an STO substrate. The resulting films will be suitable for studies of exchange coupling between oxide films, because nearly perfect single-crystal structural integrity occurs at a substrate temperature low enough (400 °C) to preclude interdiffusion at the boundary.

Interlayer exchange coupling in amorphous/crystalline $NiFe_2O_4$ thin-film bilayers

V. Korenivski, R. B. van Dover, Y. Suzuki, E. M. Gyorgy,[a] J. M. Phillips, and R. J. Felder
AT&T Bell Laboratories, Murray Hill, New Jersey 07974

Amorphous/crystalline bilayers of $NiFe_2O_4$ exhibit interlayer magnetic exchange coupling, which results from an interaction between a spin-glass material and a ferrimagnetic material. The observed effect is reminiscent of the well-known exchange coupling effect between an antiferromagnet and a ferromagnet, which is widely used in applications where field biasing of thin magnetic films is desirable. © *1996 American Institute of Physics.* [S0021-8979(96)22208-8]

I. INTRODUCTION

Bulk ferrites are widely used in discrete microwave devices owing to their high magnetization and low electrical conductivity. For integrated planar circuits operating at high frequencies, however, designs based on thin ferrite films are expected to have important applications. Generally, magnetic properties of ferrite films are more sensitive to crystalline disorder than those of metal films, such as permalloy. Studying the relationship between the structure and magnetic properties of thin films is an important step in the realization of planar ferrite devices, and is also potentially interesting for tailoring magnetic properties of thin ferrite films. There have been a number of studies addressing this issue. Booth and Crangle[1] have investigated cobalt–zinc mixed ferrite and found that the magnetic properties of their bulk specimens—low magnetization values with extremely high saturation fields—were consistent with superparamagnetism of strongly magnetic particles of diameter about 4 nm dispersed in a nonmagnetic matrix. Moreover, they found that cooling the samples in an applied field down to helium temperature produced a displaced hysteresis loop characteristic of unidirectional exchange anisotropy, and suggested that this effect may be due to the presence of antiferromagnetic regions at low temperatures. Berkowitz *et al.*[2] prepared $NiFe_2O_4$ in the form of ultrafine particles with an average diameter of 8 nm coated with an organic surfactant and observed a small low-temperature magnetization and very high saturation field. They attributed this behavior to extremely strong pinning of the ferrite surface spins to the organic molecules. Recent studies have revealed similar effects in thin films. Margulies *et al.*[3] argued that the reduced magnetization with only asymptotic saturation observed in their sputtered nickel ferrite films may be due to anisotropy caused by compressive strain normal to the film plane, which results from the film/substrate lattice mismatch present in $NiFe_2O_4$ on MgO. They pointed out, however, that the observed behavior could as well be caused by structural defects. We have previously reported epitaxial growth of $NiFe_2O_4$ films on $SrTiO_3$.[4,5] Films grown at 600 °C consist of small crystalline grains surrounded by thin regions of amorphous material.[5] These disordered regions strongly affect the magnetic behavior, resulting in extremely high saturation fields and giving rise to unidirectional anisotropy when the films are cooled in a field. Postdeposition annealing improves the crystallinity of the films, at the same time reducing the field required for saturation and eliminating the exchange anisotropy at low temperature. The anomalous magnetic behavior was therefore attributed to magnetic interactions between the crystalline and defective regions.[5] In this report we present direct evidence for magnetic exchange coupling between crystalline and amorphous components in nickel ferrite. We observe interlayer exchange coupling in amorphous/crystalline bilayers of $NiFe_2O_4$, which results from an interaction between a spin-glass material and a ferrimagnetic material. However, the exchange anisotropy is absent above 150 K and therefore cannot explain the anomalous magnetic behavior at room temperature reported in Refs. 3–5.

II. EXPERIMENTAL PROCEDURE

The films were deposited by rf magnetron sputtering using a stoichiometric $NiFe_2O_4$ target (see Refs. 4 and 5 for details). The chamber was evacuated to the base pressure of 10^{-7}–10^{-6} Torr, and the sputtering was performed at a pressure of 100 m Torr of argon gas and rf power of 100 W. Silver paste was used to attach the (001)-oriented $SrTiO_3$ substrates to a heated block, which was kept at room temperature for deposition of amorphous films and 600 °C for deposition of crystalline films. The films deposited at 600 °C were postannealed at 1000 °C in air for 3 h to improve their crystallinity and magnetic properties. Our previous structural studies[5] showed that the films deposited at room temperature are amorphous and the films deposited at 600 °C and subsequently annealed at 1000 °C are essentially single crystal with bulklike magnetic properties. Amorphous/crystalline bilayers were formed by depositing at room temperature an overlayer of $NiFe_2O_4$ on the postannealed crystalline films. For the bilayers used in this study the thickness of the single films was 100–150 nm. Amorphous films of 1 μm in thickness were prepared in order to resolve the weak paramagnetic component in the measured dc magnetic moment. Magnetic properties of the films were measured using a superconducting quantum interference device (SQUID) magnetometer in the temperature range of 5–350 K with fields up to 55 kOe. The magnetic field was applied in the plane of the films along the [100] direction. Field-cooled magnetization loops were taken after the films were cooled in 55 kOe from 350 K to a given temperature.

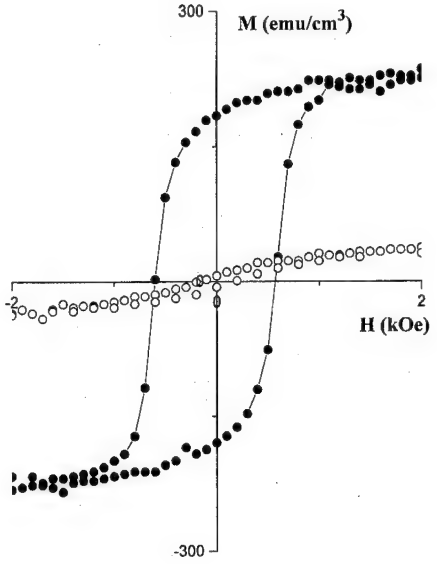

FIG. 1. Magnetization curves recorded at 10 K for crystalline (solid circles) and amorphous (open circles) $NiFe_2O_4$ films.

III. RESULTS AND DISCUSSION

Shown in Fig. 1 are magnetization curves recorded at 10 K for the crystalline and amorphous films (solid and open circles, respectively). The data shown are subsets of the major loops taken with field excursions of ±55 kOe. The saturation magnetization of the crystalline film approaches 270 emu/cc, the bulk $NiFe_2O_4$ saturation magnetization. In contrast, the amorphous film is disordered magnetically and exhibits only ~15% of the bulk saturation magnetization value. Figure 2 shows magnetization loops taken at 10 K for the crystalline film before and after the deposition of the amorphous overlayer. The saturation magnetization is practically unaffected. However, the initially symmetric field-cooled magnetic loop of the crystalline film is found to be offset by

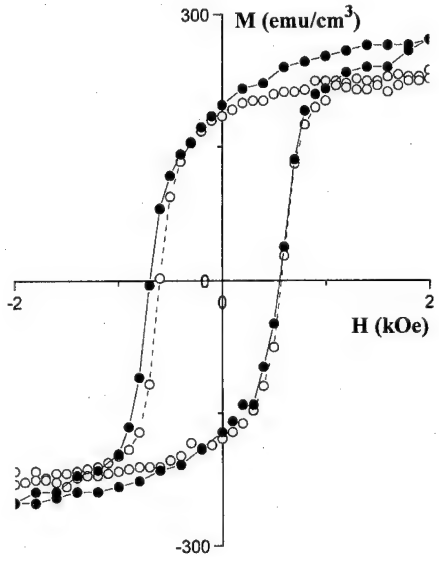

FIG. 2. Field-cooled magnetization curves recorded at 10 K for a crystalline $NiFe_2O_4$ film before (open circles) and after (solid circles) deposition of an amorphous $NiFe_2O_4$ overlayer.

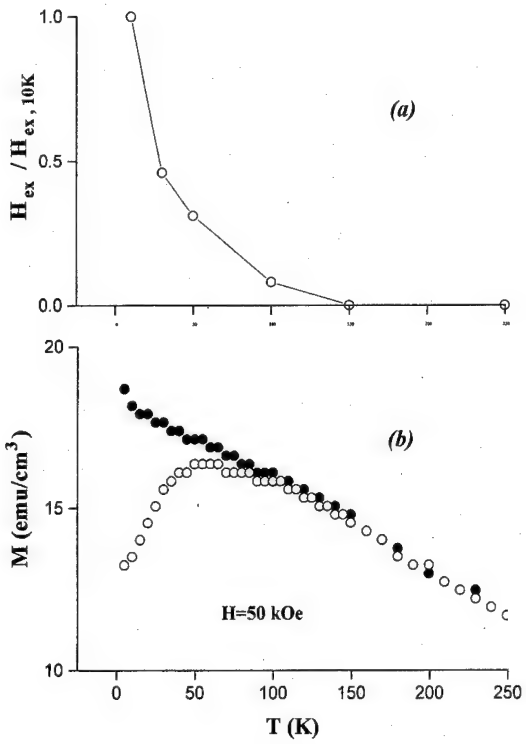

FIG. 3. (a) Normalized exchange field, H_{ex}, vs temperature for an amorphous/crystalline $NiFe_2O_4$ bilayer; (b) zero-field-cooled (open circles) and field-cooled (solid circles) M vs T data for an amorphous $NiFe_2O_4$ film.

~75 Oe after the deposition of the amorphous film, indicating unidirectional magnetic anisotropy caused by magnetic interaction between the layers. This exchange interaction takes place at the interface between the layers and causes the surface spins of the crystalline film to be pinned in the direction of the applied field when the bilayer is cooled to low temperature. For this to occur the amorphous film must be magnetically of antiferromagnetic or spin-glass character, i.e., have "magnetic memory" and retain the spin pattern once cooled below the transition temperature of the antiferromagnetic or spin-glass component. Then the interface spins of the amorphous film aligned by magnetic exchange with the interface spins of the saturated crystalline film would be "frozen in" when the bilayer is cooled through the transition temperature and create unidirectional magnetic anisotropy that would bias the magnetization. Such effect was first reported by Meikeljohn and Bean[6] for an antiferromagnetic/ferromagnetic interface and is now extensively used for field biasing of thin magnetic films. The offset field, H_{ex}, which is characteristic of the strength of the interlayer magnetic exchange interaction, is shown in Fig. 3(a) as a function of temperature. Each data point in Fig. 3(a) represents the displacement in the M-H loop taken after the bilayer was cooled in 55 kOe from 350 K to a given temperature, normalized to the displacement at 10 K. The exchange field differs from zero below ~150 K and increases with decreasing temperature, indicating a magnetic transition in the amorphous component at around 150 K. Antiferromagnetic order is not expected in our amorphous films because of the lack of any crystal structure. Spin-glass behavior, on the other hand, is likely to arise from competing local magnetic interactions

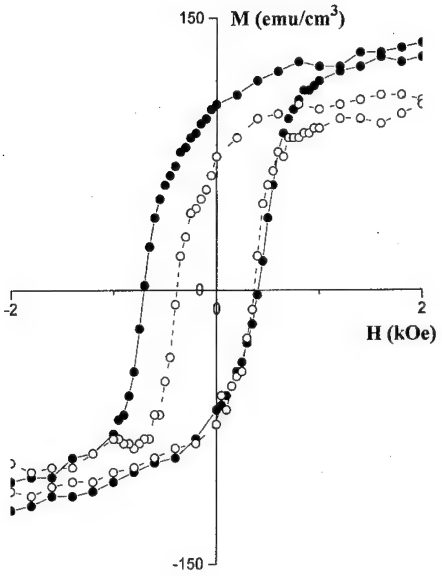

FIG. 4. Field-cooled magnetization loops taken at room temperature (open circles) and 10 K (solid circles) for an amorphous/crystalline $NiFe_2O_4$ bilayer annealed at 550 °C. The magnetization is normalized to the total volume of the bilayer.

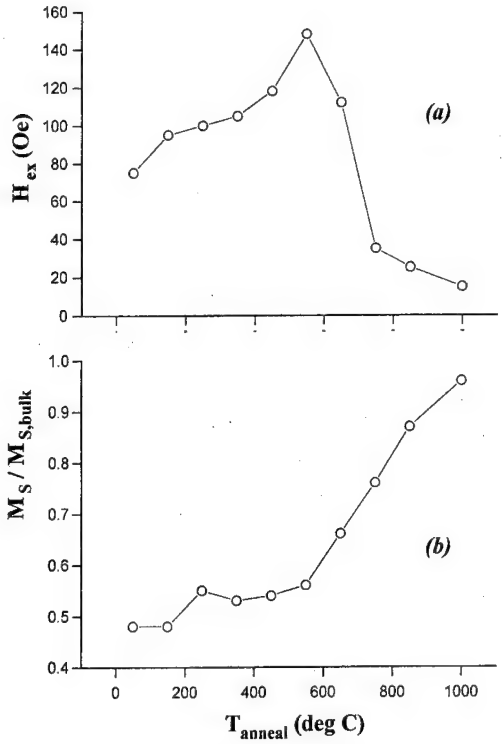

FIG. 5. (a) Exchange field, H_{ex}, and (b) saturation magnetization, M_s, for an amorphous/crystalline $NiFe_2O_4$ bilayer as a function of annealing temperature. The bilayer saturation magnetization is normalized to 270 emu/cc.

as a result of structural disorder. Figure 3(b) shows zero-field-cooled and field-cooled magnetization versus temperature curves for the amorphous film recorded with $H=50$ kOe. The data are typical of spin-glass material. The magnetization exhibits substantial relaxation below ~100 K (not shown), which is also an indication of a spin-glass behavior. The glass transition temperature correlates well with the point where the unidirectional anisotropy starts to be observed [see Figs. 3(a) and 3(b)]. We, therefore, attribute the observed interlayer exchange coupling in amorphous/crystalline bilayers of $NiFe_2O_4$ to an interaction between a spin-glass material and a ferrimagnetic material.

Annealing makes amorphous structure crystallize and is, therefore, expected to eliminate the effect we observe. We have carried out a series of annealing experiments and found that the interlayer exchange coupling increases when the bilayer film is annealed at temperatures below 600 °C. Figure 4 shows the field-cooled M-H loops taken at room temperature and 10 K for the bilayer annealed at 550 °C. The room-temperature loop is symmetric, while the exchange field at 10 K is 150 Oe—double the value of H_{ex} in the as-prepared bilayer. The results of the annealing experiments are summarized in Fig. 5. The exchange field increases with T_{anneal} for $T_{anneal}<600$ °C. This is attributed to improved contact between the ferrimagnetic and spin-glass layers. At higher annealing temperatures the overlayer crystallizes and becomes ferrimagnetic with the bulk magnetization of $NiFe_2O_4$. As this happens, the exchange field quickly decreases to zero.

IV. CONCLUSIONS

We have shown that a significant exchange anisotropy can be obtained in amorphous/crystalline $NiFe_2O_4$ bilayers, which can explain the unusual low-temperature magnetic properties reported previously.[5] However, because the glass transition temperature of the amorphous layer is only ~150 K, the observed exchange anisotropy is not likely the source of the anomalous room-temperature magnetization loops reported in Refs. 3–5. Our results nevertheless demonstrate exchange coupling in a model system relevant to the properties of bulk as well as thin-film oxides.

Polar Kerr-rotation spectra and hysteresis loops have been measured in $Co_{1-x-y}Tb_x(EuS)_y$, with $0 \leqslant x \leqslant 0.21$ and $0 \leqslant y \leqslant 0.21$, and compared to the macroscopic ferrimagnet $Co_{1-y}(EuS)_y$ and to amorphous $Co_{1-x}Tb_x$. The measurements were taken at room temperature and at 7 K over a wide photon energy range of 1.1–4.6 eV in fields up to 2.77 T. The addition of Tb retains the phase-separated nature yielding a material consisting of a Co–Tb matrix containing crystalline EuS precipitate particles with about 2 nm diameter. Up to 8% Tb is substituted for Eu in the EuS phase. The Kerr rotations are rather small reaching $-0.25°$ at room temperature and increasing to $-0.85°$ at 7 K, i.e., no optical enhancement is observed as in Co(EuS). This is most likely due to the much smaller size of the EuS crystallites. An "*s*"-shaped feature in the Kerr-rotation spectra can be assigned to an Eu^{2+} $4f \rightarrow 5d$ transition while a contribution from the Tb^{3+}-$4f$ states shows up as a decrease with increasing photon energies. At 7 K, the Tb and Eu magnetic moments are found to be parallel while the Co moment is believed to be antiferromagnetically exchange coupled to both. At room temperature, the Co moment is dominating the Tb moment which is antiferromagnetically coupled as in $Co_{1-x}Tb_x$. © *1996 American Institute of Physics.* [S0021-8979(96)22308-4]

I. INTRODUCTION

Magnetic thin films are of continuous interest to the scientific community as they have a high technological potential. They are widely used in conventional mass storage devices and—more recently—in magneto-optic data-storage devices. With the discovery of the giant magnetoresistance (GMR) effect in magnetic multilayers,[1] an application of magnetic thin films as a sensor in disk reading heads seems likely in the near future. The fact that the interface plays a crucial role in producing GMR effects has prompted interest in granular or phase-separated systems where the interface-to-volume ratio is increased as compared to multilayers.[2] A new class of such phase-separated materials has recently been found and named macroscopic ferrimagnets.[3] In these materials two magnetic phases couple antiferromagnetically across the phase boundary. An example is $Co_{1-y}(EuS)_y$ consisting of a Co matrix containing crystalline precipitate particles of EuS with 10 nm diameter. Due to a strong magnetic exchange, the Curie temperature of the EuS phase is enhanced to at least 60 K.[3] In addition, these materials exhibit a magnetoresistance effect of 2%.[4] At low temperatures, the thin films show growth-induced perpendicular magnetic anisotropy. At room temperature, the magnetization direction is in plane and an optical-enhancement effect is observed which leads to Kerr rotations up to $-2°$ at 4.5 eV.[5]

We present magneto-optic Kerr spectra of the "ternary" system $Co_{1-x-y}Tb_x(EuS)_y$ where $0 \leqslant x \leqslant 0.21$ and $0 \leqslant y \leqslant 0.21$. The motivation for adding Tb to Co(EuS) is an antiferromagnetic exchange in $Co_{1-x}Tb_x$[6] which leads to a ferrimagnetic compound with a compensation point above room temperature for $x \cong 0.2$. The single-ion anisotropy of Tb causes perpendicular magnetic anisotropy in $Co_{1-x}Tb_x$.[7] A combination of Tb with Co(EuS) promises, therefore, interesting magnetic and magneto-optic effects.

II. EXPERIMENT

Films of 200 nm thickness were prepared by co-evaporation of Co and Tb metal and EuS powder from separate crucibles at a deposition rate of 0.3 nm s^{-1} as described in more detail elsewhere.[3] The fused SiO_2 substrates were cooled to -15 °C by passing helium gas at liquid-N_2 temperature through the substrate support block. The films were characterized by x-ray diffraction analysis and vibrating-sample magnetometry. Polar Kerr-rotation spectra were taken at photon energies ranging from 1.1 to 4.6 eV using a fully automated Kerr spectrometer with an electromagnet allowing fields up to 2.77 T. In order to eliminate possible rotations of optical components within stray fields of the magnet, the rotation of an Al reference mirror was subtracted from the sample rotation at each photon energy. All spectra were measured in both positive and negative fields and then averaged to eliminate rotations of nonmagnetic origin as, e.g., stress-induced birefringence. Reflectivity spectra were taken relative to an Al mirror and corrected for the reflectivity of the Al.

III. RESULTS

The addition of Tb to the macroscopic ferrimagnet Co(EuS) retains the phase-separated nature of the material. X-ray diffraction analysis shows broadened EuS diffraction peaks with full width at half-maximum (FWHM) of 4°. From the peak position, a lattice constant of 5.90 Å for a NaCl structure is derived showing clearly a phase separation between the CoTb phase and EuS precipitate particles. In comparison to Tb-doped EuS films,[8] this indicates that about 8% of the Eu is replaced by Tb. The line broadening, on the other hand, corresponds to a crystallite size of the EuS–Tb

 0021-8979/96/79(8)/5929/3/$10.00

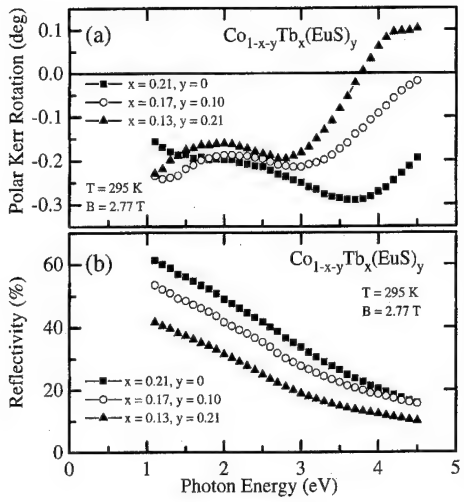

FIG. 1. Polar Kerr rotation (a) and reflectivity (b) at room temperature for $Co_{0.79}Tb_{0.21}$ (■), $Co_{0.73}Tb_{0.17}(EuS)_{0.10}$ (○), and $Co_{0.66}Tb_{0.13}(EuS)_{0.21}$ (▲).

precipitate particles of about 2 nm which is much smaller than in Co(EuS), where a crystallite size of 10 nm has been derived.[4]

In Fig. 1 the polar Kerr rotation (a) and reflectivity (b) spectra at room temperature (RT) are shown in a magnetic field of 2.77 T for three samples, $Co_{0.79}Tb_{0.21}$, $Co_{0.73}Tb_{0.17}(EuS)_{0.10}$, and $Co_{0.66}Tb_{0.13}(EuS)_{0.21}$. The Kerr rotation, θ_K, of the samples containing EuS reaches $-0.25°$. This is considerably smaller than the $-2°$ found in $Co_{1-y}(EuS)_y$.[5] The spectral dependence is rather similar to Co or Co–Tb except for a zero crossing in θ_K above 3.5 eV. For increasing photon energies, the reflectivity of all samples decreases. Contrary to Co(EuS), the reflectivity does not show a pronounced minimum with values less than 10%.[5]

In order to discuss the magnetic properties at RT, polar Kerr hysteresis loops are plotted for three samples in Fig. 2 at a photon energy of 1.5 eV. A striking asymmetry is observed in $Co_{0.79}Tb_{0.21}$ and $Co_{0.73}Tb_{0.17}(EuS)_{0.10}$ violating time-reversal invariance. The loops are shifted along the positive x axis. $Co_{0.79}Tb_{0.21}$ exhibits an additional step at -1 T. The sample containing 21% EuS (c) shows a symmetric loop with just a small coercive field, H_c. All samples have perpendicular magnetic anisotropy at RT.

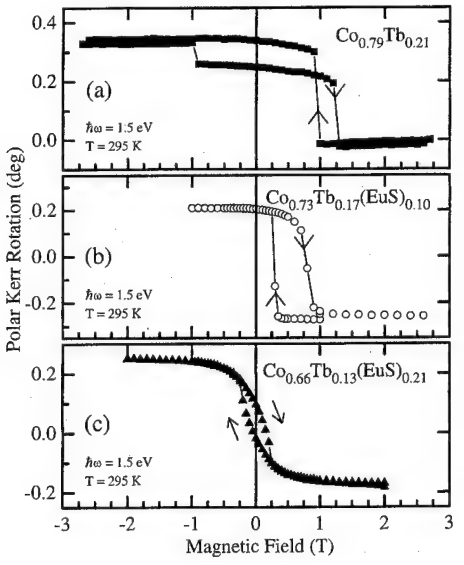

FIG. 2. Polar Kerr hysteresis loops at room temperature for (a) $Co_{0.79}Tb_{0.21}$, (b) $Co_{0.73}Tb_{0.17}(EuS)_{0.10}$, and (c) $Co_{0.66}Tb_{0.13}(EuS)_{0.21}$.

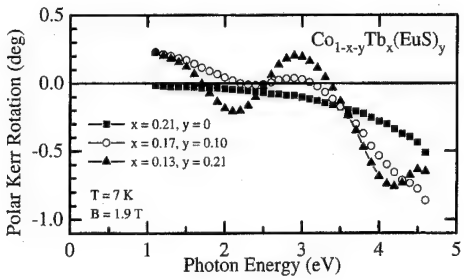

FIG. 3. Polar Kerr rotation at 7 K for $Co_{0.79}Tb_{0.21}$ (■), $Co_{0.73}Tb_{0.17}(EuS)_{0.10}$ (○), and $Co_{0.66}Tb_{0.13}(EuS)_{0.21}$ (▲).

Low-temperature (7 K) polar Kerr-rotation spectra are plotted in Fig. 3. In contrast to the RT measurements, θ_K reaches values up to $-0.85°$. For all samples, an increase in absolute value of θ_K is observed at higher photon energies. This is also true for the $Co_{0.79}Tb_{0.21}$ composition indicating a contribution of Tb-4f electronic transitions. Besides this increase, an "s"-shaped feature is apparent in the (EuS)-containing films, e.g., in a 21% EuS sample a negative peak at 2.1 eV in combination with a positive one at 2.9 eV. A third peak is seen in the 21% EuS sample at 4.2 eV.

IV. DISCUSSION

$Co_{1-x}Tb_x$ is known to be a sperimagnetic material,[6] i.e., the Tb spins couple antiferromagnetically to the Co but scatter about an average direction. The antiferromagnetic exchange leads to a compensation point, T_{comp}, which is for $x \cong 0.2$ above RT. T_{comp} varies rapidly with composition, at a rate of about 50 K/at. %.[9] Near T_{comp}, the total magnetization vanishes and the coercivity, H_c, increases to infinity. The strong asymmetry of the loops in the samples with 0% and 10% EuS can be explained if the films are assumed to be composed of regions with slightly varying composition. Let us suppose a region (A) with T_{comp} near RT. It will be impossible to switch this domain. The neighboring region, say (B), has H_c small enough to be overcome by an applied field. If the regions are exchange coupled they will act like a spin-valve system,[10] i.e., the magnetic moment of (B) will couple to a magnetic sublattice of (A) which is not reversed in an external field since H_c(A) is infinite. From Fig. 2 we can estimate a value of 1 and 0.5 T for the exchange field in the 0% and 10% EuS-doped samples, respectively. In $Co_{0.79}Tb_{0.21}$ there must exist a third region (C) weakly coupled to region (B) in order to explain the partial reversal of the loop at -1 T. The 21% EuS sample has a T_{comp} lower than RT since the Tb/(Co+Tb) ratio is only 0.16 causing finite H_c and a symmetric loop.

Let us now focus on the spectral dependence of the polar Kerr spectra at RT (Fig. 1). In Co(EuS) thin films we had previously found a strong optical-enhancement (OE) effect at 4.5 eV leading to a pronounced minimum in the reflectivity

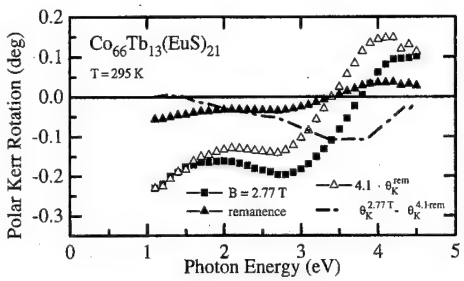

FIG. 4. Polar Kerr rotation at room temperature for $Co_{0.66}Tb_{0.13}(EuS)_{0.21}$ in a field of 2.77 T (■) and in the remanence state (▲). Dash-dotted line is the difference between the 2.77 T spectrum and 4.1 times the remanence spectrum.

spectra and to θ_K values of up to $-2°$ at RT.[5] The OE effect is most likely dependent on the size of the EuS precipitate particles as indicated by model calculations[11] and it will shift to higher energies with smaller particle size. As the size of the EuS particles of 2 nm in the CoTb(EuS) system is much smaller than the 10 nm found in Co(EuS), an OE effect is expected to occur at energies above 5 eV. This would explain the small Kerr-rotation values in the photon-energy range measured. However, the zero crossing in θ_K above 3.5 eV in the EuS-containing samples could hint to the onset of an OE effect at higher photon energies.

At 7 K, the Kerr spectra change considerably, as demonstrated in Fig. 3. In Co(EuS) a strong antiferromagnetic exchange exists between the Co and the EuS phase leading to an increase of the Curie temperature, T_C, of the EuS phase. In the CoTb(EuS) system, we find the signature of the Eu^{2+} $4f \rightarrow 5d$ transition, an "s"-shaped feature with a negative peak in θ_K at 2.1 eV and a positive one at 2.9 eV, in all EuS-containing samples. Another strong evidence for such a transition is the existence of a third peak in the 21% EuS sample at 4.2 eV belonging to the crystal-field split Eu^{2+} $4f \rightarrow 5d(e_g)$ transition. The difference of 2.1 eV is in good agreement with the crystal-field splitting found in EuS.[12] From a comparison of the sign of the feature with EuS spectra,[8] we find that the magnetic moment of the EuS phase is parallel to the applied field. From the Tb/(Tb+Co) ratio, it is evident that at 7 K the Tb moment dominates the Co moment in all three samples. Hence, the Tb and EuS magnetic moments are parallel to each other at 7 K and the Co moment is antiparallel because of the negative exchange between Tb and Co,[6] and between EuS and Co.[3] This interpretation is corroborated by a positive θ_K at low photon energies in the 10% and 21% EuS samples. At these energies, merely Co transitions contribute to θ_K.[3]

In Fig. 4 the polar Kerr spectra at RT is plotted for the sample with 21% EuS in a field of 2.77 T and in the remanence state. Using the argument that at low photon energies only Co transitions contribute to θ_K, the remanence spectra is multiplied by a factor of 4.1 (Δ) in order to overlap with the 2.77 T spectra at low photon energies. Subtracting the two spectra (dash-dotted line) eliminates the Co contributions and shows a continuous decrease with increasing photon energies reaching a minimum at 3.8 eV. Comparing this to the spectra at 7 K, we find that the $Co_{0.79}Tb_{0.21}$ sample exhibits a similar energy dependence, except for the minimum, indicating that the difference is mainly due to Tb-$4f$ transitions. Photoemission studies find the location of the Tb-$4f$ states in Tb–Fe at 3 eV below the Fermi energy.[13] In conclusion, the Co moment is dominating at RT, leading to a negative θ_K, as seen in Co metal, and the Tb moment is antiferromagnetically coupled to the Co. Applying a magnetic field will drag the Tb spins toward the field direction, breaking the coupling.

What can we say about a contribution of the EuS phase to θ_K at RT? A close look at Fig. 4 reveals a positive peak at 2.0 eV and a negative peak at 2.8 eV in the high field and the remanence spectra. This is opposite in sign to the spectrum at 7 K (see Fig. 3) suggesting that the EuS magnetic moment is antiparallel to the field at RT indicating a strong antiferromagnetic exchange to the Co. This implies that T_C of the EuS phase is enhanced up to RT. An alternative explanation is that the feature is due to the Co contribution. The Kerr spectrum of Co metal has a shallow minimum at 1.5 eV and a maximum at 2.7 eV. Since θ_K is dependent on n and k (index of refraction and absorption), the shallow features of the Co contribution could shift due to a change in n and k.

Laboratoire des Matériaux Isolants, Magnétiques et Semi-Conducteurs, CNRS, EP95, 92195 Meudon, France

The Faraday rotation of epitaxial garnet films of composition $\{R_{3-x}Bi_x\}[Fe_2](Fe_3)O_{12}$ with R=Dy, Y, and high Bi content ($x \cong 1.30$) has been measured in the temperature range 10 K$<T<$600 K at λ=1155 nm. The analysis of the data in terms of the sublattice magnetization reveals a strong contribution of the {Dy} sublattice. The "electric" dipole Faraday rotation per Dy ion has been determined and compared to its value in the bismuth-free dysprosium garnet. It turns out that Bi gives rise to a pronounced enhancement of this contribution. This result is compared with that observed for other Bi-substituted rare-earth iron garnets in the visible band. © *1996 American Institute of Physics.* [S0021-8979(96)22408-0]

I. INTRODUCTION

The garnet system allows on its three nonequivalent crystallographic sites a great variety of cation species of different valences.[1] Among these different substitutions in rare-earth iron garnets (REIG), diamagnetic Bi^{3+} and Pb^{2+} ions and some lighter rare-earth ions like Ce^{3+}, Pr^{3+}, and Nd^{3+} strongly enhance the magneto-optical (MO) activity in the wavelength range 0.4–2 μm (see Refs. 2–4 and references therein). Since the observation of large Faraday rotation (FR) without a noticeable increase of the optical absorption, there has been much work devoted to the fundamental properties of bismuth-doped iron garnets. On the other hand, these materials have been expected to be promising materials for different MO devices, especially in magneto-optical recording.[5,6]

Relevant investigations of garnet films of composition $Y_{3-x}Bi_xFe_5O_{12}$ reported earlier in the literature have been performed in the visible range by Hansen *et al.*[7] We have extended such experiments to the infrared range (λ=1150 nm) in order to confirm that the Bi ions stimulate the MO activity of the Fe^{3+} ions at both the octahedral and tetrahedral sites of the garnet.[4] At λ=633 nm, the studies of the MO properties of various Bi-substituted rare-earth iron garnets have led to the following conclusion: the bismuth affects the iron transition only, the enhancement of the iron contribution to FR being independent of the nature of the rare-earth ion.[8]

In this article, we intend to probe the intrinsic MO properties of garnet films of composition $Dy_{3-x}Bi_xFe_5O_{12}$ and $Y_{3-x}Bi_xFe_5O_{12}$ for $x \cong 1.30$ at λ=1155 nm and to quantitatively analyse the effect of bismuth presence on the MO activity of the Dy^{3+} ion.

Note that prior to this work, the FR of single crystals of $Dy_{3-x}Bi_xFe_5O_{12}$ and of $Tb_{3-x}Bi_xFe_5O_{12}$ was studied for $x=0.42$.[9,10]

We have sought to increase the amount of Bi using epitaxial thin films, the Dy^{3+} ion being chosen because of its large magnetostriction constant which induces a positive uniaxial anisotropy favorable for MO recording.

II. EXPERIMENT

Garnet films of composition $Y_{3-x}Bi_xFe_5O_{12}$ (YBiIG) and $Dy_{3-x}Bi_xFe_5O_{12}$ (DyBiIG) were grown by liquid phase epitaxy onto (111) oriented cation-doped gadolinium gallium garnet ($Gd_3Ga_5O_{12}$) substrates with a lattice parameter equal to 12.498 Å. A $PbO/Bi_2O_3/B_2O_3$ based flux was used, the Bi content being controlled by the growth rate to adjust the lattice mismatch. The growth temperatures ranged between 1000 and 1200 K and the thicknesses of the films between 5.9 (YBiIG) and 12.9 μm (DyBiIG) within an accuracy of $\pm$1%. X-ray diffraction studies confirmed the high crystalline quality of the films. The lattice constants being equal to 12.493 Å (YBiIG) and to 12.497 Å (DyBiIG), the misfits Δa are small. The film compositions were determined by electron probe analysis, the amount of Bi achieved in the two preparations was 1.30$\pm$0.03 (YBiIG) and 1.27$\pm$0.03 (DyBiIG). Note that the measured "a" lattice constant data are in very good agreement with the values calculated from the ionic radii using the previous composition determinations.[11] On the other hand, the amount of lead entering the crystals as an impurity is negligible.

Using polarization modulation techniques, very accurate FR measurements have been performed at 1155 nm wavelength in the 10–610 K range and under magnetic field along the direction [111] up to 20 kOe. Special attention was paid during the experiments to eliminate the influence of internal reflections and multilayer structures on the measurements.[12,13]

The crystallographic symmetry of pure and bismuth-substituted garnets is usually described by the cubic space group O_h^{10}–Ia3d. Within the general formula $\{RE_3\}[Fe_2](Fe_3)O_{12}$, the trivalent RE (and Bi) ions are dodecahedrally coordinated (24c) with O^{-2} ions while the iron ions occupy two different sites: octahedral (16a) sites and tetrahedral (24d) sites. The magnetic properties are interpreted in terms of a ferrimagnetic arrangement of the three corresponding sublattice magnetizations M_c, M_a, and M_d.[14] M_d and M_a are strongly coupled antiferromagnetically and M_c is antiparallel to the resultant Fe^{3+} magnetization. In heavier rare-earth garnets the macroscopic garnet magnetization which is given by $|M_c - M_{YIG}|$ vanishes at the compen-

sation temperature T_{comp}. In pure DyIG, T_{comp} is equal to (223 ± 1) K.[15] The iron garnets are known to present a large circular magnetic birefringence in the infrared and in the visible part of the spectrum as reviewed by Dillon.[16]

The FR is induced by the electric and magnetic dipole transitions and is proportional to the three sublattice magnetizations as discussed by Cooper and his co-workers.[17,18]

III. RESULTS AND DISCUSSION

The isothermal variations $FR_T(H)$ present a linear magnetic field dependence whatever the temperature (Fig. 1), and the spontaneous Faraday rotation, FR^S, defined as the FR associated with the spontaneous ferrite magnetization, was immediately deduced using a least-squares refinement technique.

The temperature dependences of the FR^S that are displayed in Fig. 2 confirm that the MO properties are strongly affected by the bismuth incorporation. The Curie temperature was found to be (600 ± 5) K for the two films in accordance with magnetic and MO measurements performed at $\lambda=633$ nm on bismuth-substituted yttrium iron garnets.[19] These data lead to a change $\Delta T_c/x$ of 34 K/Bi formula unit in thin films, while in a crystal the increase in T_c was evaluated to be 38 K.[20] In the YBiIG film, FR shows an important increase towards a large negative value (for bismuth-free YIG, the FR is equal to 250 deg cm^{-1} and is only weakly temperature dependent); the contribution $\Delta FR^S/x$ at 4.2 and 300 K is -3060 and -2460 deg cm^{-1}/Bi/f.u., respectively. Note that the MO intrinsic efficiency of Bi is not exactly proportional to the Bi content since for $x\leqslant0.6$, $\Delta FR^S/x$ was observed to be equal to -3200 and -2600 deg cm^{-1}.[4] This effect of saturation was not observed in the visible band,[7] where FR is about 10 times larger than in the infrared.

The absolute value of FR^S of DyBiIG film is smaller than that of the YBiIG film at $T<400$ K (see Fig. 2), indicating that the contribution of the Dy^{3+} sublattice is large as it is observed for bismuth-free dysprosium iron garnet.[15] A compensation temperature T_{comp} of the spontaneous FR occurs at (110 ± 5) K, causing a change of sign of FR^S. Note that in Fig. 2, we have changed the sign of FR^S values measured on YBiIG films to respect the change of orientation of the iron sublattices in DyBiIG at T_{comp}. Furthermore, it should be pointed out that the Bi free DyIG exhibits a higher T_{comp} value $(220\pm2$ K). The shift of T_{comp} towards lower temperature with increasing bismuth content ($T_{comp}=178$ K for $x=0.43$[9]) results from the presence of diamagnetic Bi^{3+} ions in the $\{c\}$ sublattice.

The contribution to the Faraday rotation of DyBiIG by iron ions is well represented by that of BiYIG measured in the same experimental conditions.[20] The total contribution to FR of the Dy^{3+} sublattice is given by

$$\mathrm{FR}(Dy^{3+})=\mathrm{FR}(\mathrm{BiDyIG})-\mathrm{FR}(\mathrm{BiYIG})$$
$$=\pm(C_e+C_m)|M_c|, \quad (1)$$

where C_e and C_m are the respective magneto-optical electric "e" and magnetic "m" dipole coefficients. The upper (rep lower) sign is valid for $T<T_{comp}$ (rep $T>T_{comp}$). As in the $\{c\}$ sublattice, only the Dy^{3+} ions contribute to FR, C_m is proportional to the Landé g-factor of the rare earth and is equal to 6.1 deg cm^{-1} μ_B^{-1} (references reviewed in Ref. 4). Knowing M_c from direct magnetization measurements, the m dipole contribution in the $\{c\}$ sublattice is easily calculated, and the e dipole transitions contribution is then deduced. The analysis of the observed data indicates that (i) the $\{c\}$ sublattice FR originates mainly from e transitions as in bismuth-free dysprosium iron garnet, (ii) the Bi substitution has no effect on the sign of this e contribution which remains negative as in DyIG; on the contrary, the e contributions of the Fe^{3+} sublattices have a resultant which changes sign under Bi substitution,[4] (iii) as shown in Fig. 3, the FR of the $\{c\}$ sublattice is strongly reduced by the Bi incorporation.

To understand precisely the influence of bismuth, we calculated the e Faraday rotation per Dy^{3+} ion in Bi free and substituted garnets and then deduced the ratio R of these two contributions. The temperature dependence of R shown in

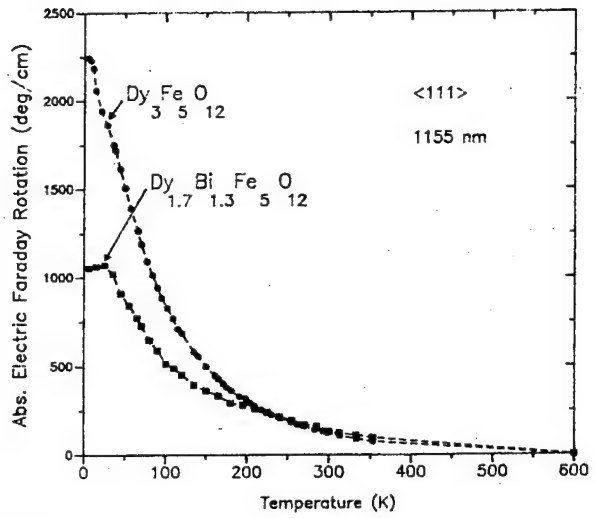

FIG. 3. Temperature dependences of the electric dipole transitions contribution of the $\{c\}$ sublattice in bismuth-free and bismuth-substituted dysprosium iron garnets at $\lambda=1155$ nm.

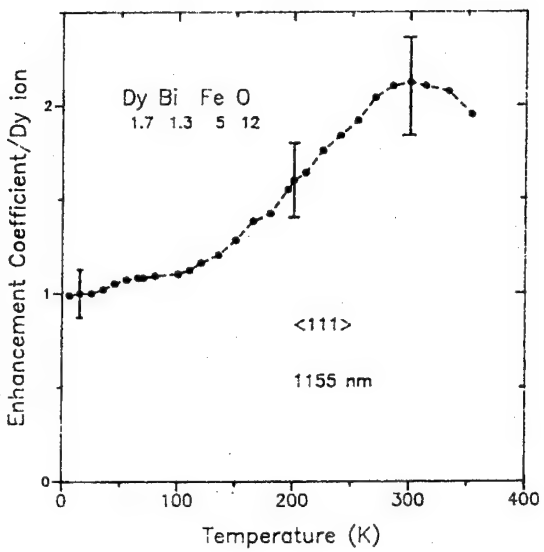

FIG. 4. Temperature dependence of electric dipole transitions contribution per Dy^{3+} ion in DyBiIG divided by the same contribution in bismuth-free DyIG.

Fig. 4 clearly demonstrates that the Dy^{3+} e Faraday rotation is affected by the bismuth except for the low-temperature range. It turns out that the enhancement of R is strongly temperature dependent and presents a maximum near room temperature.

Geller *et al.* have determined how the increase of T_c observed in BiYIG is directly related to a change of the super exchange geometry.[21] A refinement of the crystal structure has shown evidence of a small decrease of the [Fe]–O distance and of a weak increase of the (Fe)–O separation. An increase of J_{ad} (and of T_c) results from the noncompensated variations of the d-p wave function overlap between Fe^{3+} ions and nearest oxygen. An oxygen is, however, at the corner of four polyhedra: a tetrahedron, an octahedron, and two dodecahedra, the last involving two different $\{M\}$–O distances. In YBiIG crystals ($x\cong 1.8$), the {BiY}–O distance of the smallest dodecahedron is very close to the value of bismuth-free YIG, namely 2.37(9) Å, but for the second dodecahedron, the same distance (2.493 Å) is significantly larger than that of YIG (2.43 Å). It is worth noting that the effects of a small admixture of the Bi wave function into the iron orbitals and of covalency between Fe^{3+} ions are analyzed in Refs. 23 and 24. Although an in-depth analysis of the crystal structure of DyBiIG has not yet been performed, to our knowledge, this gives credence to a change of the super exchange interaction between Dy^{3+} and Fe^{3+} ions which can explain the enhancement of FR. Note that generally the dominant interaction is of {Dy}–O–[Fe] type.

At the end of this section, it seems useful to discuss briefly the possible pollution by lead of our films, since the Pb^{2+} contribution to FR was found to be comparable, in the visible range, with that of bismuth.[22] Taking into account the following data, we have concluded that the amount of lead is too weak to affect the discussion developed in this article: (i) electron probe analysis has not revealed any trace of lead, (ii) in the visible, the transparency of our films is very high, although lead is known to increase the optical absorption much more than bismuth, (iii) our YBiIG films present a monotonic decrease of FR with the temperature; with a small amount of lead, the FR variation would show an additional minimum at low temperature (iv) at $\lambda=633$ nm, we have measured, over the whole 10–600 K temperature range, a temperature variation of FR in YBi films that is in very good agreement with the data of Hansen *et al.*[19] It is noticeable that all the results observed on the two films remain unchanged after a long annealing (10 h) at 1000 °C of the two samples.

Multilayered garnet heterostructures of $Y_3Fe_5O_{12}$ (YIG) and $Eu_1Bi_2Fe_5O_{12}$ (EBIG) have been deposited on single crystalline [111] oriented $Gd_3Ga_5O_{12}$ (GGG) substrates, pulsed laser deposition (PLD). Magnetic (vibrating sample magnetometer) and magneto-optical (reflective Faraday effect) measurements have indicated out-of-plane magnetization for all YIG/EBIG films, coercivities up to 1.2 kOe, and Faraday rotations as high as 50 000 deg/cm.[1] According to x-ray diffraction experiments, all films are single crystalline, [111] oriented. Initial high resolution transmission electron microscopy studies have shown epitaxial growth of both YIG and EBIG layers. All samples had YIG deposited as the first layer of the heterostructure because of its small lattice mismatch with the substrate. As a consequence, all films showed sharp interfaces between the substrate and the first YIG layer. At the second interface, between the YIG layer and the first EBIG layer, structural defects were noted to form in the EBIG film. The thickness ratios between YIG and EBIG layers were intentionally changed during the processing to study the effect on magneto-optical properties. Transmission electron microscopy characterization indicated changes in the interface morphology, with some films displaying high coherence and sharpness of the interfaces, while others showed wavy and very incoherent interfaces. The films with sharp interfaces showed the highest values of Faraday rotation. Since there were no processing parameter changes from one film to another, the results appear to indicate that the morphology of the interfaces is the result of thickness variations in the heterostructures. An analysis of the complete dielectric tensor of bulk magnetite, Fe_3O_4, and of Fe_3O_4 substituted with a variable degree of Mg^{2+} or Al^{3+} allowed the assignment of the main magneto-optical (MO) transitions in Fe_3O_4 between 0.5 and 4.0 eV. This assignment is consistent with our reinterpretation of the $MgFe_2O_4$ and $Li_{0.5}Fe_{2.5}O_4$ MO-Kerr spectra. An analysis of the stoichiometry of a thin Fe_3O_4 layer is made, based on the Kerr spectrum, which is compared to an analysis based on the Verwey transition. The Kerr spectrum is also used to compare wavelengths for MO-Kerr effect studies of wedge-shaped samples. © *1996 American Institute of Physics.* [S0021-8979(96)22508-7]

I. INTRODUCTION

The interpretation of the magneto-optical (MO) Kerr spectrum of spinel ferrites, and notably magnetite, has been a subject of debate.[1–3] Some authors have explained the part of the spectrum around 2.0 eV in terms of $3d$ crystal field transitions of Fe^{3+} ions on the tetrahedral (A-) sites.[1] Others have assigned the major peaks in the MO-Kerr spectrum of Fe_3O_4 to $3d^n \rightarrow 3d^{n-1}4s$ orbital promotion processes.[2] The problem with these interpretations, however, is that they are based on forbidden transitions, whereas Fe_3O_4 has relatively strong MO transitions and absorption peaks with an oscillator strength of about 10^{-3} below 4.0 eV. Hence, Feil proposed that the main MO-active transitions between 0.5 and 4.0 eV are intervalence charge transfer (IVCT) transitions ($Fe^{2+}+Fe^{3+} \rightarrow Fe^{3+}+Fe^{2+}$).[3] As the Fe^{2+}–Fe^{3+} pair involved does not posses inversion symmetry, the parity selection rule is relaxed. Consequently, IVCT transitions should have much higher oscillator strengths than the transitions previously proposed.

We will show that IVCT transitions indeed explain the MO-Kerr spectrum of Fe_3O_4 between 0.5 and 4.0 eV. Key to the unraveling of the complicated Fe_3O_4 MO-Kerr spectrum were: first, the fitting of all four relevant elements of the dielectric tensor ϵ'_{xx}, ϵ''_{xx}, ϵ'_{xy} and ϵ''_{xy} *simultaneously* with one set of transitions. Secondly, the systematic substitution with nonmagnetic ions, Mg^{2+} and Al^{3+}, which allows the determination of trends in the Kerr spectra with a reduction in $[Fe^{2+}]$ and $[Fe^{3+}]$ content (round brackets denote ions on A-sites, square brackets ions on B-sites). Of these substitutions, the Mg^{2+} substitution is of special significance as it reduces the intense Fe^{2+}-dependent IVCT transitions, allowing the detection of other, overlapping transitions such as the intersublattice charge transfer (ISCT) transitions ($Fe^{3+}+Fe^{3+} \rightarrow Fe^{2+}+Fe^{4+}$). Finally, the usefulness of this understanding of the MO spectra of Fe_3O_4 in the field of thin oxidic films will be discussed.

II. RESULTS AND DISCUSSION

To arrive at a consistent transition assignment for Fe_3O_4, we determined the complete dielectric tensor for synthetic crystals of Fe_3O_4, and Mg^{2+}- and Al^{3+}-substituted Fe_3O_4, prepared by a floating zone technique.[4] The diagonal element of the dielectric tensor was determined by ellipsometry between 0.5 and 5.0 eV.[5] The polar MO-Kerr spectrum was measured between 0.7 and 4.0 eV.[6,7] From these spectra the off-diagonal element was calculated between 0.7 and 4.0 eV. Thus, for each sample the complete dielectric tensor was obtained, amounting to four spectra: ϵ'_{xx}, ϵ''_{xx}, ϵ'_{xy}, and ϵ''_{xy}. As these spectra consist of many overlapping bands, partly of opposing sign,[2,7] inspection of the spectra does not yield proper transition identification. To achieve this, rigorous fitting, using equations describing the basic line shapes of transitions in the microscopic theory of the dielectric tensor,[6] is needed. The complete dielectric tensor of Fe_3O_4 and of the Mg^{2+}- or Al^{3+}-substituted Fe_3O_4 were least-square fitted with one set of transitions for all samples. The criterion for a good fit was that the difference between the measured spectrum and the fit was on average less than 1% of the tensor element.[7]

Trends in MO-peak intensity and energy shift could be established due to the variable degree of substitution. Furthermore, as Mg^{2+} and Al^{3+} both preferentially occupy only the octahedral site, we are able to establish the nature of the MO-active transitions. The key results are summarized in Fig. 1, which depicts $\epsilon_{xy,\max}$ vs $[Fe^{2+}]$ and $[Fe^{3+}]$ content for the four major transitions which depend strongly on the Fe^{2+} content. The nonlinear dependence on $[Fe^{2+}]$ points to a pair interaction for all these transitions.[8] Given their behavior on substitution of $[Fe^{3+}]$ with Al^{3+} the transitions at 0.56 and 1.94 eV involve also this ion, while the transitions at 3.11 and 3.93 eV involve (Fe^{3+}). Consequently, four of the main transitions are assigned to intervalence charge transfer transitions (0.56 eV: $[Fe^{2+}]t_{2g} \rightarrow [Fe^{2+}]t_{2g}$, 1.94 eV: $[Fe^{2+}]t_{2g} \rightarrow [Fe^{2+}]e_g$, 3.11 eV: $[Fe^{2+}]t_{2g} \rightarrow (Fe^{2+})e$ and 3.93 eV: $[Fe^{2+}]t_{2g} \rightarrow (Fe^{2+})t_2$). For the three major transitions remaining we propose a new assignment. These transitions are assigned to intersublattice charge transfer transitions (2.61 eV: $(Fe^{3+})t_2 \rightarrow [Fe^{2+}]t_{2g}$, 3.46 eV: $[Fe^{3+}]e_g \rightarrow (Fe^{2+})t_2$ and 3.94 eV: $(Fe^{3+})t_2 \rightarrow [Fe^{2+}]e_g$), since the relative peak positions, the relative strengths and the linewidths of these transitions

 0021-8979/96/79(8)/5936/3/$10.00

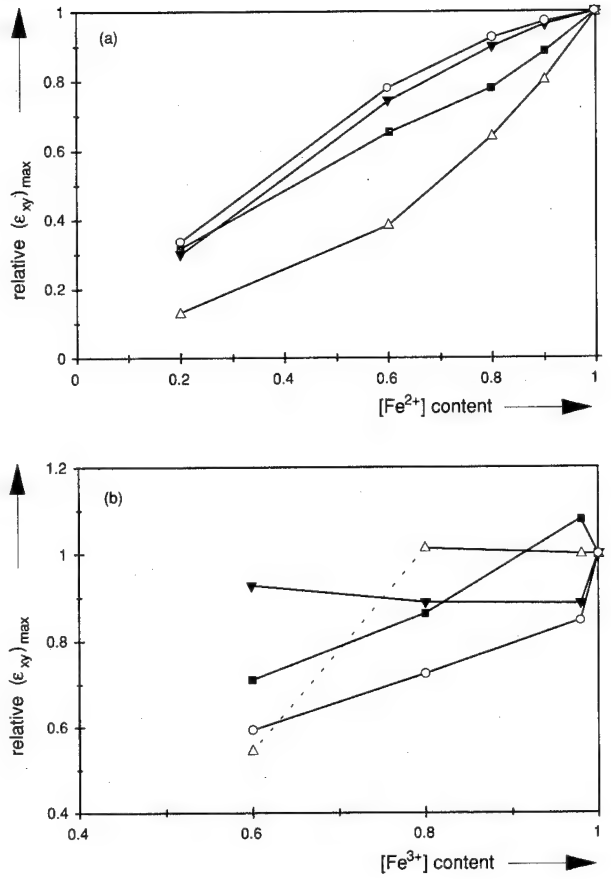

FIG. 1. Relative maximum ϵ'_{xy} value (a) vs [Fe^{2+}] and (b) [Fe^{3+}] content for the IVCT transition; (○) 0.56 eV, (□) 1.94 eV, (△) 3.11 eV, and (▼) 3.93 eV.

are consistent with the results reported for YIG.[8] From this transition assignment for Fe_3O_4 the transition assignment for related ferrites such as $MgFe_2O_4$ and $Li_{0.5}Fe_{2.5}O_4$ can be derived. This assignment should be the same as that of Fe_3O_4 without the IVCT transitions as these involve Fe^{2+}, although one should allow for some shift in transition energy and differences in intensity. We used the dielectric tensor of $MgFe_2O_4$ from the literature[9] and applied the same fit procedure. This yields three major MO transitions consistent with the ISCT transitions found in Fe_3O_4 and in YIG. Hence our assignment: 2.64 eV $(Fe^{3+})t_2 \rightarrow [Fe^{2+}]t_{2g}$, 3.48 eV: $[Fe^{3+}]e_g \rightarrow (Fe^{2+})t_2$ and 3.97 eV: $(Fe^{3+})t_2 \rightarrow [Fe^{2+}]e_{2g}$. The same transitions are observed in $Li_{0.5}Fe_{2.5}O_4$,[2,10] however, at increased intensity and at higher energies compared to $MgFe_2O_4$. The increased intensity is in part due to the increased amount of Fe^{3+} and in part due to the perturbation of the octahedral symmetry as a result of the small ion radius of Li^+. The latter is also responsible for the increase in transition energy. The same shift in transition energy is observed for Al^{3+} substitution of Fe_3O_4.[7] Thus, also the MO-Kerr spectra of $MgFe_2O_4$ and $Li_{0.5}Fe_{2.5}O_4$ can be interpreted in a consistent manner with the proposed transition assignment given for Fe_3O_4.

The data obtained for the transition assignment of Fe_3O_4 and the assignment itself can be applied to the investigation

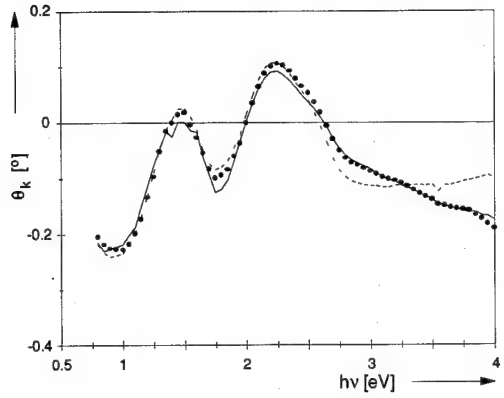

FIG. 2. The measured Kerr rotation spectrum of 115 nm Fe_3O_4 layer on $MgAl_2O_4$ (100) (—) vs the theoretical spectrum of a perfect layer (----) and the fitted spectrum (···).

of the stoichiometric quality of thin layers of Fe_3O_4. The polar Kerr spectra between 0.7 and 4.0 eV were measured of thin layers of Fe_3O_4 deposited by oxidic molecular beam epitaxy (MBE)[11] on $MgAl_2O_4$ (100) with thicknesses of 40, 115 (see Fig. 2), and 360 nm. The polar Kerr spectra of these layers are distorted by interference. From the dielectric tensor of Fe_3O_4 we were able to calculate the theoretical polar Kerr spectra of these layers (dashed line in Fig. 2), thereby isolating the interference effects from true changes in the dielectric tensor. In the measured spectra (solid line) an energy shift and a reduced intensity for the IVCT transitions is observed. Based on the transition assignment for Fe_3O_4 we could identify oxidation of part of the layer as the cause of these changes. Subsequent model calculations (leading to the dotted line in Fig. 2) enabled us to localize and quantify this oxidation to the upper 2–4 nm of the layer.[12,13]

Since the Verwey transition is often taken as an indication for the stoichiometric quality of Fe_3O_4,[14,15] we also determined the Verwey temperature, T_V, of the 40, 115, and 360 nm thick layers on $MgAl_2O_4$; see Fig. 3. T_V was identified through changes in resistivity, ρ, with temperature, T. We take as a measure for T_V the temperature at which the derivative of the ρ/T vs T^{-1} is maximum.[16] For the 360 nm thick layer this leads to $T_V = 122 \pm 1$ K, equal to the bulk value. For the 115 nm layer T_V is 109 ± 1 K. For the 40 nm thick layer a barely discernable T_V at 107 ± 1 K is found. In addition to the shift to lower transition temperature for thinner films, also a broadening of the transition and changes in the high temperature ρ are found.

Oxidation of the *total* layer might lead to the observed reduction in T_V.[14] However, the Kerr measurements point to an oxidized surface layer. The changes observed are, therefore, better explained by the influence of the substrate on the conductance of the film. As the perpendicular lattice parameter at room temperature of the 115 nm thick Fe_3O_4 layer is 8.398 ± 0.004 Å, which is within the experimental accuracy equal to the bulk lattice parameter, epitaxial strain is ruled out as the prime cause for the reduced T_V in this case. However, the difference in thermal expansion coefficients between substrate and the Fe_3O_4 film could give rise to the observed increased reduction of T_V for thinner layers. Hence,

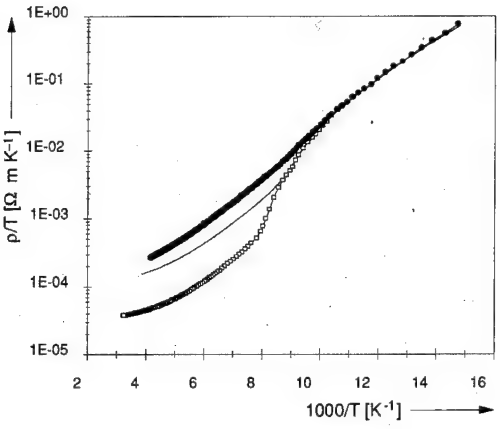

FIG. 3. Specific resistivity divided by temperature, ρ/T, of thin layers of Fe_3O_4 on $MgAl_2O_4$ as a function of inverse temperature, T^{-1}. (●) 40 nm, (–) 115 nm, and (□) 360 nm.

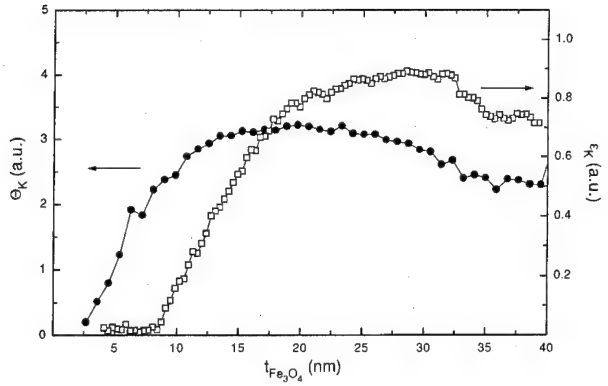

FIG. 4. Comparison of the Kerr effect vs Fe_3O_4 layer thickness, $t_{Fe_3O_4}$, for a wedge-shaped Fe_3O_4 sample at two wavelengths, λ. (□) ellipticity ϵ_K at 633 nm; (●) rotation Θ_K at 514 nm.

as strain due to differences in thermal expansion coefficient influences T_V,[17] this parameter may not be suited to assess the stoichoimetric quality of epitaxial thin Fe_3O_4 layers. In addition, it does not provide depth dependent information as the Kerr spectrum does.

Finally, we wish to point out the importance of spectral variations in MO-Kerr effect (MOKE) experiments to determine the magnetic anisotropy in ferrite layers grown on a certain substrate. As an example we give the Kerr ellipticity and rotation at a wavelength $\lambda=514$ and 633 nm versus the Fe_3O_4 thickness, $t_{Fe_3O_4}$, for a wedge of Fe_3O_4 grown on MgO (100) covered with a 2 nm MgO/3 nm NiO capping layer. MgO was chosen as substrate as previous work has shown that growth on this substrate results in proper Fe_3O_4.[18] Figure 4 shows that $\lambda=633$ nm (HeNe laser) and $\lambda=514$ nm (the green line of an Ar^+ laser) allow the polar MOKE detection of hysteresis loops down to 9 and 2.5 nm, respectively. We should remark that reliable hysteresis loops for anisotropy analysis are only obtained at somewhat larger thicknesses than those listed above, e.g., 12 nm for $\lambda=633$ nm and 8.5 nm for 514 nm. The fact that 514 nm allows the detection at lower thickness is caused by several effects. We have found that interference shifts the MO-Kerr spectrum of thin Fe_3O_4 layers to the blue; a capping layer may enhance this effect. Furthermore, the Fe_3O_4 absorption is larger at shorter wavelengths. From Fig. 4 we conclude that for studies of wedged-shaped samples judicious selection of the wavelength is important.

III. CONCLUSIONS

We have found through systematic substitution with Mg^{2+} and Al^{3+} that the main transitions in the magneto-optical (MO)-Kerr spectrum of Fe_3O_4 can be assigned to intervalence charge transfer transitions at 0.56, 1.94, 3.11, and 3.93 eV and intersublattice charge transfer transitions at 2.61, 3.46, and 3.94 eV. Also the MO-Kerr spectra of $MgFe_2O_4$ and $Li_{0.5}Fe_{2.5}O_4$ can be assigned consistently. Two applications of this understanding of the MO-Kerr spectrum of Fe_3O_4 have been shown in the field of thin oxidic films: first in a stoichiometry analysis of an Fe_3O_4 layer, second, in the wavelength selection in MO-Kerr effect studies of such layers.

In order to understand the magnetic properties of the substituted rare-earth-iron alloys, it is especially important to know the location of the substitutional atoms within the iron lattice. The site distributions of some nontransition-metal substituents in the substituted $Nd_2Fe_{17-x}T_x$ alloys have previously been reported. Here we report the site distributions of some transition-metal substituents (Cu,Zr,Nb,Ti,V) in the $Nd_2Fe_{17-x}T_x$ alloys and compare them with those of the nontransition-metal substituted compounds. Rietveld analysis of neutron powder diffraction data indicates that the nontransition-metal substituents show very similar site affinity at low substituent content. For example Al, Ga, and Si all prefer the 18*h* sites. The transition-metal substituents show a more complex site affinity. Ti and V atoms strongly prefer the 6*c* sites, Cu atoms prefer the 9*d* and 18*f* sites, Nb atoms prefer the 6*c* and 18*h* sites, and Zr atoms prefer 6*c* and 18*f* sites. It was also noted that the site affinity can change if carbon is included in the melting procedure of the sample preparation. The superconducting quantum interference device measurements show that all the substituted compounds have a Curie temperature higher than the unsubstituted parent compound. The relationship between the site distribution of substituents and the magnetic properties of the substituted $Nd_2Fe_{17-x}T_x$ alloys is discussed. [S0021-8979(96)33208-3]

INTRODUCTION

High performance permanent magnets should exhibit a Curie temperature (T_c) high enough to ensure the stability of the magnetic properties under operating conditions. Moving more and more of the iron–iron bonds into the optimum ferromagnetic exchange distance range while leaving a sufficiently concentrated iron lattice is one possible way of improving the Curie temperature of the rare-earth-iron compounds. Intensive research on enhancing the magnetic properties of the rare-earth-iron compounds by incorporation of interstitial atoms[1–6] and incorporation of substitutional atoms[7–15] (or by a combination of those two methods)[16,17] has been carried out recently.

It is well accepted that different Fe sites are of differing importance in the magnetic exchange coupling. Thus, it is especially important to know the location of substituents because new materials may be optimized by the elimination of particular exchange interactions detrimental to strong ferromagnetic interaction. The only tool capable of extracting this information directly is neutron diffraction. Analysis of the site substitution mechanism may lead to substituted compounds in which the desirable Fe–Fe bond lengths are maintained while the Fe atoms of the less desirable bonds are replaced by nonmagnetic species to give Curie temperatures high enough to be of technological interest.

We have previously reported the site distribution of some nontransition-metal substituents[6–8,14,15] in the substituted $Nd_2Fe_{17-x}T_x$ alloys. Little is known about the site distributions for most transition-metal substituents except Co.[18] The site distributions of some transition metal substituents (Cu,Zr,Nb,Ti,V) in $Nd_2Fe_{17-x}T_x$ alloys are reported. Our focus is on low substituent content because high substituent content will result in a larger reduction of magnetization.

EXPERIMENT

Samples of $Nd_2Fe_{17-x}T_x$ (T=Ti,V,Cu,Zr,Nb) were prepared from 99.9% or higher purity elements by rf induction melting in a flowing argon atmosphere at the Materials Research Center of the University of Missouri–Rolla. After melting, the ingots were wrapped in tantalum foil and were vacuum annealed at 950 °C for one week. The ingots were then crushed and ground finely in an acetone bath.

The powder neutron diffraction patterns were collected at the Missouri University Research Reactor Center by using a linear position sensitive detector with a wavelength of 1.4783 Å. The data for each sample were collected at room temperature on ~2 g of a finely powdered sample placed in a thin wall vanadium container. The two-theta range is from 5° to 105°.

Refinements of the neutron diffraction data were carried out using the program FULLPROF, which permits multiple phase refinement as well as magnetic structure refinement of each of the coexisting phases. In each of the samples, a small amount of α-Fe, ranging from 0.5% to 5% in volume, was the only detectable second phase. The Curie temperatures were measured by a superconducting quantum interference device using a Quantum Design MPMS system.

RESULTS AND DISCUSSION

The site occupancies of the transition-metal substituents and the lattice parameters of $Nd_2Fe_{17-x}T_x$ (T=Ti, V, Cu, Zr, and Nb), obtained from neutron diffraction data, are given in Table I. For comparison, the site occupancies of some nontransition-metal substituents and their lattice parameters in $Nd_2Fe_{17-x}T_x$ (T=Al,Si,Ga), obtained in previous studies, are also given in Table I.

The unsubstituted parent compound Nd_2Fe_{17} has a unit cell volume of 799.7 Å^3. The substituents will change the unit cell volume due to the different "size" of different substituents and/or some other chemical/electronic effects. Previous studies showed that the nontransition-metal Al and Ga will increase the unit cell volume[6–8] while Si will decrease it.[14,16] That behavior can be explained by the "size effect" because Al and Ga have an atomic radius larger than that of Fe while Si has a radius smaller than that of Fe. However, the case of transition metal substitution is complex. Although most of the transition metals, such as Ti, V, Zr, and Nb, have a free atom radius much bigger than Al or Ga, the volume effect of the transition-metal substitutions are much weaker than those of the nontransition-metal substitutions. The Al or Ga expands the unit cell of Nd_2Fe_{17} compound by more than 8.5 Å^3/per substituent atom.[6–8] In contrast, the first-row transition metals Ti and V only increase the unit cell by 1.4 Å^3/V atom and 5.0 Å^3/Ti atom, respectively, while the second-row transition metals Zr and Nb even decrease the unit cell slightly (Table I). This behavior strongly suggests that the transition-metal substituents bond to Fe and Nd atoms in the 2:17 compound more strongly than do the nontransition metals.

For a singly substituted compound, the site distribution of substituents can be determined directly from the neutron diffraction data. From Table I, we see that nontransition metal substituents have a strong preference for the 18h site, which can be explained by the coordination effect, because 18h sites have the most rare earth neighbors (three) and the fewest transition neighbors (nine). Nontransition metal substituents show a preference for bonding to rare earth atoms. The transition metal substituents show more complex site affinities. For the first-row transition metals Ti, V, and Cu, the steric effect alone can be used to explain the site affinity. For the Cu compound, the small atom radius of Cu results in Cu occupancy of the 9d (which has the smallest size) and the 18f sites (which have the second smallest size). For the Ti and V compounds, the large atom radii of Ti and V force them to occupy the largest 6c sites and leave the other sites almost empty of substituents. For the second-row transition-metal substituents Zr and Nb, the site affinities of the transition-metal substituents appear to be the result of a combination of the steric effect and the coordination effect. Because they have large atom radii, the steric effect will promote occupancy of the largest 6c sites or the second largest 18h sites. However, because of their negative affinity for rare-earth neighbors, they avoid the 18h site, but take the 18f site. While Nb has a stronger affinity for the 6c site than for the 18f site, Zr shows an inverse site affinity.

Another interesting behavior which has recently been observed is also given in Table I. When carbon is included in the melt, the site affinity of Ti is totally changed. As can be seen from Table I, the Ti atoms strongly prefer the 6c sites if the sample contains no C. However, if C is introduced into the sample by melting (not the gas phase reaction method), the Ti atoms prefer the 18h and 18f sites. This phenomenon does not occur for nontransition-metal substituents.[19] A broader and deeper study of this phenomenon is underway.

The Curie temperatures of some samples were measured by a superconducting quantum interference device and the results are given in Table I. All the substituted samples have a Curie temperature higher than that of the unsubstituted parent compound Nd_2Fe_{17} (330 K) regardless of the unit cell size.

CONCLUSIONS

The nontransition-metal substituents show very similar site affinities at low substitutent content: all prefer the 18h sites. The transition-metal substituents show a more complex site affinity, e.g., Ti and V atoms prefer the 6c sites, Cu atoms prefer the 9d and 18f sites, Zr and Nb atoms prefer the 6c and 18f sites. The site affinity of the transition-metal substituent can change if carbon is included in the sample preparation by melting. All the substituted compounds have Curie temperatures higher than the unsubstituted parent compound.

Electronic structure and magnetism in $Sm_2Fe_{17-x}A_x$ (A=Al,Ga,Si)

R. F. Sabirianov and S. S. Jaswal
Behlen Laboratory of Physics and Center for Materials Research and Analysis, University of Nebraska, Lincoln, Nebraska 68588-0111

Self-consistent spin–polarized electronic structure calculations have been carried out to derive the magnetic properties of the $Sm_2Fe_{17-x}A_x$ (A=Al, Ga, Si and $x=0$ and 1). The influence of impurities on the Curie temperature (T_C) of Sm_2Fe_{17} has been studied using the spin–fluctuation approach of Mohn and Wohlfarth. The calculated T_C generally goes up with the addition of each impurity but the relative increase in T_C depends on the type of the impurity and its site. The calculated T_C enhancement weighted with the impurity-site occupancy from Mössbauer data are in good agreement with the experimental data. © *1996 American Institute of Physics.*
[S0021-8979(96)33308-X]

Recently a substantial enhancement in T_C has been observed with a low concentration of impurities substituting for Fe in R_2Fe_{17} compounds.[1–8] For example a substitution of Al, Ga, and Si for one of the Fe atoms in Sm_2Fe_{17} raises its T_C from 391 (Refs. 2–5) to 410 (Ref. 7) to 417 (Ref. 2), 468 (Ref. 5) to 512 (Ref. 6), and 490 (Ref. 7), respectively. In this paper we start with the study of the magnetovolume effect of the parent compound Sm_2Fe_{17}. Then we examine how various impurities substituting for Fe in Sm_2Fe_{17} modify its magnetization and Curie temperature (T_C). Calculated results are compared with the available data.

We employ the linear-muffin-tin-orbitals (LMTO) method in the atomic sphere approximation to calculate the self-consistent spin–polarized electronic structure and magnetic properties of ferromagnetic (FM) $Sm_2Fe_{17-x}A_x$ (A =Al, Ga, Si and $x=0,1$) alloys. Sm $4f$ electrons are treated as core electrons with their spins antiparallel to those of the majority of Fe electrons (Total energy calculations show that this state is more stable than the parallel–spin-alignment state.) We use the linear tetrahedron method with 65 k points in the irreductible part of the Brillouin zone for Sm_2Fe_{17}. The calculations with impurities were carried out for the same cell as for Sm_2Fe_{17}. Because of the changes in the point-group symmetry due to a large number of the impurities considered here we performed all the impurity calculations at 64 k points distributed throughout the entire Brillouin zone. The lattice parameters for the various alloys were taken from Refs. 1–8.

The Sm_2Fe_{17} has a rhombohedral Th_2Zn_{17} structure. The unit cell contains 19 atoms with 1 Sm and 4 Fe sites. The number of nearest neighbors is 12 for d, f, and h Fe sites, and 14 for c Fe sites. The relative positions of neighbors are similar for d, f, and h sites with icosahedral symmetry environment. The d site has some rotational distortion and distortion in interatomic distances, but f and h sites are almost ideally icosahedrally coordinated.

Self-consistent spin–polarized electronic structure calculations are used to calculate the magnetic moments at various sites in Sm_2Fe_{17} as a function of the volume. The magnetization decreases rapidly with decreasing volume [Fig. 1(a)]. This behavior is similar to the magnetovolume effect in fcc Fe, but transition to the state with low magnetic moment is not as steep. Beuerle *et al.* obtained similar results for Y_2Fe_{17}.[9] The site decomposed magnetic moments are presented in Fig. 1(b). The c site has the largest while the d site has the smallest magnetic moment of all the Fe atoms. This is the expected magnetovolume effect because the $c(d)$ site has the largest (smallest) Wigner–Seitz (WS) volume of all the Fe atoms. Finally the induced non-$4f$ spin moment on Sm is antiparallel to those of Fe moments, the well-known hybridization effect.

Substitutional impurities modify hard-magnet properties due to changes in hybridization produced by changes in bonding and volume. We use the Mössbauer data as a guide to study the effect of impurities on the magnetic properties of Sm_2Fe_{17}. Due to the complexity of this problem we consider a single impurity per cell, i.e., $Sm_2Fe_{16}A$ (A=Al, Ga, Si). Furthermore we consider one site at a time for each impurity. The calculated magnetization results are compared with the

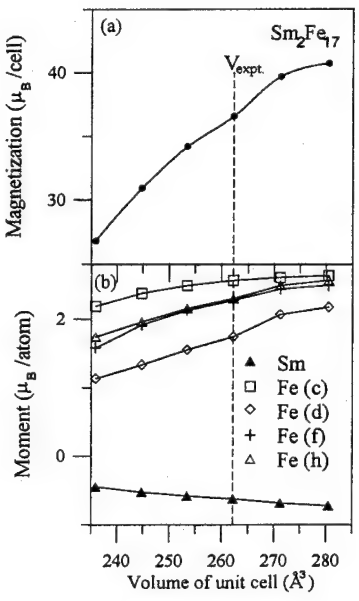

FIG. 1. (a) Magnetization and (b) site decomposed magnetic moment per atom as a function of the cell volume for Sm_2Fe_{17}.

available experimental data in Table I. In this comparison one should keep in mind that the 0 K calculated results depend on the degree of $4f$ polarization and the experimental data depend on the temperature.

Finally, we consider the enhancements in T_C due to various impurities in Sm_2Fe_{17}. The exchange–parameter analysis described earlier gives only a qualitative description of magnetism in Sm_2Fe_{17} but the T_C estimated from this model is too high. The spin–fluctuation model of Mohn and Wohlfarth[11] has been reasonably successful[12] in predicting the changes in T_C. We use this model here to study the changes in T_C. In this model

$$T_C \propto \frac{M_0^2}{\chi_0}, \tag{1}$$

where M_0 is the Fe magnetization per unit cell and χ_0 is the enhanced ferromagnetic susceptibility, both at 0 K,

$$\frac{1}{\chi_0} = \frac{1}{4\mu_B^2}\left(\frac{1}{N^{\uparrow}(E_F)} + \frac{1}{N^{\downarrow}(E_F)} - 2I\right), \tag{2}$$

where $N^{\uparrow}(E_F)$ and $N^{\downarrow}(E_F)$ are, respectively, the average spin-up and spin-down density of states (DOS) per Fe atom at the Fermi energy (E_F) and I is the Stoner parameter. Our calculations give I=0.91 eV. As can be seen from Table I, the changes in the calculated magnetization for the various impurities are quite small. Thus most of the changes in T_C must come from the changes in $N^{\uparrow}(E_F)$ and $N^{\downarrow}(E_F)$. In general, a decrease in DOS at E_F enhances T_C as can be seen from Eqs. (1) and (2). To qualitatively see how impurities enhance T_C we show the site-projected DOS for Sm_2Fe_{17} in Fig. 2. The result for the four Fe sites are qualitatively similar with the DOS near E_F dominated by the d states. An impurity modifies the width of the Fe d band and promotes new Fe states at the impurity p band (~8 eV below E_F) through magnetovolume and hybridization effects. These changes lead to changes in M_0 and χ_0 and hence T_C. Since E_F is located at different points along a steep edge of majority DOS for different Fe sites, the narrowing of their bands due to volume expansion and lower impurity–Fe (s–d) hybridization compared to that of Fe–Fe (d–d) will lower $N^{\uparrow}(E_F)$ (raise T_C) by varying amounts. As can be seen from Fig. 2, the $c(d)$ sites will make the least (most) contribution. Also while volume expansion enhances M_0, the promotion of new unpolarized Fe p states by the impurity lowers M_0.

The overall effect on T_C of the various changes in the electronic structure produced by different impurities is shown in Table II. All three impurities at c, f, and h sites enhance T_C with the enhancement being minimum for the c site and the maximum for the h site. The result for the c site is in agreement with the prediction in the last paragraph. No calculations were carried out for the d site because the Mössbauer data, also shown in Table II, do not give any occupancy for this site. The calculated ratios of T_C weighted with the experimental site occupancy are also shown in Table II along with the experimental data. The reasonable agreement between theory and experiment supports the Mössbauer results for the relative site occupancies. What determines the relative site occupancies for different impurities is an interesting but difficult question.

Finally it is interesting that T_C increases by ~21% with the Si impurity even though the volume decreases slightly.[7] This is primarily due to the narrowing of d bands of Fe atoms surrounding the impurity because the Si–Fe hybridization is lower than that of Fe–Fe.

In conclusion we have used the changes in electronic structure in going from Sm_2Fe_{17} to $Sm_2Fe_{16}A$ (A=Al, Ga, Si) and the spin–fluctuation theory to explain substantial enhancements in the Curie temperature.

We are thankful to I. A. Al-Omari and Professor D. J. Sellmyer for many helpful discussions. This work is supported by the U.S. Department of Energy under Grant No.

The magnetic properties of a series of $Ce_2Fe_{17-x}Al_x$ solid solutions with x equal to 0.0, 0.88, 2.06, 2.80, 3.98, 5.15, 6.08, 7.21, 8.20, 9.08, 9.84, and 10.62 have been studied by magnetic measurements, neutron diffraction, and Mössbauer spectroscopy. Neutron diffraction data indicate that the compounds all crystallize in the rhombohedral Th_2Zn_{17}-type structure. The aluminum atoms are excluded from the 9*d* site and show a distinct preference for the 6*c* site for x greater than 6. The substitution of aluminum leads to an expansion of the a and c axis by 0.5% and 0.4% per aluminum atom. The unit cell volume increases by approximately 1.4% per aluminum atom. The magnetic moment per formula unit, measured at 295 K, shows very little change for x less than or equal to 4, but decreases rapidly with increasing aluminum content for higher values of x, indicating that aluminum acts as a magnetic hole at the lower concentrations. The Curie temperature increases from 238 K in Ce_2Fe_{17} to a maximum of 384 K in $Ce_2Fe_{14}Al_3$. The $Ce_2Fe_{17-x}Al_x$ solid solutions behave as spin glasses for x greater than 7. The Mössbauer spectra have been fit with a binomial distribution of the near-neighbor environments in terms of a maximum hyperfine field, H_{max}, for an iron atom with zero aluminum near neighbors, and a decremental field, ΔH, per aluminum near neighbor. Mössbauer spectral results indicate both that the samples are ferromagnetically ordered in the basal plane for x values between 0.2 and 7 and that a magnetic phase transition occurs from helimagnetic in Ce_2Fe_{17} to ferromagnetic in $Ce_2Fe_{16.8}Al_{0.2}$. However, at 295 K ferromagnetic ordering is observed only for x values between 2 and 5. The average value of H_{max} decreases by about 25 kOe per aluminum atom. The isomer shift increases with aluminum content, an increase which can be explained by the screening of the 4*s* conduction electrons by the 3*d* band electrons. ΔH decreases by about 1.0 kOe per aluminum atom, a decrease which can be explained by the indirect exchange interaction between iron atoms modified by the presence of non-magnetic aluminum atoms through the 4*s* conduction band. *Note added in proof:* A full account of this work has been published in *J. Magnetization and coercivity of $Mn_{3-\delta}Ga$ alloys with a $D0_{22}$-type structure

The $D0_{22}$-type (Al_3Ti-type) phase in the Mn–Ga system is ferrimagnetic; the spin direction is parallel to the tetragonal c axis. The Curie temperature is about 765 K (for δ=0.67), near the decomposition temperature. We have prepared the $D0_{22}$-type alloys by annealing the quenched ingots of the high-temperature phase (γ_{Mn} phase) at 400 or 300 °C for a long time. The preparation becomes much easier if the ingots are powdered by filing before the annealing. The single-phase specimens of $Mn_{3-\delta}Ga$ were obtained in the composition range $0.15 \leqslant \delta \leqslant 1.06$. The coercivity of some specimens was so large that we measured the magnetization curve in high magnetic fields up to 150 kOe. The room-temperature values of saturation magnetization, remanent magnetization, and coercivity of the powder sample of the alloy with δ=0.67 are 50 emu/g, 25 emu/g, and 13.5 kOe, respectively. We have also studied the effect of magnetic annealing during the transition from the γ_{Mn} phase to the $D0_{22}$-type phase and the effect of the addition of Fe to $Mn_{3-\delta}Ga$ of the $D0_{22}$-type phase. © *1996 American Institute of Physics.* [S0021-8979(96)33408-6]

I. INTRODUCTION

The $D0_{22}$-type (Al_3Ti-type) phase in the Mn–Ga system is known to be ferrimagnetic; the magnetic structure is revealed by neutron diffraction experiments,[1] as shown in Fig. 1. It has also been reported that the $D0_{22}$-type alloy with 74.7 at. % Mn ($Mn_{3-\delta}Ga$ with δ=0.05) shows a large coercivity of 4.5 kOe[2] probably because of a large uniaxial magnetic anisotropy. But, detailed studies on these alloys have not been published to date.

We have made x-ray diffraction experiments and magnetic measurements for the Mn–Ga alloys in a wide composition range. The $D0_{22}$-type phase is unstable at the stoichiometric composition (Mn_3Ga), so we have examined $Mn_{3-\delta}Ga$ with appropriate values of δ. We have investigated the composition dependence of the lattice constants, Curie temperature, decomposition temperature, saturation magnetization, remanent magnetization, coercivity, and magnetic annealing effect of these alloys.

II. EXPERIMENTS

Ingots were prepared by melting gallium (99.9999%) and electrolytic manganese (99.9%) using an argon arc furnace. The ingot was sealed in an evacuated quartz tube with argon gas of 2.2×10^4 Pa, annealed for more than 24 h at 900 °C, and quenched into water to obtain homogeneous alloys of the γ_{Mn} phase with a fcc structure. Further, powder samples were prepared by filing a small portion of the ingot. We have prepared the $D0_{22}$-type alloys by annealing the ingots or the powder samples at 400 or 300 °C for several days. The preparation is much easier for the powder samples since the stress caused by filing enhances the rate of transition from the γ_{Mn} phase to the $D0_{22}$-type phase. We have confirmed by x-ray diffraction experiments that the single $D0_{22}$-type phase specimens of $Mn_{3-\delta}Ga$ are obtained in the composition range $0.15 \leqslant \delta \leqslant 1.06$.

Magnetization measurements were made using a Faraday-type automatic magnetic balance and a Foner-type magnetometer in magnetic fields up to 10 or 20 kOe. Some measurements were extended to 150 kOe using a Bitter magnet.

III. RESULTS AND DISCUSSION

The 400 °C annealing of $Mn_{3-\delta}Ga$ with $\delta > 1.2$ was found to give the $L1_0$- (CuAu) type phase, which is rather similar to the $D0_{22}$ type, as shown in Fig. 1. Figure 2 shows x-ray diffraction patterns of $Mn_{3-\delta}Ga$ with (a) δ=1.30 and (b) δ=0.97 at 293 K. The pattern (a) exhibits the $L1_0$ type

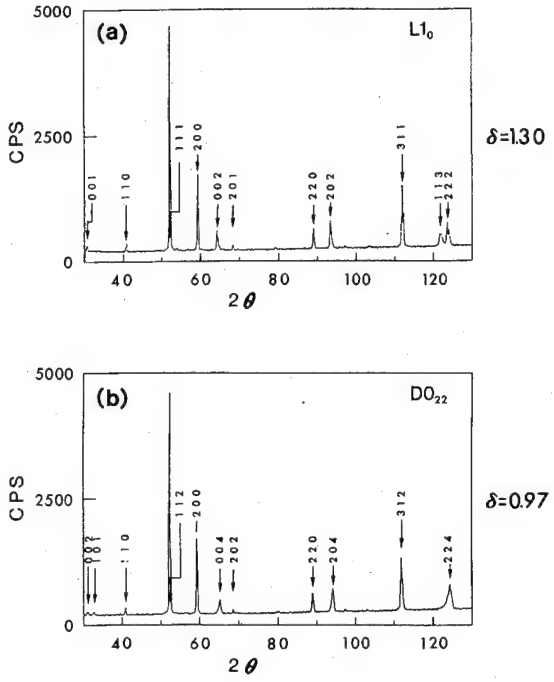

FIG. 2. X-ray diffraction patterns of $Mn_{3-\delta}Ga$ with (a) $\delta=1.30$, and (b) $\delta=0.97$ at 293 K (Fe K_α radiation).

with lattice parameters $a=3.8974$ A and $c=3.6249$ A, while pattern (b) exhibits the $D0_{22}$ type with $a=3.9049$ A and $c=7.1724$ A.

Figure 3 shows the composition dependence of a and c for $Mn_{3-\delta}Ga$. It should be noted that a is constant for both $D0_{22}$- and $L1_0$-type phases while c of $D0_{22}$ type is not so different from $2c$ of $L1_0$ type. The pattern for the alloy with $\delta<0.15$ exhibits the coexistence of the β_{Mn} phase with a complex cubic structure.

Magnetic measurements were made only for the $D0_{22}$-type phase. Figure 4 shows the temperature dependence of magnetization σ in a magnetic field of 10 kOe for $Mn_{3-\delta}Ga$ with (a) $\delta=0.97$ and (b) $\delta=0.43$. In Fig. 4(a) the magnetization during cooling is larger than that during heating. This is due to the fact that the 10 kOe field is insufficient to saturate the magnetization below the Curie temperature T_C (770 K). In Fig. 4(b), on the other hand, the $D0_{22}$-type phase begins to decompose at about 770 K (T_{dec}), resulting in an

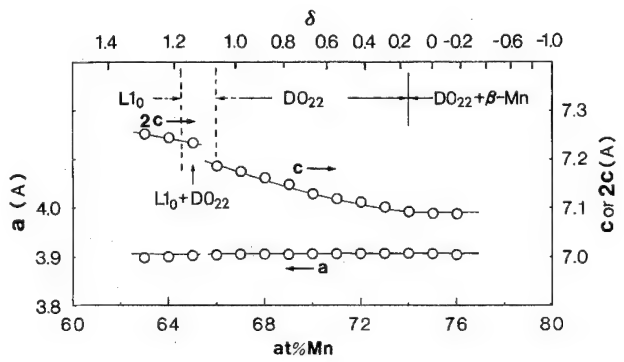

FIG. 3. Lattice constants a and c of $Mn_{3-\delta}Ga$ at room temperature.

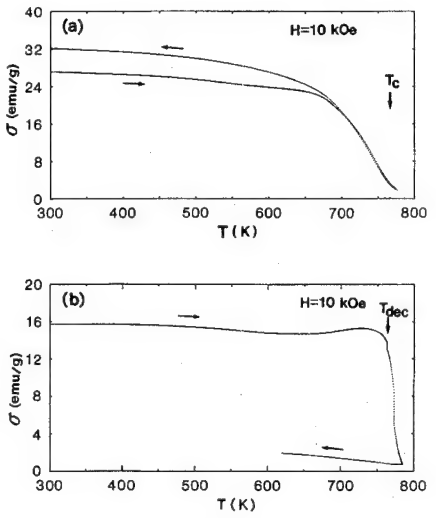

FIG. 4. Temperature dependence of magnetization σ for $Mn_{3-\delta}Ga$ with (a) $\delta=0.97$, and (b) $\delta=0.43$.

irreversible decrease in σ. The Curie temperature of this alloy is evidently higher than T_{dec}.

We have also made high-field magnetization measurements since the coercivity of some specimens is so large that we cannot obtain a major hysteresis loop in a conventional field of 20 kOe. As an example, a high-field magnetization curve at room temperature for the powder sample $Mn_{3-\delta}Ga$ with $\delta=0.67$ is shown in Fig. 5. The room temperature values of saturation magnetization σ_s, remanent magnetization σ_r, and coercivity H_c are 50 emu/g, 25 emu/g, and 13.5 kOe, respectively. The fact that $\sigma_r=0.5\sigma_s$ suggests the existence of a large uniaxial magnetic anisotropy with random orientation. The large coercivity has not been observed for the bulk samples probably because of the existence of a coarse magnetic domain structure.

Figure 6 shows the composition dependence of σ_s, σ_r, and H_c of the powder samples at room temperature. (Instead of σ_s, the magnetization at 15 T, $\sigma_{15\ T}$, is shown.) With increasing δ, both $\sigma_{15\ T}$ and σ_r increase, while H_c decreases. The composition dependence of σ_s can be explained on the basis of the spin structure shown in Fig. 1, if we assume that

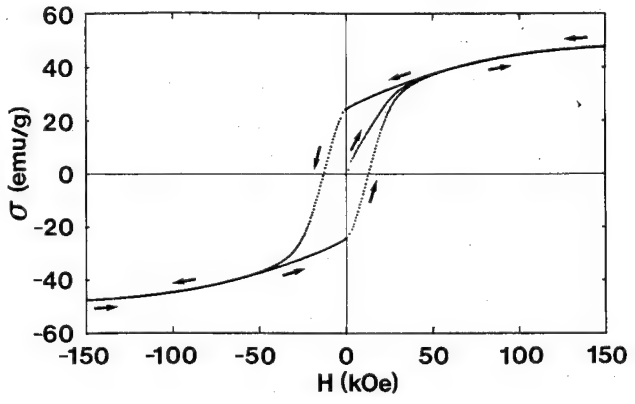

FIG. 5. High-field magnetization curve at room temperature for $Mn_{3-\delta}Ga$ with $\delta=0.67$.

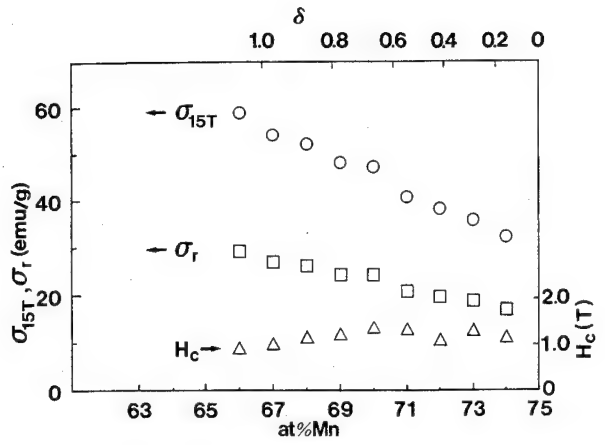

FIG. 6. Composition dependence of the saturation magnetization at 15 T $\sigma_{15\ T}$, the remanent magnetization σ_r, and the coercivity H_c of the powder samples of $Mn_{3-\delta}Ga$ at room temperature.

the excess Ga in the $D0_{22}$-type structure prefers the Mn_I site to the Mn_{II} site. It should be noted, however, that the σ_s value extrapolated to the stoichiometric composition ($\delta=0$) is about 3 times larger than that expected from the spin structure in Fig. 1. Therefore, we are planning to make more detailed neutron diffraction experiments on these alloys.

Because of the rather large values of σ_s and H_c, we may expect the possibility of $Mn_{3-\delta}Ga$ as a hard magnetic material. The characteristics will be much improved if we can align the magnetic anisotropy axis. For this purpose we have made the magnetic annealing during the preparation of the $D0_{22}$-type (tetragonal) alloy from the γ_{Mn} (cubic) phase alloy. Since the annealing temperature is sufficiently lower than the Curie temperature, the c axis of the $D0_{22}$-type structure is expected to align in the direction of the applied field.

As an example, the magnetic annealing of the powder sample of $Mn_{3-\delta}Ga$ with $\delta=0.67$ at 300 °C in a field of 10 kOe is illustrated in Fig. 7, where the magnetization σ measured during annealing is plotted against time, together with the temperature T. The transition from the γ_{Mn} phase to the $D0_{22}$-type phase is almost completed at 360 min (6 h). (A further increase in σ in the Fig. 7 corresponds to the temperature dependence of σ_s of the $D0_{22}$-type alloy.)

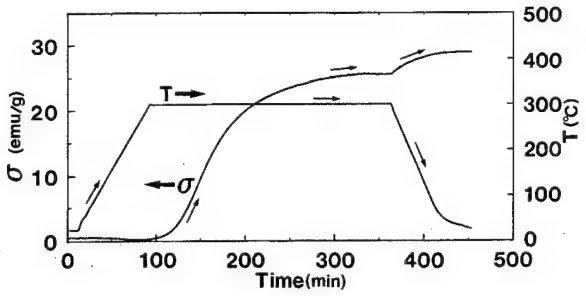

FIG. 7. Magnetic annealing during the transition from the γ_{Mn} phase to the $D0_{22}$ phase for $Mn_{3-\delta}Ga$ with $\delta=0.67$. σ is the magnetization and T is the temperature. The applied field is 10 kOe.

Unfortunately, however, the alignment of the magnetic anisotropy axis was not so remarkable by this magnetic annealing, probably because the transition from the γ_{Mn} (cubic, nonmagnetic) phase to the $D0_{22}$ (tetragonal, magnetic) phase is not direct but through the medium of the $D0_{19}$-type (hexagonal, nonmagnetic) phase, as was confirmed by x-ray diffraction.

A detailed study on this subject is now in progress.

As another effort of the materials research, we have also studied the effect of the addition of Fe to the $D0_{22}$-type $Mn_{3-\delta}Ga$. Single-phase alloys of $(Mn_{1-x}Fe_x)_{3-\delta}Ga$ with $\delta=0.30$ were obtained in the range $0\leqslant x\leqslant 0.25$. We have made high-field magnetization measurements for the powder samples. For example, the room-temperature values of saturation magnetization, remanent magnetization, and coercivity of $(Mn_{1-x}Fe_x)_{3-\delta}Ga$ with $\delta=0.30$ and $x=0.25$ are 38 emu/g, 18.5 emu/g, and 12 kOe, respectively. In general, no remarkable effect on σ_s, T_C, and H_c was observed by the addition of Fe.

ACKNOWLEDGMENTS

In conclusion, the authors express their thanks to M. Kudo, K. Sai, and Y. Ishikawa of High-Field Laboratory, Tohoku University, for operation of the Bitter magnet.

The magnetism of $LaCo_{13}$-type alloys such as $LaCo_{13}$, $PrCo_{13-x}Si_x$, etc., has recently received considerable attention as potentially useful magnetic materials. The present study is concerned with $RCo_{13-x}Si_x$ where R=La, Pr, Nd, Gd or Dy.
[S0021-8979(96)33508-2]

I. INTRODUCTION

The alloys $LaCo_{13}$ and $La(Co,Fe)_{13}$ have a high content of $3d$ elements. The high concentration of $3d$ elements leads to a large magnetization and, in some cases, a high T_C. Because of these properties these alloys have attracted attention as potential high energy permanent magnet materials.[1–6] In earlier studies from this laboratory, Ido *et al.* have studied $La(Co,Fe,Al)_{13}$ (Ref. 1) and Huang *et al.* have studied $PrCo_{13-x}Si_x$.[7] The earlier works have been extended in the present study to include the ternaries $RCo_{13-x}Si_x$, in which R=Nd, Gd, and Dy.

II. EXPERIMENTAL DETAILS

The ternary alloys were prepared by induction melting under argon, after which they were heat treated at 1273 K for about one week. X-ray diffraction (XRD) with Cu radiation was used to determine crystal structure, lattice parameters, and the phases present.

The magnetic properties (M and T_C) were measured using vibrating sample magnetometers (VSM) at temperatures ranging from 10 to 1173 K and fields ranging from 500 Oe to 17 kOe. The TMA measurements were made in such a manner [low applied field (500 Oe) and variable heating rate] to provide the most reliable information about the phases present and the values of T_C and to clearly identify the spin reorientation

III. RESULTS AND DISCUSSION

A very large body of data was acquired. Due to space limitations, only a few representative data can be presented. The results are exemplified by the data given in Tables I and II and Figs. 1–7.

A. Phases formed and structural information

Information concerning the phase relationships is obtained by XRD measurements such as those shown in Figs. 1 and 2. The phase relationships are rather similar for the five systems studied: (1) At low Si content, $1.5 \leqslant x \leqslant 2.0$, the alloys form in the fcc $NaZn_{13}$ structure. (2) At high Si content, $3.5 \leqslant x \leqslant 4.5$, they form in the body-centered tetragonal (bct) $Ce_2Ni_{17}Si_9$ structure. (3) At intermediate Si concentrations the systems are a mixture of fcc and bct alloys. There are, however, some exceptions to these generalizations: (1) The fcc phase forms at $x=0$–2 for R=La. (2) The fcc structure begins to form at $x=1.5$ for R=Pr, whereas it forms only for

x exceeding 3–3.5 for the heavier rare earths, Nd, Gd, or Dy. Also as noted in Table I, some of the alloys contained minor amounts of other phases: 2:17, 1:11, and Co_2Si. The lattice parameters (Table I) show that Si doping causes a shrinkage of the lattice.

In summary, the ternaries (and $LaCo_{13}$) are fcc for low Si content and one bct at high Si content. Further details are given in Table I.

B. Magnetic properties

Magnetization results are given in Figs. 3–7 and in Table II. From the results presented, it is to be noted that $LaCo_{13}$, which is fcc, is a strongly ferromagnetic material (moment =131 emu/g) with a high T_C, 1297 K. It thus satisfies two of the requirements for a high energy permanent magnet material. However, it lacks a third requirement—a uniaxial crystal

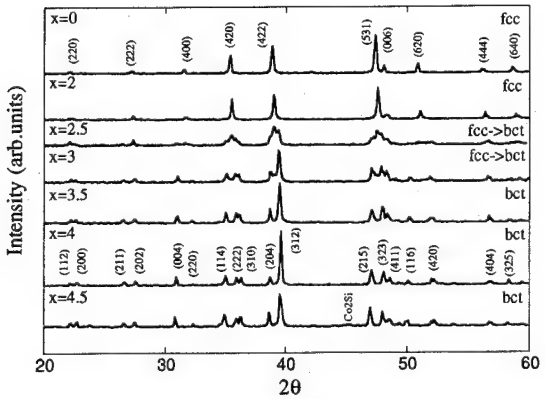

FIG. 1. XRD patterns for $LaCo_{13-x}Si_x$. The splitting of the 422 peak at $2\theta \sim 39°$ is a clear indication of the transformation from cubic to tetragonal symmetry.

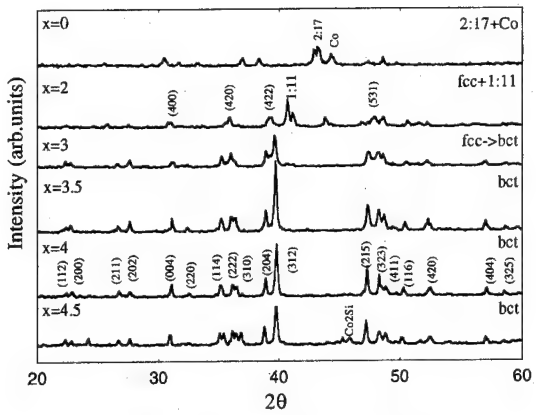

FIG. 2. XRD pattern for $NaCo_{13-x}Si_x$.

structure. The present study (and earlier studies) shows that the third requirement can be induced by Si doping.[1,6,7] Unfortunately, however, as indicated in Figs. 3–7 and in Table II, the tetragonal materials have a low T_C—room temperature or below. The fcc alloys have a T_C ranging from 880 K (for $LaCo_{11}Si_2$) to 1297 K for $LaCo_{13}$. For a given Si content, the T_C of the fcc phase is dependent on the nature of R. As expected, the dominant interaction is the Co–Co interaction.

In regard to the magnetic moment, there is a decrease as Si replaces Co, but the decrease is larger than expected due to the simple dilution of the Co sublattices. The decrease begins in the fcc alloys and continues in the bct alloys. The bct alloys have small moments, <10 emu/g, as measured at ~10 K.

The TMA for bct alloys with R=Pr and Nd show clear indications of a spin reorientation when cooled to tempera tures in the liquid hydrogen range (Figs. 4 and 5). As shown in Table II, T_{sr}=55 and 48 K for $PrCo_{9.5}Si_{3.5}$ and $NdCo_{9.5}Si_{3.5}$, respectively. No spin reorientation was observed for the La, Gd, and Dy ternaries. This is as expected for $La(Co,Si)_{13}$—since La carries no moment—and for $Gd(Co,Si)_{13}$—in which the rare earth is spherical and hence is isotropic. It is unclear why there is no indication of spin

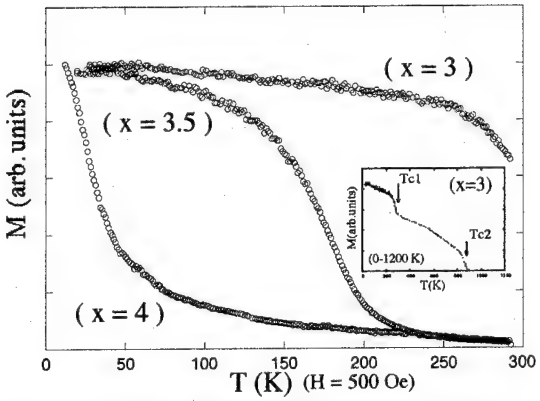

FIG. 3. M vs T for three representative bct $La(Co,Si)_{13}$ alloys. The alloys with x=3.5 and 4 are nearly single-phase material. Their Curie temperatures are about 200 and 40 K, respectively. The alloy with x=3 is a two-phase system composed of fcc and bct alloys (see Table I). The presence of the fcc impurity phase strongly affects the magnetization of the bct phase.

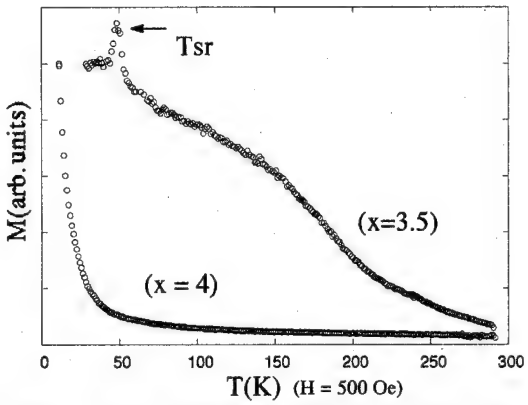

FIG. 4. M vs T for two representative $Nd(Co,Si)_{13}$ alloys. The T_C's for $NdCo_9Si_4$ and $PrCo_9Si_4$ are essentially identical. The spin reorientation at ~50 K is clearly evident.

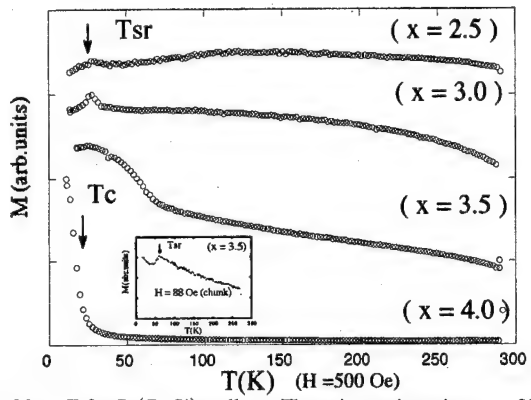

FIG. 5. M vs T for $Pr(Co,Si)_{13}$ alloys. The spin reorientation at ~28 K is clearly evident for x=2.5–3.5.

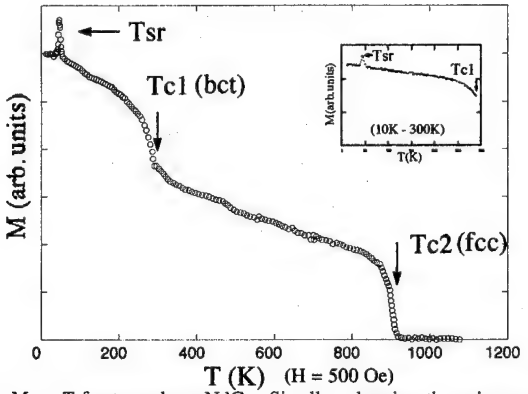

FIG. 6. M vs T for two-phase $NdCo_{10}Si_3$ alloy showing the spin reorientation at ~45 K and the T_C's for the bct and fcc components.

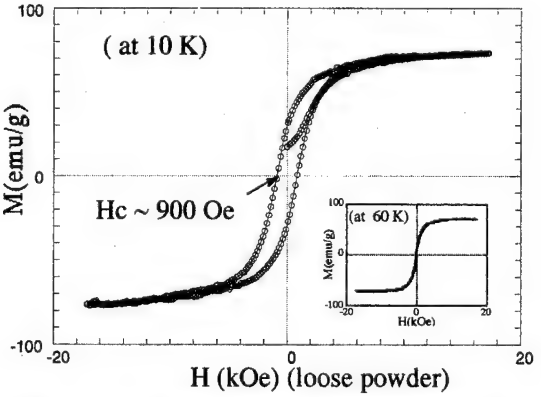

FIG. 7. Hysteretic behavior of $PrCo_{10.5}Si_{2.5}$, showing significant coercivity for $T<T_{sr}$, but not for $T>T_{sr}$.

rotation for the Dy-containing ternaries. Boltich, Pedziwiatr, and Wallace showed[8] some years ago that spin reorientation in rare earth–d-transition metal alloys occurs as a result of a complex interplay between the crystal field interaction for the R sublattice and exchange primarily involving the d sublattice. The temperature of the spin reorientation and the shape of the aberration in the TMA depend on the details of this interplay. Perhaps in $Dy(Co,Si)_{13}$ the spin reorientation takes place at a temperature lower than that covered in this study. Interestingly, the Dy alloy exhibits coercivity in its hysteresis loop even though it does not indicate spin reorientation in its M vs T plot.

Hysteresis loops were measured at temperatures above and below T_{sr} for the ternaries in loose powder form. A representative loop (for $PrCo_{10.5}Si_{2.5}$) is shown in Fig. 7. There is negligible coercivity for $T>T_{sr}$ but appreciable coercivity for $T<T_{sr}$. This suggests that magnetization is along the c axis below T_{sr} and shifts to the ab plane above $T>T_{sr}$.

IV. CONCLUSION

$LaCo_{13}$ exists in the fcc $NaZn_{13}$ structure. The corresponding Pr alloy also forms in the same structure if a small portion of the Co is replaced by Si. At higher Si content, all the systems adopt the bct $Ce_2Ni_{17}Si_9$ structure. The fcc alloys have high T_C and are strongly magnetic. The bct alloys are weakly magnetic with T_C at or below room temperature. $Pr(Co,Si)_{13}$ and $Nd(Co,Si)_{13}$ exhibit spin reorientation at ~60 and 50 K, respectively. Hysteresis results suggest a uniaxial material at temperatures below T_{sr} and ab plane anisotropy for $T>T_{sr}$. Si doping stabilizes the $NaZn_{13}$ structure in $R(Co,Si)_{13}$ alloys. This does not appear to be exclusively a size effect.

The electronic structure of YCo_5 was calculated self-consistently by the scalar-relativistic linear muffin–tin orbital method using an atomic sphere approximation within the framework of the local spin density approximation. Using the spin–orbit interaction (SO) and orbital polarization term (OP), magnetocrystalline anisotropy energy due to 3*d*-electrons (3*d*-MAE) was calculated as a function of bandfilling q [Ea(q)]. At the Fermi level, the calculated Ea(q), including SO and OP, depended greatly on whether an *f* basis was used for Co. Just below the Fermi level, however, Ea(q) showed a large and *c*-axial 3*d*-MAE comparable with the experimental data. This behavior of Ea(q) is closely related to the calculated anisotropy of orbital magnetic moments and the shape of density of states of the 3*d* band. © *1996 American Institute of Physics.* [S0021-8979(96)33608-9]

The magnetocrystalline anisotropy energy (MAE) of rare-earth (or Y) transition metal intermetallics has been studied by many researchers concerning its application to permanent magnetic materials.[1,2] Although the MAE of these compounds is mainly due to the electrostatic interaction between the 4*f* electrons on rare-earth elements and the crystalline field, the spin–orbit splitting of the 3*d* band on the transition metal elements can contribute substantially to the anisotropy energy (3*d*-MAE). For example, the *c*-axial 3*d*-MAE of YCo_5 (3.8 meV/f.u.)[3] is smaller than that of $SmCo_5$ (16 meV/f.u.)[4–6] only by a factor of 4. The contribution per Co atom in YCo_5—0.76 meV/Co—is by far the largest value among the Y–Co compounds, which is about ten times as large as that of a simple hcp Co (0.065 meV/Co).[7] This large anisotropy of YCo_5 is explained from the viewpoint of the localized 3*d* electron model.[3] However, magnetism of the 3*d* electrons is discussed from the viewpoint of band magnetism.

Recently, the 3*d*-MAE of YCo_5 was calculated by Daalderop *et al.*[8] and Nordström *et al.*[9] with the linear muffin–tin orbital method with atomic sphere approximation (LMTO-ASA), including both spin–orbit interaction (SO) and an orbital polarization term (OP). They used experimental lattice parameters and *s*, *p*, *d*, and *f* bases for both Y and Co. However, we were not able to obtain the theoretical lattice constant a_{cal} determined so as to minimize the total energy in the region of ±7% of the experimental lattice constant a_{exp} when we used their calculation parameters. On the other hand, we were able to obtain the a_{cal} which is only about 2% smaller than a_{exp} when we did not use an *f* basis for Co. In this work, we calculated the 3*d*-MAE of YCo_5 using the LMTO-ASA method under the two different sets of parameters.

Before calculating the 3*d*-MAE, the self-consistent electronic structures were calculated using the LMTO-ASA method based on the local spin density approximation. Here, the parameters of Janak, Moruzzi, and Williams[10] were used and the calculations were carried out in scalar relativistic approximation, neglecting SO interaction. We calculated the self-consistent potential using the two different sets of calculation parameters, in which the most influential difference is whether an *f* basis is used for Co. In set (1), we used parameters similar to Daalderop *et al.*[8] and Nordström *et al.*[9] For atomic positions, lattice constant a, and c/a ratio, the experimental data were used. The *s*, *p*, *d*, and *f* bases were used for both Y and Co. The ratio of the atomic sphere radius was chosen as $r_Y/r_{Co}=1.32$. In set (2), we used the following parameters. For atomic positions and c/a ratio, the experimental data were used. The bases we used consist of *s*, *p*, *d*, and *f* for Y, and of *s*, *p*, and *d* for Co. The ratio of the atomic sphere radius was chosen as $r_Y/r_{Co}=1.35$ so that a_{cal} and the spin magnetic moments agreed well with the experimental data. We obtained a_{cal} (4.84 Å), which is only 2% smaller than a_{exp} (4.94 Å). The number of **k** points we used in the irreducible Brillouin zone (IBZ) was 225 in both sets.

Using the self-consistent potential, the full Hamiltonian including only SO or both SO and OP was diagonalized to obtain an energy eigenvalue $\epsilon_i(\hat{\mathbf{n}},\mathbf{k})$, where i was the electronic states, $\hat{\mathbf{n}}$ the direction of quantum axis (magnetization direction). According to the *force theorem*,[11] the total energy difference between the two directions of the quantum axis is given by the difference between the sum of the calculated energy eigenvalues of the occupied states as follows: $\mathrm{Ea}=\sum_{i,k}^{occ}\epsilon_i([0001],\mathbf{k})-\sum_{i,k}^{occ}\epsilon_i([1000],\mathbf{k})$, where [0001] denotes the direction of the c axis while [1000] denotes the direction within the ab plane. The summation on i and **k** was carried out by means of the tetrahedron method. Furthermore, the occupation number of the valence electrons was treated as a variable. Thus, 3*d*-MAE was calculated as a function of bandfilling q:Ea(q). The calculated spin and orbital magnetic moments in the case of [0001] are shown in Table I.

In the case of the [0001] quantum axis, the number of sampling **k** points in IBZ, on which the $\epsilon_i([0001],\mathbf{k})$'s were calculated, were 225. The size of the irreducible part of BZ in the case of the [1000] quantum axis is three times larger than IBZ in the case of [0001]. The variation among the

calculated Ea(q)'s using three sets of 112, 225, and 396 **k** points on a rough bandfilling mesh (0.5 electrons) were within the range of 0.05 meV/Co.

The calculated Ea(q)'s of YCo_5 in four cases are shown in Fig. 1(a). From the left-hand side, the four numbers of bandfilling q correspond to the numbers of valence electrons in a unit cell of Mn, Fe, Co, and Ni compounds, respectively.

Only in the case of (1)SO+OP, the value of Ea(q) at the Fermi level (q=48) agrees well with the experimental data. As can be seen from Table I, the calculated orbital magnetic moments in the case of (1)SO+OP agree with experimental data better than the other results. These results are similar to those of Daalderop *et al.*[8] and Nordström *et al.*[9] However, we mentioned that the a_{cal} could not be determined in set (1). In set (2), we did not use an f-basis for Co and were able to obtain the a_{cal} as stated above. In the cases of both (2)SO and (2)SO+OP, however, the Ea(q) does not agree with the experimental data at the Fermi level. In addition, the values of Ea(q) at the Fermi level for (2)SO+OP are greatly different from that for (1)SO+OP.

The calculated 3d-MAEs at the Fermi level depend greatly on the calculation parameters. However, the overall features of the four Ea(q)'s are similar with one another. All Ea(q)'s have very large peaks at q=46–47, which are comparable to experimental data. This feature can be seen in the anisotropy of orbital magnetic moments calculated in the case of (2)SO, as can be seen from Fig. 1(b). We can see that this feature is mainly due to the Co(2c).

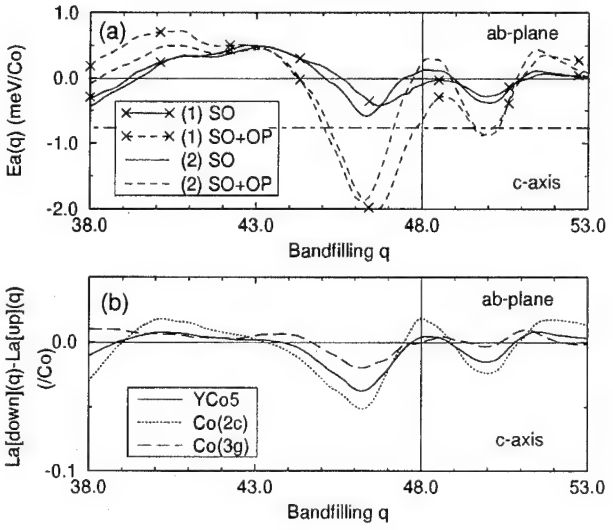

FIG. 1. (a) The calculated 3d-MAE as a function of bandfilling q:Ea(q) (meV/Co). The vertical line shows the actual Fermi level. The horizontal dot-dashed line shows the experimental data. (b) The calculated anisotropy of orbital magnetic moments of the down-spin band minus that of the up-spin band as a function of bandfilling q:La[down](q)-La[up](q) (μ_B/Co).

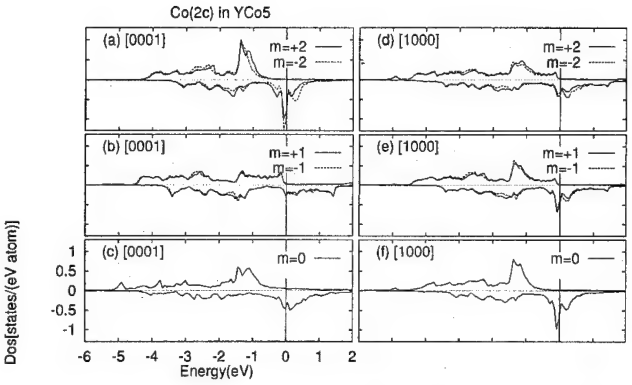

FIG. 2. The density of states of the 3d band projected to the m states.

To investigate the behavior of Ea(q), we show the density of states of the 3d band projected to the states of the magnetic quantum number m=±2, ±1, 0. Those density of states (DOS) were calculated in the case of (2)SO. We found that the DOS of Co(2c) has a large anisotropy, which is shown in Figs. 2(a)–2(f). This situation cannot be found in the case of Co(3g). In Figs. 2(a)–2(c) the quantum axis lies in the [0001] (c-axis) direction, while in Figs. 2(d)–2(f) they lie in the [1000] (ab-plane) direction. Seeing the DOS in Figs. 2(a)–(c), we notice that the shape of the DOS greatly depends on $|m|$. The very large peaks are found near the upper edge of the 3d band in the ±2 states in Fig. 2(a). Similar peaks are also found in the ±1, 0 states for [1000] quantum axis in Figs. 2(e) and 2(f). Those large peaks near the upper edge of the 3d band for Co(2c) indicate that there are many electronic states that do not contribute to covalent bonding. In the [0001] quantum axis, the m=±2 states of the 3d band extended in the ab plane. While in the [1000] quantum axis, the states extending in the ab plane are mainly expressed by the m=0, ±1 state. The Co(2c) atom is surrounded by Co(2c) atoms and Y atoms in the ab plane, which can be seen in Fig. 3. Therefore, the large peaks in the DOS of Co(2c) indicate that Co(2c) has a weak bonding with the surrounding Y and Co(2c) atoms within the same ab plane. This can be understood from the fact that the Co(2c)—Co(2c) [Co(2c)—Y) bonding distance in the ab plane is much longer than the other bonding distances.

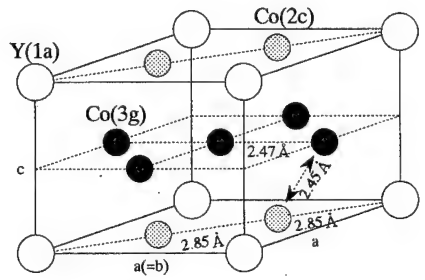

FIG. 3. The crystal structure of YCo_5 ($CaCu_5$ type).

The calculated coefficients of the SO interaction of Co are 77.0, 75.0, 77.1, and 74.8 meV for $\xi_d^{\uparrow}(2c)$, $\xi_d^{\downarrow}(2c)$, $\xi_d^{\uparrow}(3g)$, and $\xi_d^{\downarrow}(3g)$, respectively. As can be seen from Figs. 2(a), 2(b), 2(d), and 2(e), this interaction splits the $\pm m(m=2,1)$ states of the $3d$ band. Because of the large difference in the shape of DOS near the Fermi level between the two quantum axes, the large $3d$-MAE and anisotropy of the orbital magnetic moments are expected to be induced.

In conclusion, we showed qualitatively the relation between the experimental large c-axial $3d$-MAE and the weak bonding around Co($2c$) within the ab plane through the shape of the DOS of the $3d$ band in Co($2c$).

Ba hexaferrite samples having average particle sizes in the range from the tens up to the thousands of nm have been prepared by using conventional ceramic techniques and the exothermic reaction between Ba and Fe nitrates and oxalic dihydrized acid. The magnetic characterization of these samples included the measurement of the temperature dependence of the high field magnetization, the coercive force, and the evaluation, from thermally activated demagnetization measurements, of the activation volume at different temperatures. From the results of this characterization it was possible to reach conclusions about the occurrence of remarkable differences between the average particle size dependence of the coercive force and that corresponding to the activation volume: whereas the coercive force value increased monotonically with the decrease of the particle size, an activation volume minimum was observed for particle diameters of the order of hundreds of nm. We suggest that this minimum reflects a change of the mechanism ruling the magnetization reversal of the particles forming our samples.
[S0021-8979(96)33708-5]

I. INTRODUCTION

The existence in ordered magnetic materials of remanence-type states (in which the global magnetization is essentially antiparallel to the applied demagnetizing field) is a direct consequence of the high energy of the states the system should traverse when globally reversing its magnetization. This "energy barrier," having a complex structure due to both the coupling of the local magnetic moments with the microstructure[1] and to the many degrees of freedom of the system,[2] is then of the origin of the coercivity (field induced reversal) and of the magnetic viscosity (thermally activated reversal). Our aim in the present work is to discuss the relationship between coercivity, magnetic viscosity, and particle size in Ba hexaferrite samples covering three orders of magnitude in particle dimensions.

II. PREPARATION OF SAMPLES AND EXPERIMENTAL TECHNIQUES USED

In order to cover a wide range of particle dimensions our samples were prepared by means of two different procedures. The largest particles were obtained through a ceramic technique consisting of the firing during 12 h in air at 1623 K of a stoichiometric mixture of $BaCO_3$ and α-Fe_2O_3. The corresponding product was ball milled for different times in the range from 600 to 5400 min. The second preparation method, allowing one to obtain small particles, was based on the exothermic redox reaction of the Ba and Fe nitrates with the dihydrized oxalic acid. In this case, the reaction product was heat treated in air during 10 h at different temperatures in the range from 973 to 1123 K. This treatment allowed us to control the final particle size and to improve the crystallinity of the samples. In this paper we will name the samples obtained via the ceramic method (CE series) and milled for 5400, 1800, and 600 min as CE-3, CE-8, and CE-18, respectively, and those prepared through the exothermic reaction (CA series) and treated at 973 and 1123 K as CA-0 and CA-1, respectively. The phase distribution of the samples was examined by means of x-ray diffraction (Cu $K\alpha$). Transmission and scanning electron microscopies were used in order to obtain information about the morphological characteristics of the particles forming the samples. The magnetic properties study was carried out by measuring pressed powder samples on a superconducting quantum interference device magnetometer.

III. RESULTS

In Fig. 1 we show two typical diffractograms obtained in samples of both series. In the case of the CE samples the diffraction patterns evidenced the presence of traces of α-Fe_2O_3 and BaO. No secondary phase reflections were detected in the case of the CA samples. As a general feature the widths of the main Ba hexaferrite reflections were smaller in the CA samples than in the CE ones, indicating that the milling process resulted in the introduction of a large amount of residual stresses. The morphology and particle size of the samples is illustrated in Figs. 2 and 3 where micrographs corresponding to the CA-1 and CE-18 samples are presented.

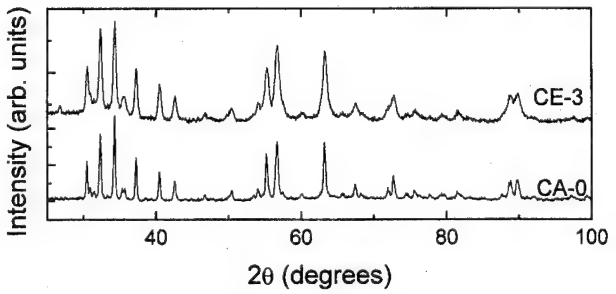

FIG. 1. X-ray diffraction patterns recorded in the CA-0 and CE-3 samples.

 0021-8979/96/79(8)/5955/3/$10.00

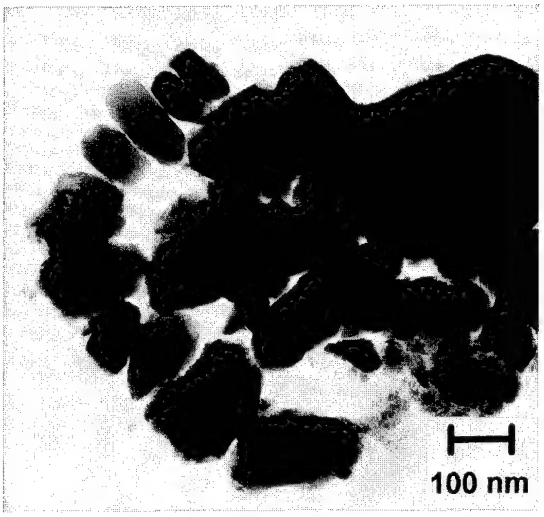

FIG. 2. Transmission electron micrograph (bright field) showing particles of the CA-1 sample.

Both kinds of samples were formed by platelike particles with more or less rounded corners: The particles appeared to be packed at random although in some cases (see Fig. 2) chainlike structures as well as ringlike ones, evidencing interparticle dipolar coupling, were observed. From the micrographs, the average plate diameter was estimated to be 65 $\pm$20, 150$\pm$50, 300$\pm$95, 800$\pm$120, and 1800$\pm$250 nm for the CA-0, CA-1, CE-3, CE-8, and CE-18 samples, respectively. It is interesting to note that the single-domain critical size of Ba hexaferrite particles has been estimated to be 900 nm.[3] The particle size dependence of the specific magnetization of the samples measured under an applied field of 5 T is plotted in Fig. 4. The values obtained in the CA-1 and CE-18 samples are close to the saturation value measured in Ba hexaferrite single crystals (68 A m^2 kg^{-1}).[3] The differences with this value observed in the CA-0, CE-3, and CE-8 samples are related to incomplete saturation (linked to defects and residual stresses) and/or to the presence of secondary nonmagnetic phases. The hysteresis loops of all the measured samples evidenced the occurrence of some degree of reversible demagnetization. To take this fact into account we measured, in addition to the conventional coercive force, H_c, the so-called critical field, H_{crit}, defined as that for which the

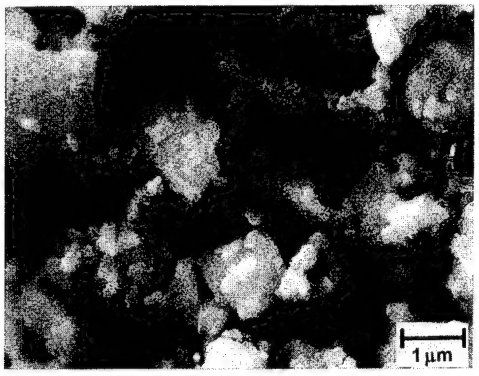

FIG. 3. Scanning electron micrograph showing particles of the CE-18 sample.

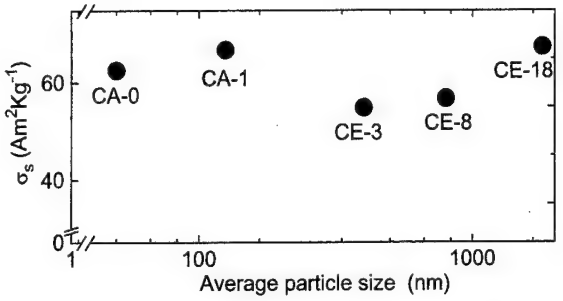

FIG. 4. Particle size dependence of the 5 T specific magnetization of our samples.

maximum of the differential susceptibility measured along the demagnetizing branch of the loop was observed and giving specific information about the irreversible demagnetization processes[1] (H_c and H_{crit} should coincide in a highly textured sample). As is shown in Fig. 5, where we present the room temperature dependence of H_c and H_{crit} on the particle size, both quantities (as well as their difference) increased with a decrease of the particle dimensions. As shown in Fig. 6, where we present the temperature dependence of the critical field of all the samples, this particle size dependence of the coercivity was observed for all the temperatures in the studied range (the weak temperature dependence of the critical field should be linked to that of the anisotropy field, showing a shallow minimum at 100 K).[4]

The study of the magnetic viscosity was carried out, at temperatures in the range from 4.2 to 300 K, by saturating the samples under a field of 5 T and then applying demagnetizing fields (of the order of H_{crit}) which were kept constant for 2000 s. During this time the magnetization of the samples was continuously recorded. In all cases, we observed a linear dependence of the magnetization on the logarithm of the time [$M(t)$=constant$-S$ ln t] in the range from 200 to 2000 s. The evaluation of the viscosity parameters,[5] i.e., the magnetic viscosity S_v ($S_v=S/\chi_{\text{irr}}$, where χ_{irr} is the irreversible susceptibility) and the activation volume v_{ac} ($v_{\text{ac}}=k_BT/\mu_0 M_s S_v$), was carried out following a method compatible with the magnetic equation of state discussed in Ref. 5. Figure 7 presents the temperature dependence of v_{ac} in all our samples. The inset of Fig. 7 presents the particle size dependence, evaluated at 200 K, of the diameter, d_{ac}, corresponding to the activation volume (assumed to be

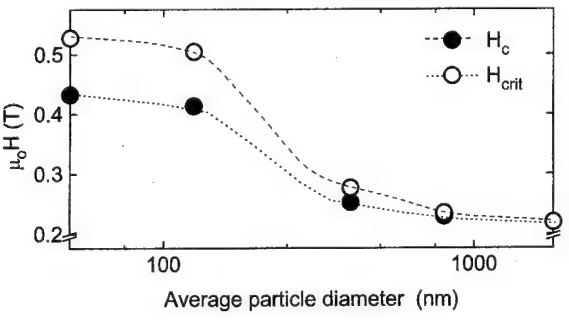

FIG. 5. Particle size dependence at 295 K of H_c and H_{crit}.

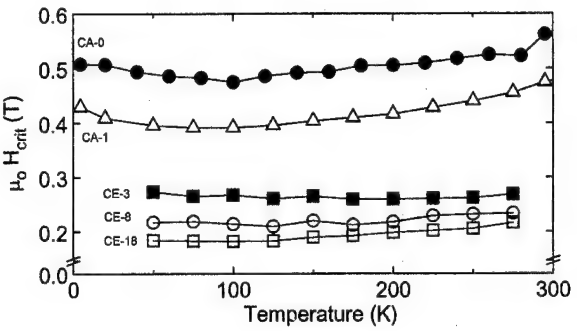

FIG. 6. Temperature dependence of H_{crit} in all the samples.

spherical). Interestingly, that dependence is characterized by the occurrence of a minimum at particle sizes of the order of the hundreds of nm.

IV. DISCUSSION

We attribute the observed difference between the H_c and the H_{crit} values to the isotropic character of the samples (the reduced remanence of all them was slightly above the 0.5 value corresponding to isotropic systems);[6] the widening, associated with the reduction of the particle size, of the distribution of local reversal fields and the occurrence of some degree of collective demagnetization (which, according to the similar values of H_c and H_{crit} should be particularly relevant in the case of the CE-18 sample). The measured particle size dependence is incompatible with a magnetization reversal ruled by coherent rotation. Two other reversal mechanisms can be consistent with that dependence (there is no microstructural evidence of the occurrence of effective pinning centers in Ba hexaferrite samples): (1) nucleation (coercivity ruled by the energy required to originate the first departure from saturation;[7] this mechanism is conceivable in both the small and the large particles) and (2) propagation (coercivity ruled by the energy associated with the achievement of the conditions of steady propagation of a preexistent wall limiting a reversed nucleus,[1] a mechanism which due to the relative dimension of domain walls and particles is solely conceivable with large particles). For these two mechanisms the increase of coercivity associated with the particle size decrease will be linked to the decrease of the number of defects per particle (these defects located at the surface region could allow a reduction of the field required to form a reversed magnetization nucleus or to propagate a wall).

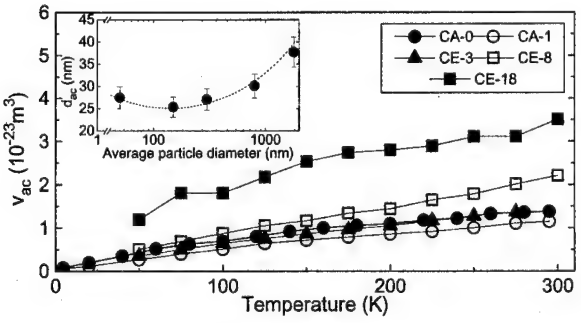

FIG. 7. Temperature dependence of the activation volume measured in all the samples. Inset: particle size dependence, at 200 K, of the diameter (d_{ac}) corresponding to a spherical activation volume of the measured magnitude.

The activation volume gives a measure of the size of the region of the samples which is involved in thermally activated demagnetization. It can be identified with the volume of the magnetization inhomogeneity leading to the reversal (nucleation mechanism) and with the reversed area existing prior to wall propagation.[1] In this sense it is interesting to remark that the activation volume measured in all our samples was clearly lower than the average volume of the particles and that, despite the fact that the volume of the CE-18 particles was three orders of magnitude larger than that of the CA-0 ones, the corresponding activation volumes differed by a factor of less than 4. As was already mentioned, a minimum was observed in the particle size dependence of the transverse dimension of the activation volume and, concretely, our estimation of that quantity in the CA-1 (single-domain type) and CE-3 (mixture of single-domain and multidomain particles) samples, yielded very similar values, despite the fact that these two samples were prepared using different methods. Considering this and the differences observed in the critical field values of the CA and CE samples, we propose the occurrence of different demagnetization mechanisms in both kinds of samples. In agreement with the coercivity analysis presented by the authors,[8] where the temperature dependence of the critical field of the CE samples was analyzed, we propose wall propagation as the basic reversal mechanism of the larger (CE) particles and suggest the occurrence of a nucleation ruled process in the smaller (CA) samples.

Rare earth–cobalt (RCo, R=Sm, Pr) films with thicknesses from 30 to 700 nm have been prepared with and without a Cr underlayer by dc magnetron sputtering from a R_2Co_7 composite target. The as-deposited SmCo films with a Cr underlayer (SmCo‖Cr) have magnetic coercivities of about 500–2800 Oe and the PrCo‖Cr films have coercivities of about 100–300 Oe, but after annealing at 500 °C coercivities as high as 31 kOe for SmCo‖Cr films and 10 kOe for PrCo‖Cr films were observed. The as-deposited PrCo films are composed mostly of an amorphous phase with about 30 vol % of crystallites but after annealing at 500 °C the film is transformed completely to crystallites of about 10 nm diameter as revealed by high-resolution transmission electron microscopy (HRTEM). Nanodiffraction and HRTEM studies show that the crystallites have a closed-packed hexagonal structure. HRTEM study also shows that the annealed SmCo films with a Cr underlayer have grain sizes of about 20 nm and the SmCo films without the Cr underlayer have grain sizes of about 10 nm. The large increase in coercivity for the annealed films is due to the growth of the crystallites. [S0021-8979(96)33808-1]

INTRODUCTION

Thin films of hard magnetic materials such as rare earth–transition metal alloys are of interest for device applications and magnetic recording media. Among rare earth semi-hard magnetic films, SmCo films with a Cr underlayer prepared at room temperature with high magnetic coercivity (H_c) of 3–4 kOe, small grain size and high uniaxial anisotropy have shown good potential for high density recording media.[1–3] Velu *et al.*[4] have shown that $SmCo_4$ films on a Cr underlayer have a coercivity value of 3 kOe at room temperature. Recently, Okumura *et al.*[5] reported H_c of about 3.5 kOe for $Sm_{15}Co_{85}$‖Cr films. Liu *et al.*[6–8] reported systematic studies of the microstructure of SmCo‖Cr films including the Cr underlayer, SmCo layer, and the nanocrystallites in the SmCo layer. The dependence of H_c on the SmCo composition[1–3] is unclear but it has been shown that the H_c strongly depends on the sputtering condition such as substrate temperature and Ar pressure during deposition of Cr and SmCo. This dependence may be related to the microstructure of the films. The Cr underlayer helps to increase the coercivity by controlling the grain size and morphology of the SmCo layer and also improves the in-plane magnetization. Hence if crystallinity and grain growth is promoted in the SmCo layer a much higher value of coercivity can be obtained. This can be achieved by either depositing the film at high substrate temperature or by post-annealing the as-deposited films. A coercivity of 30 kOe was obtained for 4000-Å-thick $Co_{3.65}Cu_{1.35}Sm$ films prepared at substrate temperature of 600 °C by Theurer *et al.*[9] Cadieu *et al.*[10] have shown that $SmCo_5$ films directly crystallized on to a heated substrate have H_c of about 23 kOe. The reason for this high coercivity was associated with the high magnetic anisotropy and the fine grain structure.

In the rare earth–cobalt system the low Co phase adjacent to $SmCo_5$ is in general of the Sm_2Co_7 type which has reasonably high anisotropy field $H_A>200$ kOe.[11] The PrCo compounds also feature excellent intrinsic magnetic properties comparable to the SmCo compounds. The Pr_2Co_7 phase has $H_A>100$ kOe[11] and the Pr_5Co_{19} phase has $H_A>38$ kOe.[12] In this work we report the effect of post-annealing for Pr_2Co_7 and Sm_2Co_7 films with and without the Cr underlayer.

EXPERIMENTAL PROCEDURE

R_2Co_7 (R=Sm, Pr) films with thickness from 30 to 700 nm were prepared with and without a Cr underlayer by dc magnetron sputtering from a composite target. All the films have a Cr overlayer of 10 nm to protect the RCo layer. The Sm_2Co_7 target was made by pressing the Sm_2Co_7 powder and then sintering in vacuum at 1100 °C for 30 min and the Pr_2Co_7 target was made by pressing the Pr_2Co_7 powder and then sintering in vacuum for 30 min at 1050 °C. The Cr target was obtained commercially and had a 99.9% purity. The base pressure of the sputtering system was 5×10^{-8} Torr and the Ar pressure during sputtering was 20 mTorr. The sputtering rate for Pr_2Co_7 and Sm_2Co_7 was 1.1 Å/s and for Cr was 5 Å/s.

The magnetic properties of the films were measured with an alternating gradient force magnetometer (AGFM) and SQUID magnetometer. The composition of the films was analyzed by energy dispersive x-ray analysis (EDAX) and was found to be close to the target composition. The structure was studied by x-ray diffraction and high resolution electron microscopy (HRTEM).

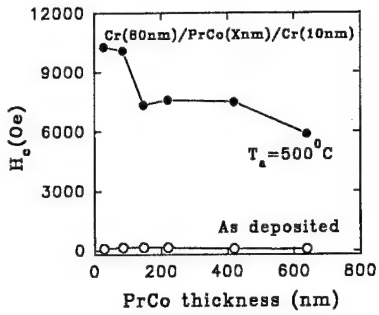

FIG. 1. Coercivity vs PrCo layer thickness for the as-deposited and annealed at 500 °C PrCo‖Cr films with a Cr underlayer of 80 nm.

RESULTS AND DISCUSSION

We first discuss the magnetic and structural properties for the as-deposited and annealed PrCo films. Figure 1 shows the dependence of the coercivity on the PrCo layer thickness for the PrCo‖Cr films with a Cr underlayer of 80 nm. The as-deposited films show a coercivity of only about 100–300 Oe but after annealing at 500 °C in vacuum for 20 min there is a large enhancement of coercivity. The H_c of the films annealed at 500 °C decreases from about 10 to 5.9 kOe as the film thickness increases from 28 to 640 nm. It was also observed for the 28-nm-thick PrCo‖Cr film that upon annealing up to 350 °C, H_c was nearly unchanged but at 400 °C H_c increased drastically to about 7.7 kOe[13] and at 500 °C the H_c reached about 10 kOe. A bright-field TEM micrograph of the 28-nm-thick PrCo‖Cr film annealed at 500 °C is shown in Fig. 2. The as-deposited films are composed of a mostly amorphous PrCo layer with about 30% volume fraction of crystallites and have small coercivity values because of the mostly amorphous PrCo layer. The film annealed at 500 °C shown in Fig. 2(a) contains nearly 100% crystallites with a grain size of 10 nm resulting in the large increase in the coercivity. The x-ray diffraction pattern of the as-deposited 420-nm-thick PrCo film only shows the (110) diffraction peak of bcc Cr and no PrCo peaks are observed for the films with and without the Cr underlayer. This is due to the large amount of amorphous phase and small crystallites in the PrCo films. After annealing at 500 °C the PrCo layer is crystallized and we observe a few sets of peaks from the x-ray diffraction pattern. The two most intense reflections are observed for 2θ=35.5° and 2θ=42°. It is difficult to identify the crystal structure unambiguously from the x-ray diffraction pattern because of the limited number of peaks and the several possible phases around the Pr/Co atomic ratio of 3.5, these include the $PrCo_3$, Pr_2Co_7 and Pr_5Co_{19} phases. The detailed crystal structure of the annealed 28-nm-thick PrCo‖Cr film was then investigated by nanodiffraction and HRTEM. It was found that the crystallites as shown in Fig. 2(b) have a hexagonal closed packed structure with frequent stacking faults. The nanodiffraction pattern can be well matched to the hexagonal closed packed structure.

In order to investigate whether the Cr underlayer was crucial for the enhancement of coercivity after annealing we compared the magnetic properties of a 420-nm-thick PrCo film with and without a Cr underlayer. It was observed that for the 420-nm-thick PrCo film with no Cr underlayer but

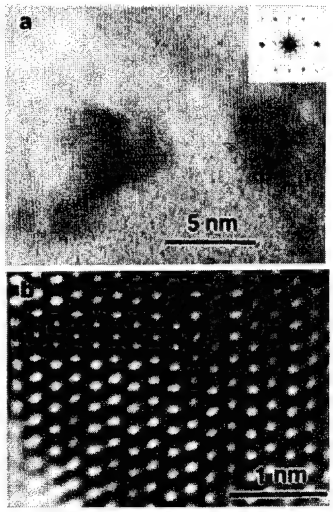

FIG. 2. (a) HRTEM image of Cr(80 nm)/PrCo(28 nm)/Cr(10 nm) film annealed at 500 °C. (b) HRTEM image of a crystallite in (a).

with a Cr overlayer of 10 nm the H_c was about 9 kOe and $M_S \approx 400$ emu/cc after annealing at 500 °C whereas for the 420-nm-thick PrCo film with a Cr underlayer of 80 nm and a Cr overlayer of 10 nm the H_c was about 7.5 kOe and $M_s \approx 300$ emu/cc after annealing at 500 °C. Both the samples have squareness $S(M_r/M_s)=0.8$, but the coercivity squareness S^* for the film with the Cr underlayer was 0.7 and for the film without the Cr underlayer the S^* was about 0.35. Hence we show that if crystallinity and grain growth are promoted a large increase in coercivity can be obtained for the PrCo films with and without the Cr underlayer, except that the films with a Cr underlayer have a better hysteresis loop squareness.

Next we report the magnetic properties of the as-deposited and annealed SmCo films with and without the Cr underlayer. Figure 3 shows the dependence of the coercivity on the SmCo layer thickness for the SmCo‖Cr films with and without the Cr underlayer. The as-deposited films show H_c of about 500–2800 Oe but after annealing at 500 °C for 20 min in vacuum there is a large increase in coercivity. The coercivity of the films with the Cr underlayer of 80 nm and a Cr overlayer of 10 nm annealed at 500 °C varies from 21 to 29 kOe with the maximum coercivity value obtained for 100-nm-thick SmCo film. The H_c of the SmCo film without the

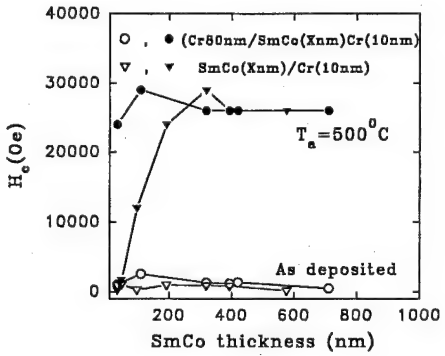

FIG. 3. Coercivity vs SmCo layer thickness for the as-deposited and annealed at 500 °C SmCo films with and without a Cr underlayer.

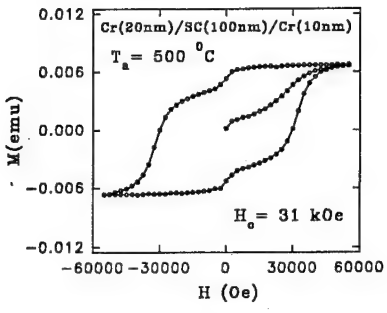

FIG. 4. Hysteresis loop for the 100-nm-thick SmCo film with a Cr underlayer of 20 nm annealed at 500 °C.

Cr underlayer but with a Cr overlayer of 10 nm after annealing at 500 °C shows a large increase in coercivity only for SmCo films with thickness of at least 100 nm and above. A maximum H_c value of 29 kOe is obtained for 300-nm-thick SmCo film. For films without the Cr underlayer and SmCo layer thickness less than 100 nm the reason for no remarkable increase in coercivity after annealing is not clear at this point. This behavior is also observed for the PrCo film with thicknesses less than 100 nm and no Cr underlayer. The M_s of the as-deposited SmCo films is about 400 emu/cc and after annealing at 500 °C the M_s value for the films with the Cr underlayer of 80 nm is about 200 emu/cc and for the films without the Cr underlayer the M_s is about 300 emu/cc. For the SmCo films with a Cr underlayer thickness less than 80 nm there is not a significant change in the coercivity but the M_s value of the films is slightly higher compared to the films with a Cr underlayer of 80 nm. For the 100-nm-thick SmCo film with a Cr underlayer of only 20 nm the M_s was about 250 emu/cc and the H_c was about 31 kOe after annealing at 500 °C. The hysteresis loop for the annealed 100-nm-thick SmCo film with a Cr underlayer of 20 nm measured with a maximum applied field of 55 kOe parallel to the film surface is shown in Fig. 4. The film shows a coercivity of 31 kOe.

Liu *et al.*[6] have observed that for the as-deposited films the Cr underlayer has grain size of about 24 nm and the SmCo layer consist of nanocrystallites about 5 nm diameter embedded in an amorphous matrix. Figure 5 compares the dark field images taken from the SmCo films with and without a Cr underlayer. The film with the Cr underlayer has grain sizes of about 20 nm while the film without the Cr underlayer has grains sizes of about 10 nm. Nanodiffraction and HRTEM study to determine the crystal structure of the annealed films is in progress. The reason for the large enhancement in coercivity after annealing is very likely due to the crystallization of the SmCo grains.

CONCLUSION

In this work we have shown that 28-nm-thick PrCo films with a Cr underlayer of 80 nm after annealing at 500 °C have in-plane coercivity as high as 10 kOe, $S=0.9$ and $S^*=0.75$. The PrCo‖Cr films have magnetic properties and microstructure which show potential as high density recording media. Nanodiffraction and HRTEM studies show that the crystallites in the annealed film have a hexagonal closed packed

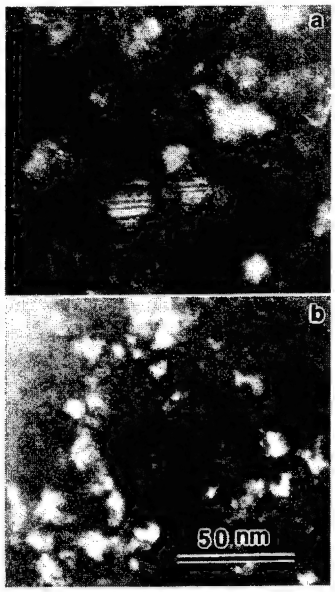

FIG. 5. Comparison of dark field images taken from a SmCo films (a) with the Cr underlayer and (b) without the Cr underlayer.

structure with frequent stacking faults. The enhancement of H_c after annealing is likely due to the crystallization of the PrCo grain.

After annealing at 500 °C H_c as high as 31 kOe was obtained for 100-nm-thick SmCo film with a Cr underlayer of 20 nm and H_c of about 29 kOe for 300-nm-thick SmCo film without the Cr underlayer. By post-annealing the as-deposited films with and without the Cr underlayer, crystallization, and grain growth is promoted for the SmCo films resulting in a large increase in coercivity.

High-temperature magnetic properties of $TbCu_7$-type SmCo-based films

H. Hegde, X. R. Qian, Jong-Guk Ahn, and F. J. Cadieu
Physics Department, Queens College of CUNY, Flushing, New York 11367

In applications where large remanent moments and energy products are required at elevated temperatures, SmCo-based permanent magnets provide the best properties. In addition to their high Curie points, these SmCo-based ordered phases of 1-5, 2-17, and the disordered 1-7 phase show large uniaxial anisotropies at elevated temperatures. We have now measured the high-temperature hysteresis properties of single-phase $TbCu_7$-type SmCo-based permanent magnet films. Such single-phase samples have the advantage that optimal magnetic properties can be obtained from the as-sputtered films without any subsequent heat treatments. Normally bulk samples in this composition range form the two phase cellular structure whose magnetic properties are very sensitive to heat treatments. Single-phase $TbCu_7$-type films of composition $Sm_{13}Co_{58}Fe_{20}Cu_7Zr_2$ were sputter synthesized such that the crystallite c axes were oriented in the film plane. The net anisotropy field of the films remained larger than the maximum applied field of 18 kOe even at the highest measurement temperature of 460 °C. Thus all measurements were from minor hysteresis loops. The in-plane coercivity showed a monotonic decrease from 6.0 kOe at room temperature to 1.3 kOe at 460 °C. The in-plane remanent flux density decreased from 8.5 kG at 50 °C to 5.8 kG at 460 °C. [S0021-8979(96)33908-8]

Permanent magnets of the rhombohedral-based $Sm_2(CoFeZrCu)_{17}$ type are attractive for high-temperature applications because of their high ferromagnetic Curie point, high saturation magnetization, and high-energy product.[1,2] These magnets exhibit a cellular structure of rhombohedral 2-17 phase and 1-5 type grain boundaries.[3] As a result, the structural and magnetic properties of these magnets are very sensitive to the heat treatments required to develop coercivity. It has been shown that single-phase $TbCu_7$-type film magnets of Sm(CoFeCuZr) can be synthesized by sputtering nonepitaxially so as to exhibit strong in-plane c-axis alignment for a wide range of film thicknesses.[4,5] The structural properties of such films are insensitive to thermal treatments below 500 °C, making them extremely suitable for high-temperature applications. $TbCu_7$-type film magnets with magnetic easy axis in the film plane have been shown to be useful in magnetoresistive and magneto-optic devices,[6,7] whereas $Nd_2Fe_{14}B$-type films with magnetic easy axis perpendicular to film plane have been used in a millisize motor.[8] However, in applications at elevated temperatures, as a result of their relatively low Curie points the 2-14-1 type films are intrinsically inferior to the 1-7 type films. While there have been high-temperature studies of the hysteresis properties of bulk multiphase magnets of the type Sm(CoFeCuZr),[9,10] there have been no corresponding studies for single-phase $TbCu_7$-type magnets in either film or bulk form. In this article we present the high-temperature hysteresis properties of single-phase $TbCu_7$-type Sm(CoFeCuZr)-based film magnets.

The films in this study were sputter synthesized from commercially available 2-17 bulk magnets of the type $Sm_2(CoFeCuZr)_{17}$. The films were sputter deposited on polycrystalline Al_2O_3 substrates in 80 mTorr of Ar. The film composition was $Sm_{13}Co_{58}Fe_{20}Cu_7Zr_2$. Film deposition temperature was around 350 °C, so that the $TbCu_7$-type phase was formed with the c axis of the crystallites randomly aligned in the film plane. These films needed no post-deposition heat treatments to obtain optimum magnetic hysteretic properties. Further details of film synthesis, crystallographic details, microstructure, and room-temperature magnetic properties have previously been published.[11] The high-temperature magnetic hysteresis measurements were made using a PAR model 151 high-temperature oven attached to a vibrating sample magnetometer. The temperature readings were calibrated against measurements made on a standard Ni sample. While no protective overcoating of the films was used, a positive flow of He gas was used in the high-temperature oven to shield against contamination as much as feasible.

In Fig. 1 hysteresis loops of a film at a temperature of 50 °C for applied field directions in the film plane (solid line) and perpendicular to the film plane (dashed line) are shown. In Fig. 2 similar measurements at a temperature of 250 °C are shown. The in-plane loop measured at 250 °C exhibited a slight shoulder on entering the second quadrant. Such a shoulder was more pronounced in thinner samples. The

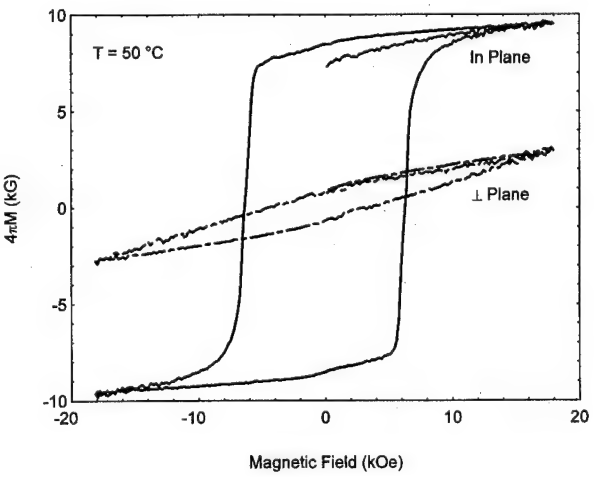

FIG. 1. Magnetic hysteresis loops at 50 °C, for measurements in-plane and perpendicular to film plane.

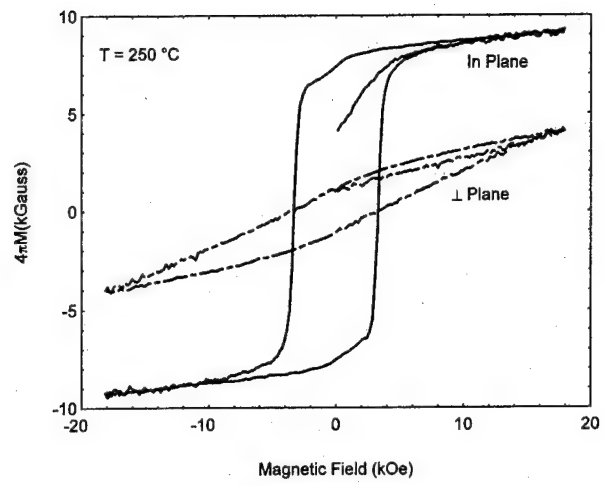

FIG. 2. Magnetic hysteresis loops at 250 °C, for measurements in-plane and perpendicular to film plane.

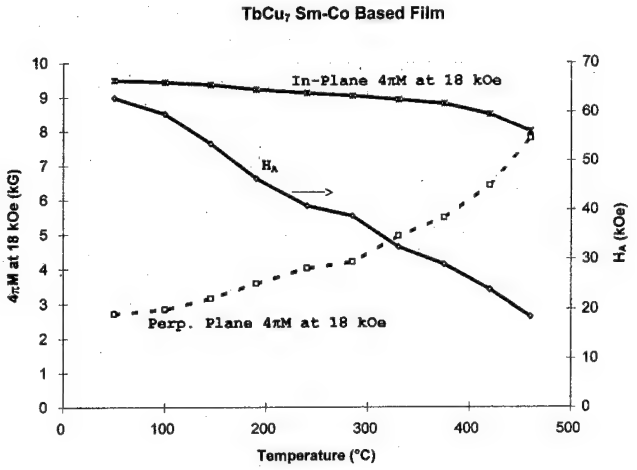

FIG. 4. Temperature dependence of in-plane and perpendicular to film plane flux densities at an applied field of 18 kOe (left axis). Temperature dependence of estimated anisotropy field H_A (right axis).

shoulder is believed due to surface contamination in the high-temperature oven since the film coercivity was unchanged upon thermal cycling to 460 °C. This is shown in Fig. 3 which shows in-plane measurements at room temperature, before and after the sample was subjected to 460 °C high-temperature oven measurements. In films that were subjected to a similar 460 °C thermal cycling in a high vacuum chamber pumped to $\sim 2\times 10^{-7}$ Torr, no hysteresis loop deterioration was observed on remeasuring the loop at room temperature. Instead, such loops only reproduced the before thermal cycling loop. This showed that the high-temperature oven sample deterioration was a result of residual gases causing surface contamination.

Figure 4 shows the magnetic flux density of a SmCo-based $TbCu_7$ film as a function of the temperature, measured in-plane and perpendicular to the plane for an applied field of 18 kOe. Figure 4 also shows the variation of the estimated effective anisotropy field H_A as a function of temperature.

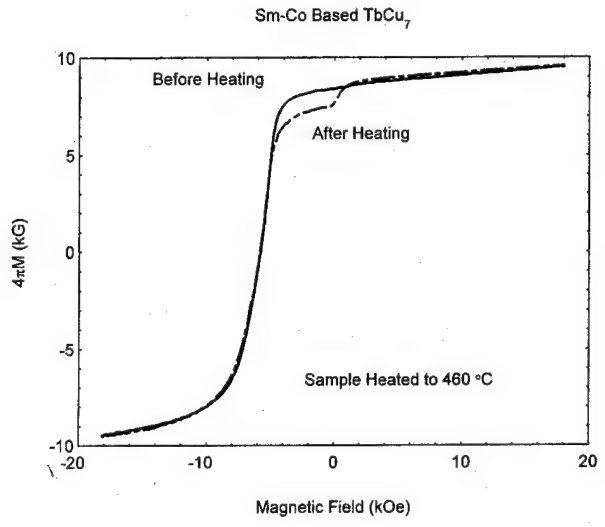

FIG. 3. In-plane hysteresis measurements on a film at room temperature, before and after the sample was subjected to 460 °C high-temperature measurements in the magnetometer oven.

The films were so deposited as to have only crystallites with c-axis in-plane orientation, thus making the perpendicular to the plane direction the magnetocrystalline hard axis. In addition, since the planar dimensions are much larger compared to film thickness, the shape anisotropy field in the perpendicular to the plane direction is simply $4\pi M$. Thus, for these films, the effective anisotropy field is the sum of shape anisotropy and magnetocrystalline anisotropy. From Fig. 4, it can be seen that while the effective anisotropy field H_A is around 65 kOe at 50 °C, it drops to around 40 kOe at 250 °C and around 19 kOe at 460 °C. Comparison of temperature variations of the anisotropy field and coercivity as shown in Fig. 4 and Fig. 5 reveals a strong linear correlation between the two. As seen in Fig. 5, the coercivity of the film decreased below 2 kOe above a temperature of 350 °C. Figure 5 also shows the remanent flux density as a function of the temperature, measured in-plane and perpendicular to the plane.

In conclusion, the high-temperature magnetic properties of single-phase $TbCu_7$-type SmCo-based permanent magnet films have been studied. The study shows that after thermal

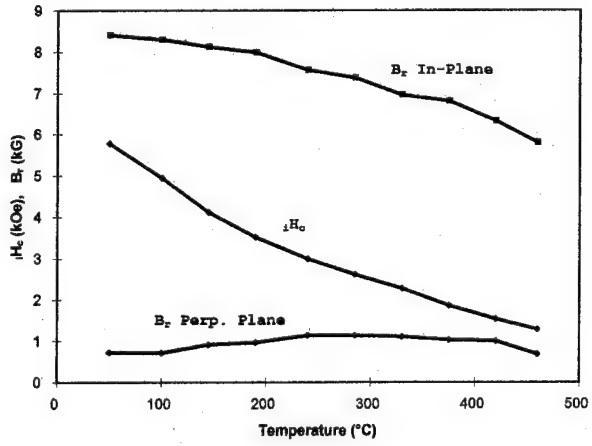

FIG. 5. Temperature dependence of in-plane coercivity $_iH_c$, in-plane B_r, and perpendicular to film plane B_r.

cycling to 460 °C, these films exhibited no decrease in coercivity. Decreases in room-temperature coercivity following similar thermal cycling has been observed for multiphase cellular structured SmCo-based 2-17 type bulk magnets.[12] Even at a temperature of 350 °C, the inplane coercivity of these films remained in excess of 2 kOe, while at the same temperature, the effective anisotropy was greater than 30 kOe.

Nanocomposite Sm_2Co_{17}/Co permanent magnets by mechanical alloying

S. K. Chen and J. L. Tsai
Department of Materials Science, Feng Chia University, Taichung, Taiwan, Republic of China

T. S. Chin
Department of Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan, Republic of China

Mechanically alloyed magnets $SmCo_x$ ($x=6.0-11.0$) have been prepared using starting materials of commercial $SmCo_5$ and Co powders. X-ray diffraction data indicate that the equilibrium Sm_2Co_{17} phase can be achieved in a nanocomposite Sm_2Co_{17}/Co system at $x=8.5-11.0$, while a $Sm_2Co_{17}/SmCo_5$ structure occurs at $x=6.0-8.0$. The best magnetic properties obtained at $x=10.0$ are as follows: $(BH)_{max}=10.2$ MGOe, $B_r=9.4$ kG, $H_c=4.0$ kOe, and $S=0.82$. Wohlfarth's remanence analysis indicates that the high remanence can be attributed to the intergranular interaction between neighboring cobalt and Sm_2Co_{17} grains. © *1996 American Institute of Physics.* [S0021-8979(96)34008-2]

I. INTRODUCTION

Nanocomposite permanent magnetic alloys have been studied extensively. The alloys include $Nd_2Fe_{14}B/\alpha$-Fe,[1–6] $Sm_2Fe_{17}N_3/\alpha$-Fe,[7] and Sm-Co,[8–10] which can be prepared by melt spinning, mechanical alloying (MA), and thin-film processes, etc. The remanence enhancement for the isotropic nanocomposites have been discussed in terms of exchange coupling between two suitably dispersed magnetically hard and soft phases.[11] The two-phase alloys may have potential applications in resin bonded magnets due to the advantages of cost saving and high-energy product. However, the saturation magnetizing field of nanocomposite alloys is still high (close to that of some MQ powders) in spite of the moderate coercivity.

In this article, we will report nanocomposite $SmCo_x$ alloys with high-energy product and acceptable magnetizability. Efforts are focused on the range of $x=8.5-11.0$, because experimental data of the MA powders indicate the existence of the equilibrium Sm_2Co_{17}, which is not easy to obtain using melt spinning or thin-film process. The alloys is easy to magnetize because the magnetic anisotropy constant K_1 of Sm_2Co_{17} (3.3 MJ/m^3) is lower than that of $Nd_2Fe_{14}B$ (5.0 MJ/m^3) in the popular $Nd_2Fe_{14}B/\alpha$-Fe system. Moreover, the Sm_2Co_{17}/Co alloys should possess the highest magnetization in the binary Sm-Co system.

II. EXPERIMENT

Commercial powders of cobalt (1.47 μm) and prealloyed $SmCo_5$ (250 μm) were used as starting materials. The powders were ball milled in a cylindrical steel container using a planetary vibration mill, which was operated in air. To maintain an inert atmosphere during mechanical alloying, a vacuum valve was mounted into the cover of the container. Through the valve, the container was evacuated to a high vacuum of about 10^{-5} Torr, then purged with a positive pressure (2 atm) of high-purity Ar. The vacuum tubes were finally disconnected from the container before ball milling. The MA powders were annealed at 700–900 °C for 20 min in Ar for crystallization. The existing phases of the annealed powders were identified with an x-ray diffractometer.

Vibrating sample magnetometer (VSM) samples were prepared by dispersing the powder in molten wax in a sample capsule. Magnetic properties were measured at room temperature in a maximum field of 20 kOe. Dc− demagnetized samples, as described by Vajda and Torre,[12] were used for Wohlfarth's remanence analysis.

III. RESULTS AND DISCUSSION

Figure 1 shows the x-ray diffraction patterns of mechanically alloyed powders $SmCo_x$ ($x=6.0-11.0$). The samples were annealed at 900 °C for 20 min. For the cobalt-rich samples with $x=8.5-11.0$, a two-phase Sm_2Co_{17}/Co structure appears. A small amount of free Co is still visible in the stoichiometric Sm_2Co_{17} samples. For $x<8.5$, $SmCo_5$ coexists with Sm_2Co_{17}. No free cobalt was observed in the high-Sm alloys. The grain sizes of cobalt was estimated to be less than that of Sm_2Co_{17}. Both phases have a grain size of

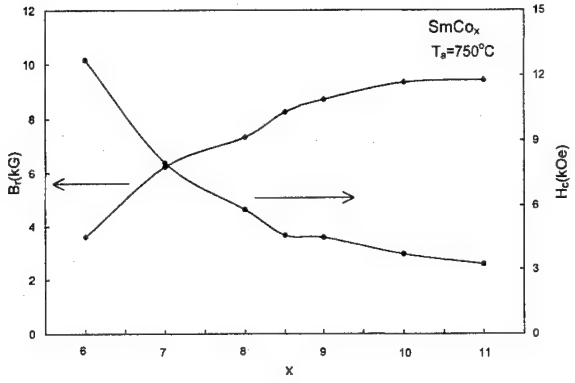

FIG. 2. Composition dependence of coercivity H_c and remanence B_r for mechanically alloyed $SmCo_x$ after milling for 16 h and a subsequent annealing at 750 °C for 20 min.

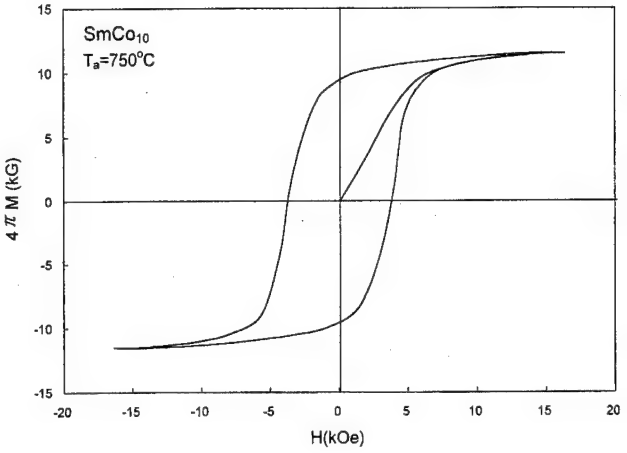

FIG. 3. Magnetic hysteresis loop of mechanically alloyed $SmCo_{10}$.

tens of nanometers, depending on the annealing temperatures. However, the grain sizes are beyond the limit of precise measurements using Scherrer formula.

Composition dependence of the coercivity H_c and the remanence B_r for $SmCo_x$ ($x=6.0-11.0$) is indicated in Fig. 2. The coercivity decreases with increasing x. For the low-Sm alloys ($x=8.5-11.0$), the decrease in H_c may be attributed to the change in the morphology of the cobalt phase in the Sm_2Co_{17} phase, which needs further study using a transmission electron microscope (TEM). The measured values of H_c (4–5 kOe) for $SmCo_x$ ($x=8.5-10.0$) is close to some grades of commercial Sm_2TM_{17} magnets, although the Sm-Co alloys contain no precipitation hardening elements, such as Cu and Zr. Coercivity mechanism of this Sm_2Co_{17}/Co system can be explained by the domain-wall pinning effect from the cobalt precipitates or the grain boundaries of the Sm_2Co_{17} phase, as studied using Gaunt's model. For the high-Sm alloys ($x=6.0-8.0$), the high coercivity is obviously due to the existence of high-anisotropy $SmCo_5$. Sm-rich system was previously reported by Ding and Wecker *et al.*[8,9]

The variation of B_r values with cobalt contents is also shown in Fig. 2. A maximum value of 9.4 kG was achieved for the samples with $x=10.0$. The high remanence, which is approximately equal to the typical value of some MQ powders, is due to the existence of cobalt phase, of which the $4\pi M_s$ value (18 kG) is about 40% higher than that of Sm_2Co_{17} (13 kG).

The magnetic hysteresis loop of the $SmCo_{10}$ alloys is shown in Fig. 3. The magnetic properties are measured to be as follows: $B_r=9.4$ kG, $H_c=4.0$ kOe, $(BH)_{max}=10.2$ MGOe, and squareness ratio $(M_r/M_s)=0.82$. The alloy is calculated to contain 12 vol. % cobalt and 88 vol. % Sm_2Co_{17}. The high remanence and squareness ratio can result from the exchange interaction between neighboring Sm_2Co_{17} and Co grains, so-called exchange-spring magnet.[11] However, the remanence and energy product remain the possibility for further improvement, considering the $SmCo_{10}$ alloy has a theoretical saturation magnetization of 13.6 kG.

To understand if the remanence enhancement is related to the interaction between neighboring grains, we investigate the $SmCo_{10}$ and Sm_2Co_{17} samples using Wohlfarth's well-known remanence relationship[13,14]

$$m_d(H)=1-2m_r(H), \tag{1}$$

where $m_r(H)$ means the isothermal remanence which was normalized by the remanence obtained at a maximum field of 20 kOe, and m_d means the normalized dc demagnetization. The staring samples were dc− demagnetized before m_r and m_d measurements. The plots of m_r vs m_d, so-called Henkel plots,[15] were applied to the $SmCo_{10}$ and Sm_2Co_{17} samples, as indicated in Fig. 4. A linear relationship with a slope of $-1/2$, as shown in Eq. (1), should hold for a noninteracting system during magnetization or demagnetization processes.[16] In the case of the $SmCo_{10}$ sample, the Henkel plot shows a large deviation from linear Wohlfarth relationship, which can be the result from the exchange coupling between the neighboring Sm_2Co_{17} and Co grains. For the Sm_2Co_{17} sample, which shows a nearly single-phase structure, the smaller deviation from Eq. (1) can be due to the different nature of interaction arising from different microstructures.

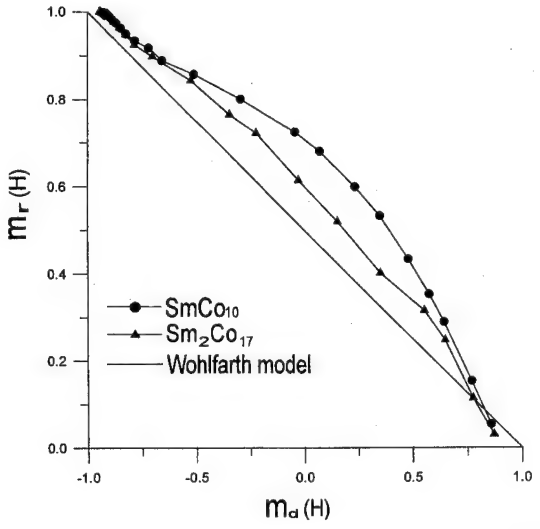

FIG. 4. Wohlfarth's remanence analysis for mechanically alloyed $SmCo_{10}$ and Sm_2Co_{17}. The diagonal represents the ideal case according to Eq. (1).

To precisely explain a Henkel plot, the demagnetization states of the sample should be well defined. The effect of demagnetization states (including dc−, dc+, and ac demagnetized states) on Henkel plots have been studied using Preisach models.[12] In our case, a dc− demagnetized state appears to be suitable for the analysis of exchange interaction. Wohlfarth's remanence analysis for various demagnetized Sm-Co samples will be discussed elsewhere.

Growth of epitaxial films of the $L1_0$ phase of FePt, with the tetragonal c axis along either the film normal or in-plane, is described. Films were grown by coevaporation of Fe and Pt, under ultrahigh vacuum conditions, onto a seed film of Pt grown on MgO or $SrTiO_3$ substrates. The perpendicular or in-plane orientation of the c axis was controlled by selecting the (001) or (110) substrate plane, respectively. Nearly complete chemical ordering was achieved for growth at 500 °C for both orientations. Magnetic and magneto-optical characterization of these films confirmed the huge magnetic anisotropy expected for this phase. In the most highly ordered films, anisotropy fields in excess of 120 kOe were measured. © *1996 American Institute of Physics.* [S0021-8979(96)34108-9]

The magnetic and magneto-optical properties of intermetallic FePt alloy films are of current interest. The magnetic anisotropy, and magneto-optical Kerr rotation of FePt both correlate[1] with the degree of chemical ordering and the magnetic anisotropy energy K_u is predicted[2] to reach a value of $>10^8$ erg/cc for complete ordering. This is one of the highest predicted[2] anisotropy energies of transition metal alloys and results from spin-polarization of the Pt $5d$ bands combined with the large spin-orbit coupling for Pt. Chemically ordered FePt films with their c axis oriented along the film normal have been prepared by annealing sputtered epitaxial films,[3] cosputtering onto heated substrates,[4] and by molecular beam epitaxy (MBE).[1,5] The c-axis normal configuration was obtained by growing FePt onto (001) Pt seed films on MgO(001) substrates to symmetry match the fourfold FePt basal plane with the Pt. The lattice misfits for FePt(001)/Pt(001) and Pt(001)/MgO(001) are -1.8% and -7.3%, respectively. Despite these large misfits FePt grows epitaxially with perpendicular mosaic spreads of only ~1°, as we report in this paper. Up until now, there have been no reports of growth of FePt epitaxy with the c axis in plane. In view of the technological interest[6] in $L1_0$ FePt films for longitudinal magnetic recording media, there is a need to control the orientation of the c axis. In this article we describe the growth and characterization of FePt films with the c axis either perpendicular or in-plane.

The films were grown by coevaporation in a VG Semicon V80M MBE system using e-gun sources for both Fe and Pt. The fluxes were controlled by Leybold Inficon Sentinel III rate monitors and film growth rates of Pt and FePt were ~0.1 and 0.2 Å/s, respectively. Film growth was characterized, *in situ* using both reflection high-energy electron diffraction (RHEED) and low-energy electron diffraction (LEED). Following growth, the films were characterized by x-ray diffraction, vibrating sample and torque magnetometry, and magneto-optical Kerr studies. MgO(001) and (110) substrates were supplied by Harrick Inc.; $SrTiO_3$(110) by Marketech Inc. They were polished on one side using a syton finish and prepared as described earlier[7] for sapphire substrates.

We have earlier reported[1] growth of FePt films on 150-Å-thick Pt template films on MgO(001) substrates. Much thinner Pt films also act effectively as templates for FePt(001) growth. Pt films ~7 Å thick, grown at a substrate temperature of 700 °C, exhibited "spotty" RHEED patterns, consistent with transmission electron diffraction through (001)-oriented Pt islands. Overgrowth of FePt[8] resulted in a progressive transition to elongated streaks in the RHEED pattern at ~100 Å consistent with growth of a smooth, con-

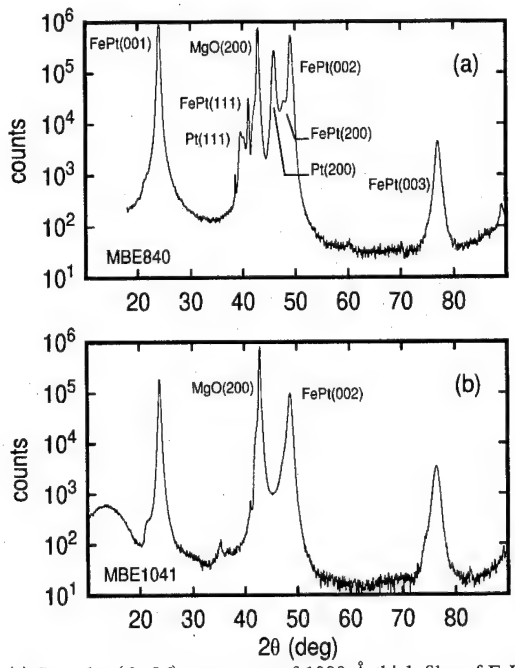

FIG. 1. (a) Specular (θ–2θ) x-ray scan of 1000-Å-thick film of FePt(001)/MgO(001). The complete structure was 18 Å Pt/$Fe_{0.52}Pt_{0.48}$/150 Å Pt/MgO(001). (b) Specular x-ray scan of 943-Å-thick film of FePt(001)/MgO(001). The complete structure was 18 Å Pt/$Fe_{0.50}Pt_{0.50}$/7 Å Pt/MgO(001).

TABLE I. Compositions, long-range order parameters and mosaic spread for FePt(001) films.

Seed film	FePt (%Fe)	S_{max}	S_{meas}	⊥ mosaic (°) (001)	⊥ mosaic (°) (002)	⊥ mosaic (°) (003)
150 Å Pt/MgO(001)	52	0.96	0.93±0.02	1.05	0.78	0.84
7 Å Pt/MgO(001	50	1.0	0.92±0.02	2.49	1.99	2.08

tinuous epitaxial (001)-oriented film. The RHEED pattern showed little change as the film increased in thickness from 100 to 1000 Å. Specular x-ray diffraction scans for FePt films with thick and thin Pt seed layers are shown in Figs. 1(a) and 1(b). The intense (001) and (003) superstructure peaks in both scans indicate a high degree of chemical ordering with the tetragonal c axis along the film normal. However, structural differences between the two samples are evident from these data. For example, minority structural domains with the tetragonal c axis in plane or inclined to the film plane are indicated by the presence of FePt(200) and (111) specular peaks, respectively, in Fig. 1(a) (thick Pt). For the film of Fig. 1(b) (thin Pt) these minority domains are absent. The long-range order parameter,[1] s, for the two samples was quantified using integrated intensities for the (001), (002), and (003) peaks extracted from fits to scans over these peaks using a high-resolution diffractometer. This procedure is described in detail elsewhere.[8] Here we point out that the mosaic spread of each of the peaks was included in the calculation and an experimental Debye–Waller factor (σ=0.136 Å) was used. Differences in mosaic spread for the superstructure and fundamental peaks are considerable and must be included in the calculation of S for meaningful results. The agreement between S determined from the (001)/(002) and (003)/(002) intensity ratios was within 4%. Table I summarizes film compositions, maximum possible order parameters at these compositions and perpendicular mosaic spreads (FWHM of rocking curves) for the (001), (002), and (003) peaks. The order parameter for both samples is close to the maximum possible values at the compositions stated.

FePt(110) films were prepared in two different ways. Initially, $SrTiO_3$(110) substrates were used with a seed film of 30 Å Pt(110). The growth of this structure has been described earlier.[9] Unfortunately, the cubic perovskite structure of $SrTiO_3$ gives rise to a (110) peak which makes extraction of the FePt(110) superstructure intensity imprecise. MgO has no (110) peak and was used as an alternative substrate. In this case a 7-Å-thick Pt seed film was used. RHEED studies[9] showed facetted Pt(110) film growth on the $SrTiO_3$ and islanded growth of Pt(110) on MgO(110). X-ray specular scans for films grown at 500 °C on $SrTiO_3$ and MgO are

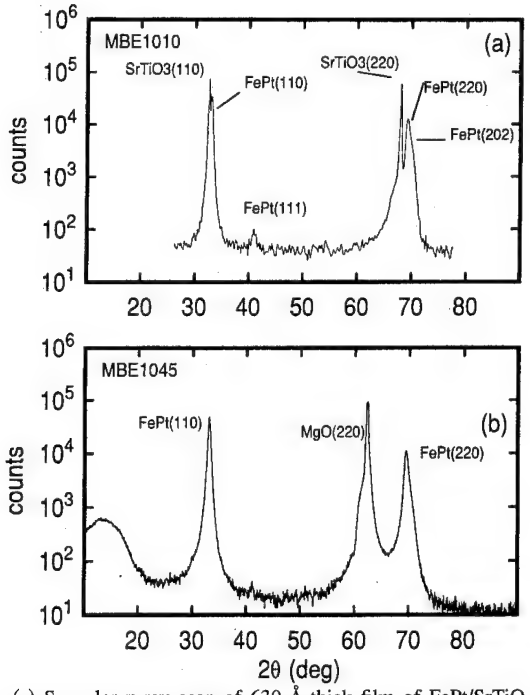

FIG. 2. (a) Specular x-ray scan of 630-Å-thick film of FePt/$SrTiO_3$(110). The complete structure was Pt 18 Å/$Fe_{0.56}Pt_{0.44}$/30 Å Pt/$SrTiO_3$(110). (b) Specular x-ray scan of 830 Å-thick film of FePt(110)/MgO(110). The complete structure was Pt 18 Å/$Fe_{0.58}Pt_{0.42}$/7 Å Pt/MgO(110).

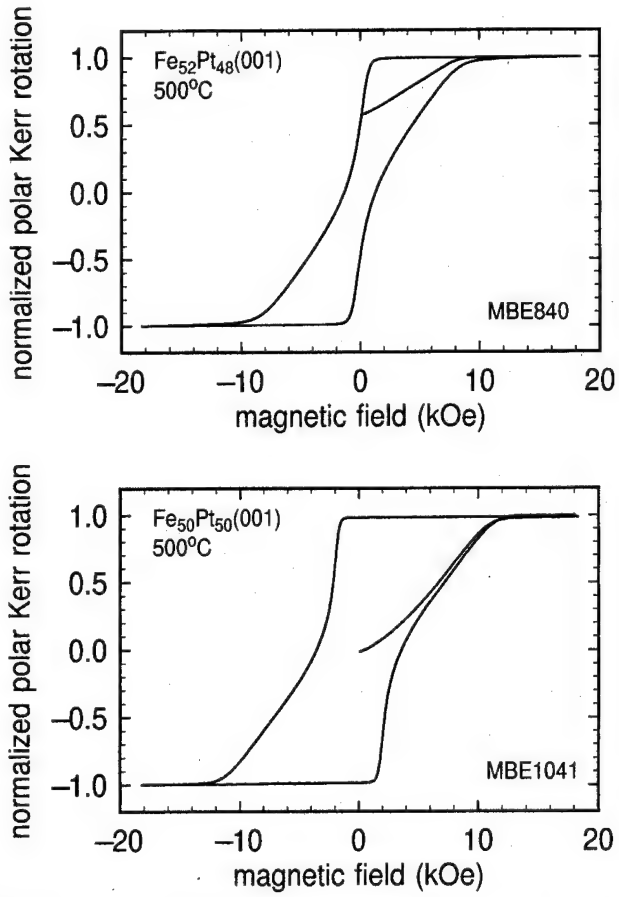

FIG. 3. Magneto-optical polar Kerr loops for FePt(001) films of Figs. 1(a) and 1(b). Laser wavelength 633 nm.

TABLE II. Compositions, long-range order parameters, perpendicular mosaic spread for FePt(110) films.

Seed film	FePt (%Fe)	S_{max}	S_{meas}	⊥ mosaic (°) (110)	⊥ mosaic (°) (220)
30 Å Pt/$SrTiO_3$(110)	56	0.88	0.78±0.10	1.70	1.45
7 Å Pt/MgO(110)	58	0.84	0.81±0.02	1.64	1.22

shown in Figs. 2(a) and 2(b), respectively. A high degree of chemical ordering in both samples is evident from the intense FePt(110) peak. However, in the $SrTiO_3$ sample, the FePt(110) peak appears as a shoulder on the $SrTiO_3$ peak. The majority orientation of both FePt films is FePt(110)‖$SrTiO_3$, MgO(110). In this orientation, the c axis of the FePt is oriented in the film plane. Both RHEED and x-ray diffraction confirm that: FePt[001]‖Pt, MgO, $SrTiO_3$[001], and FePt[1$\bar{1}$0]‖Pt, MgO, $SrTiO_3$[1$\bar{1}$0]. The presence of a strong FePt(202) shoulder, for the $SrTiO_3$ sample, reveals a minority structural domain with the tetragonal c axis inclined at ≃44° to the film plane. Peak fitting suggests that ~30% of the film volume is comprised of the minority domain. A small FePt(111) peak in Fig. 2(a) shows that this film also has a very weak (~0.1% of the sample volume) minority (111) orientation. The long-range order parameter for these two samples is given in Table II. Note that for the sample grown on MgO(110) the long-range order parameter is close to the maximum possible value.

Magneto-optical polar Kerr loops and M-H loops for the FePt(001) samples of Figs. 1(a) and 1(b) are shown in Fig. 3. For both samples the easy axis is along the film normal. Perpendicular remanence is 60% and 100%, respectively and the saturation Kerr rotations are 0.71 and 0.75°, respectively. In-plane remanence is small for both samples and in-plane M-H loops show that the magnetization is not saturated in the maximum applied field of 20 kOe. For these samples the estimated anisotropy fields are ≃75 and 120 kOe, respectively. Figure 4 shows M-H loops for the FePt(110) samples with the field applied along the easy axis: FePt[001] (parallel) or along the film normal: FePt[110] (perpendicular). The in-plane remanence is 100% for both samples but there is a large difference in the out-of-plane magnetization data. The FePt/$SrTiO_3$ sample has a much larger remanence than the FePt/MgO(110) sample. The anisotropy fields for the samples are ≃75 and 140 kOe, respectively.

The structural and magnetic data for the FePt(001) films confirm that near-complete chemical ordering is achieved for film growth on Pt(001)/MgO for both 150 and 7-Å-thick Pt seed films at 500 °C. There are, however, significant differences in structural quality of the two samples which probably lead to the observed differences in magnetic properties. For example, the minority (111) and (100) structural domains may provide minority magnetic domains which contribute to the reduced remanence seen in the film with the thicker Pt seed film. Kern microscopy[10] reveals reverse-nucleated domains in zero field for this film. Similarly, for the FePt(110) samples the presence of (111) and (101) minority structural domains, in the film grown on $SrTiO_3$, may contribute to the perpendicular remanence and reduced magnetic anisotropy field for this sample. The huge magnetic anisotropy for the FePt $L1_0$ phase is confirmed by the magnetic data for these films. Torque magnetometry data, to be presented in detail elsewhere,[10] confirms K_u to be ~10^8 erg/cm^3 for these films.

We acknowledge the work of Sherry Hom in x-ray data collection and peak fitting and are grateful to Andrew Kellock for sample composition and film thickness analysis using Rutherford backscattering.

Ba ferrite films with large saturation magnetization and high coercivity prepared by low-temperature sputter deposition

K. Noma, N. Matsushita, S. Nakagawa, and M. Naoe
Department of Physical Electronics, Tokyo Institute of Technology, Meguro, Tokyo 152, Japan

Ba ferrite films were deposited in a mixture of Xe, Ar, and O_2 by using facing targets sputtering apparatus with sintered targets of Fe-excessive BaM ferrite. By using Xe as sputtering gas, the bombardment of energetic Ar atoms recoiled from target to film surface was sufficiently suppressed and Fe content in Ba ferrite crystallites was significantly increased. It was found that the segregation of spinel crystallites among BaM ones were not observed and these BaM crystallites revealed the excellent c-axis orientation normal to film plane and clear perpendicular magnetic anisotropy. At substrate temperature T_s of 600 °C, saturation magnetization $4\pi M_s$ of 5.1 kG, which is larger than that of BaM ferrite single crystal, and perpendicular coercivity $H_{c\perp}$ of 2.4 kOe were obtained. BaM ferrite films composed of well c-axis oriented crystallites with large perpendicular magnetic anisotropy constant, large saturation magnetization $4\pi M_s$ of 4.7 kG and high perpendicular coercivity $H_{c\perp}$ of 2.4 kOe were obtained at substrate temperature T_s as low as 475 °C. © *1996 American Institute of Physics.* [S0021-8979(96)34208-5]

I. INTRODUCTION

Ba ferrite films are candidate materials for magnetic recording media, milliwave devices, and permanent magnet components because of their large perpendicular magnetic anisotropy constant and high electric resistivity.

It was already reported that the facing targets sputtering (FTS) system are suitable for depositing the BaM ferrite films composed of well c-axis oriented crystallites normal to the film plane at low substrate temperature T_s because the bombardment of energetic particles such as γ-electrons and negative ions to film surface is negligible.[1] In this study, Fe-excessive BaM ferrite plates with the composition of $BaO \cdot 6.5Fe_2O_3$ were used as sputtering targets for increasing the saturation magnetization $4\pi M_s$.

When the BaM ferrite sintered target was sputtered by Ar ions, neutral Ar atoms recoiled from the target attack the growing film surface resulting in the $4\pi M_s$ as small as 2.1 kG. It has been found that the bombardment of energetic particles to the film surface and incorporation of noble gases in the film interior can be sufficiently suppressed by using Xe instead of Ar as the sputtering gas.[2]

The suppression of the particle bombardment and the increase of kinetic energy of sputtered atoms arriving at film surface caused the significant decrease of critical T_s for forming well c-axis oriented crystallites, of 450 °C for Xe sputtering and about 550 °C for Ar sputtering.[1] Films composed of well c-axis oriented BaM crystallites were deposited at T_s as low as 475 °C by using mixture of Xe, Ar, and O_2 as sputtering gas.

II. EXPERIMENT

The sintered ferrite plates with Fe-excessive composition of $BaO \cdot 6.5Fe_2O_3$ were used as sputtering targets, where the stoichiometric composition of BaM ferrite is $BaO \cdot 6.0Fe_2O_3$. The mixture of Xe, Ar, and O_2 was used as sputtering gas and Xe partial pressure P_{Xe} was varied in the range of 0–0.18 Pa, where the total gas pressure and O_2 partial pressure were fixed at 0.20 and 0.02 Pa, respectively. At first, the ZnO underlayer with well c-axis oriented crystallites was deposited on the substrate of thermally oxidized SiO_2/Si wafer, and then 400-nm-thick Ba ferrite layer was deposited successively on the ZnO underlayer.

Film composition was analyzed by inductive coupled plasma spectrometry (ICPS). Microstructure of BaM/ZnO bilayered films were observed with scanning electron microscope (SEM). Crystallographic and magnetic characteristics were evaluated by x-ray diffraction (XRD), vibrating sample magnetometer (VSM), and torque magnetometer, respectively.

III. RESULTS AND DISCUSSION

A. Optimization of Xe partial pressure P_{Xe}

The XRD diagrams of all specimen films deposited at T_s of 600 °C revealed the existence of spinel ferrite as well as c-axis oriented BaM ones. Figure 1 shows the P_{Xe} dependences of Ba content x, ratio in diffraction intensity of spinel

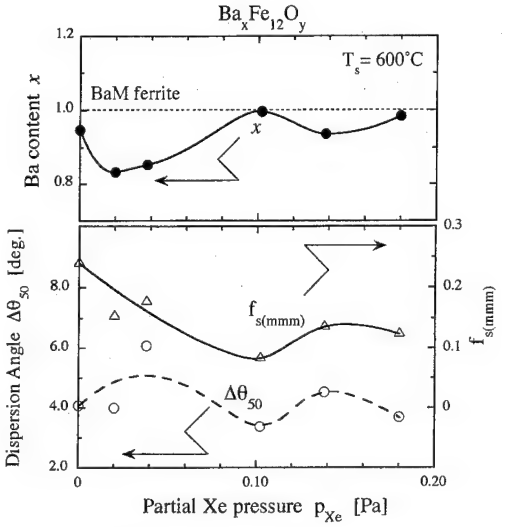

FIG. 1. P_{Xe} dependencies of Ba content x, $f_{s(mmm)}$ and $\Delta\theta_{50}$.

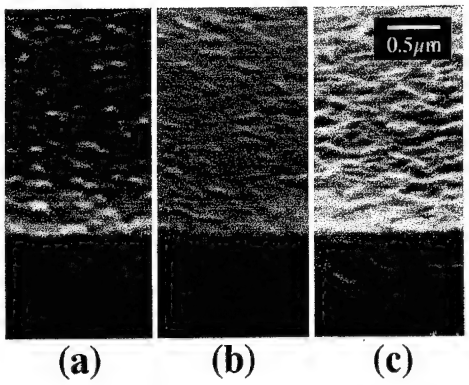

FIG. 2. SEM images of BaM/ZnO bilayered films deposited at P_{Xe} of (a) 0, (b) 0.10, (c) 0.18 Pa.

(mmm) peaks $f_{s(\mathrm{mmm})}$ and dispersion angle of c-axis orientation of BaM crystallites $\Delta\theta_{50}$, where x of 1.0 corresponds to the stoichiometric composition of BaM ferrite and the $f_{s(\mathrm{mmm})}$ were defined as follows:

$$f_{s(\mathrm{mmm})}=(\Sigma I_{\mathrm{spinel(mmm)}})/(\Sigma I_{\mathrm{BaM}(00n)}+\Sigma I_{\mathrm{spinel(mmm)}}),$$

where $I_{\mathrm{spinel(mmm)}}$ and $I_{\mathrm{BaM}(00n)}$ are the diffraction intensity of spinel(mmm) and BaM(00n).

The maximum value of x of 1.0, the minimum value of $\Delta\theta_{50}$ of 3.4° and that of $f_{s(\mathrm{mmm})}$ of 0.086 were attained at P_{Xe} of 0.10 Pa. The decrease of x and the increase of $\Delta\theta_{50}$ at P_{Xe} below 0.04 Pa seemed to be caused by heavy bombardment of energetic Ar atoms. Figure 2 shows the cross-sectional SEM images of the films deposited at various P_{Xe}. The film deposited at P_{Xe} of 0.10 Pa had very smooth surface. Figure 3 shows the P_{Xe} dependencies of the electron temperature (T_e) and the electron density (N_e) at the anode ring measured by Langmuir's single-probe method. T_e was almost constant but N_e had minimum value at P_{Xe} of 0.10 Pa. The increase of N_e at P_{Xe} below 0.04 Pa and P_{Xe} above 0.14 Pa were caused by enhancement in the degree of ionization of the atmospheric gases which collided with energetic Ar atoms and by an increase in body plasma density originating from the larger collision cross-section coefficient of Xe than

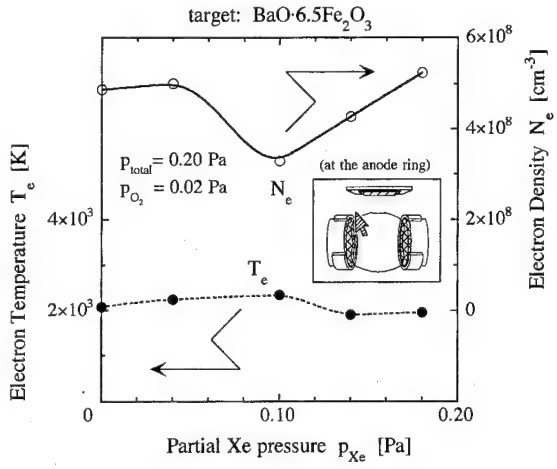

FIG. 3. P_{Xe} dependencies of T_e and N_e.

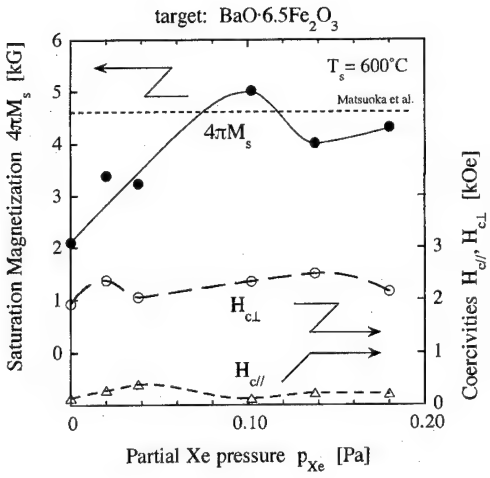

FIG. 4. P_{Xe} dependencies of $4\pi M_s$, $H_{c\parallel}$, and $H_{c\perp}$.

that of Ar, respectively. These results indicate that the damage of film surface during sputtering was minimized at P_{Xe} of 0.10 Pa.

Figure 4 shows the P_{Xe} dependencies of the saturation magnetization $4\pi M_s$, the in-plane and perpendicular coercivities, $H_{c\parallel}$ and $H_{c\perp}$. At P_{Xe} of 0.10 Pa, $4\pi M_s$ took the maximum value of 5.1 kG and $H_{c\parallel}$ took a minimum value of 0.14 kOe and then, $H_{c\perp}$ was 2.4 kOe. The value of $4\pi M_s$ of 5.1 kG was larger than that of 4.8 kG of BaM single crystal with the stoichiometric composition. $4\pi M_s$ of sintered targets used in this study was 3.7 kG, much smaller than that of the specimen films, and that of good crystalline films deposited by using targets with the composition of $BaO{\cdot}6.0Fe_2O_3$ and mixture of Ar and O_2 as sputtering gas was 4.6 kG,[1] which is rather smaller than that of the specimen films in this study. The increase of $4\pi M_s$ seemed to be caused by the increase of Fe content and the number of layers of spinel blocks in the BaM unit cells. Figure 5 shows the P_{Xe} dependences of the effective uniaxial anisotropy constant $K_\perp$ and the anisotropy field H_k. The P_{Xe} dependence of $K_\perp$ corresponds well to that of $f_{s(\mathrm{mmm})}$ as shown in Fig. 1 and $K_\perp$ took the maximum value of 3.3×10^5 J/m^3 at P_{Xe} of 0.10 Pa.

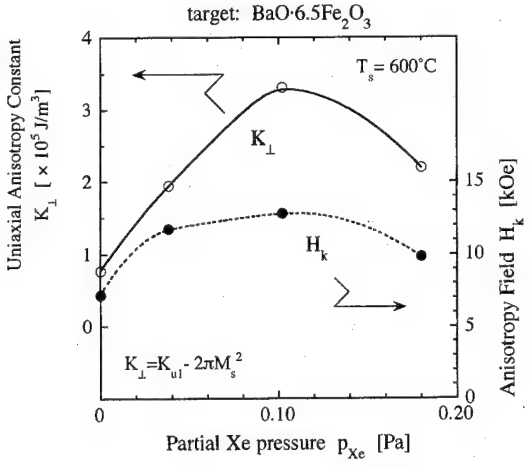

FIG. 5. P_{Xe} dependencies of $K_\perp$ and H_k.

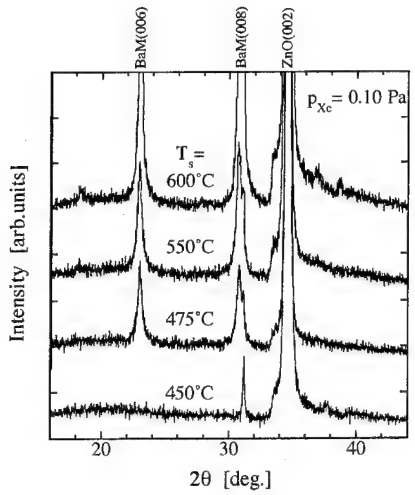

FIG. 6. XRD diagrams of BaM/ZnO bilayered films deposited at P_{Xe} of 0.10 Pa for various T_s.

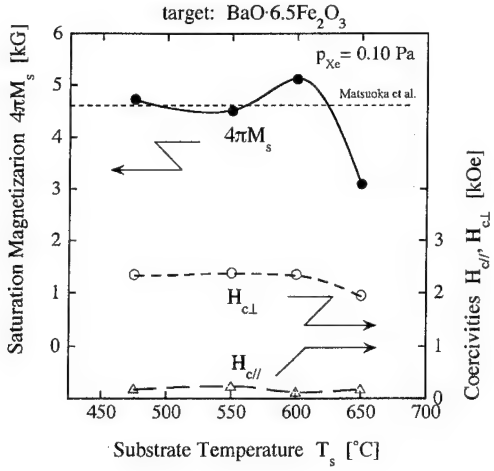

FIG. 7. T_s dependencies of $4\pi M_s$, $H_{c\parallel}$, and $H_{c\perp}$.

It was found that the increase of $K_\perp$ corresponds well to the increase of $4\pi M_s$. These results suggest that the increase in Fe content and number of layers of spinel blocks and the excellent c-axis oriented BaM crystallites should increase $4\pi M_s$ and $K_\perp$, significantly. Consequently, BaM ferrite films deposited at P_{Xe} of 0.10 Pa with Fe-excessive targets may be suitable for the perpendicular magnetic recording media.

B. Deposition at lower substrate temperature T_s

Figure 6 shows the XRD diagrams of BaM/ZnO bilayered films deposited at various T_s. It was found that the BaM ferrite film composed of well c-axis oriented crystallites was obtained even at T_s as low as 475 °C. The decrease of critical T_s for depositing the films seemed to be attributed to the plasma-free film surface and the moderate arrival energy of sputtered atoms at P_{Xe} of 0.10 Pa. Figure 7 shows the T_s dependencies of $4\pi M_s$, $H_{c\parallel}$ and $H_{c\perp}$ of the films deposited at various T_s. $4\pi M_s$ of 4.7 kG was obtained even at T_s of 475 °C, of which the value is almost same value as that of BaM ferrite single crystal. These results indicate that the higher Fe content promoted the formation of spinel blocks of several monolayers during the initial growth, which causes the crystallization of Ba ferrites at much lower temperature than pure BaM crystallites, and subsequently results in the decrease of critical T_s.

Even at lower T_s of 475 °C, the sufficient magnetic properties seemed to be attained by sputtering of Fe-excessive BaM ferrite targets at P_{Xe} of 0.10 Pa.

IV. CONCLUSIONS

In this study, BaM ferrite films composed of well c-axis oriented crystallites were deposited by using the mixture of Xe, Ar, and O_2 as sputtering gas and the Fe-excessive BaM ferrite plates as targets. The obtained results were as follows:

(i) The plasma damage of the growing film surface was significantly suppressed at P_{Xe} of 0.10 Pa.

(ii) The suppression of plasma damage and the formation of spinel block layer in initial growth due to higher Fe content seemed to cause the promotion of excellent c-axis oriented crystallites and the decrease of critical T_s for crystallization down to 475 °C.

(iii) The higher Fe content in the films increased $4\pi M_s$. As a result, $4\pi M_s$ of 5.1 and 4.7 kG were obtained for the films deposited at T_s of 600 and 475 °C, respectively.

These results suggest that the further improvements of magnetic characteristics of BaM ferrite films will be achieved by increasing Fe content as high as possible and by adjusting P_{Xe}, P_{Ar}, and P_{O_2} to optimum values.

Characterization of $Fe_{17}R_2$ phases (R=Pr and Sm) oxidized at 200 °C

S. Gama, C. A. Ribeiro, F. A. O. Cabral,[a] C. C. Colucci, E. de Morais, N. L. Sanjurjo, C. Campos, J. D. Ardisson,[b] and A. I. C. Persiano[b]

The results of oxygen absorption in temperatures ranging from 200 to 500 °C are reported for the phases $Fe_{17}R_2$, R=Pr and Sm. It was observed that the oxygen saturation limit is temperature dependent, being of 3 at/fu at 200 °C, 12.8 at/fu at 300 °C, 20.3 at/fu at 400 °C, and 28.5 at/fu at 500 °C. This implies that above 200 °C the phase is deeply altered by oxygen absorption. Samples with absorption at 200 °C were studied as prepared and heat treated at 500 °C/40 h. The results show that the heat-treated samples consist of $Fe_{17}R_2$, Fe, and R_2O_3. Metallographic examination, susceptibility, and Mössbauer spectroscopy data support the hypothesis that the as-prepared samples consist of a mixture of $Fe_{17}R_2$ and ordered interstitial $Fe_{17}R_2O_x$. © *1996 American Institute of Physics.* [S0021-8979(96)34308-1]

I. INTRODUCTION

Since Coey's[1] discovery that the $Fe_{17}R_2$ phases (R=rare earths) absorb three nitrogen atoms per formula unit (at/fu), it has been shown that these phases can absorb other interstitials, e.g., hydrogen and carbon. For all these interstitials there occurs a lattice expansion, preserving the same crystallographic structure, but with changes in the magnetic properties.[2] In the nitrogen case, it is observed a direct precipitation of a nitrogen saturated phase, without the formation of any solid solution.[3]

It is expected that oxygen should have the same behavior as nitrogen in regard to absorption by the 17:2 phases. We studied previously oxygen absorption, at 600 °C or higher, by Fe-Pr and Fe-Nd multiphase alloys.[4,5] The results showed only phases that were decomposition products, as mixed oxides or oxides, none of them magnetically ordered. In the present work we describe results obtained for oxygen absorption conducted in the temperature range typical for nitrogen absorption.

II. EXPERIMENT

The $Fe_{17}Sm_2$ samples were obtained from Goldschmidt Co. (Germany) in powder form. In the case of $Fe_{17}Pr_2$, the samples were arcmelted in argon and heat treated at 1000 °C during ten days, and turned into powder. The samples were sieved to have particle sizes in the range 32–50 μm. Gas absorption was done in a Sieverts apparatus, with strict temperature control through a type *K* thermocouple inside the reactor chamber. As the absorption is strongly exothermic, gas was admitted in small amounts each time, never allowing the sample temperature to deviate from the reactor temperature. Absorptions were done, from partial to saturation concentrations at 200, 250, 300, 400, and 500 °C. Some of the samples were heat treated at 500 °C/40 h in quartz ampoules under high-purity argon.

Samples were analysed by metallography, by ac thermomagnetic analysis (TMA), by x-ray diffraction using Fe $K\alpha$ radiation, and magnetic measurements at room temperature using a vibrating sample magnetometer (VSM). Also absorption in a Netzsch thermogravimetric analyser (TGA) using heating rate as low as 0.2 °C/min up to 800 °C in flowing oxygen has been done. We did also Mössbauer spectroscopy measurements at room temperature.

III. RESULTS AND DISCUSSIONS

Our observations show that the $Fe_{17}R_2$ phases (R=Sm and Pr) can absorb large amounts of oxygen. At 200 °C the samples absorb up to 3 at/fu. This is similar to what is observed in the nitrogen case, the difference being that nitrogen absorption takes place at higher temperatures (300 °C). As the temperature increases, the oxygen saturation limit increases dramatically. So, at 300 °C saturation occurs at 12.8 at/fu, at 400 °C at 20.3 at/fu, and at 500 °C at 28.5 at/fu. This last result is confirmed by the TGA experiment, in which the total gas absorbed amounted to 29 at/fu. This indicates that for absorption temperatures above 200 °C the original 17:2 phase is profoundly altered. Similar results were obtained for the Pr case. For this reason, we concentrated this work on the samples of the two materials with absorption temperature of 200 °C. Samples with oxygen nominal contents of 0.5, 1.0, 1.5, 2.0, 2.5 at/fu and saturation were prepared.

The microstructure of a partially oxygenated sample at 200 °C [Fig. 1(A)] is similar to a partially nitrogenated one at 500 °C or higher temperature.[3] It presents a diffusion microstructure of the shell-core type, but it can be clearly seen that diffusion along phase and grain boundaries is competing with bulk diffusion. TMA results (Fig. 2) indicate that for partial absorptions we have the signature of the oxygen-free 17:2 phase and, beginning at 300 °C, a marked susceptibility increase, leading to a maximum at or above 500 °C. We note that this maximum does not appear in the cooling part of the TMA curve.

Comparing visually the samples before and after the TMA runs and after heat treatment, it is seen clearly a remarkable color change. They change from dark gray after oxidation to metallic gray after heat treatment or TMA measurement. Comparing the microstructures of the as-prepared and the TMA samples, we see a big modification of the origi-

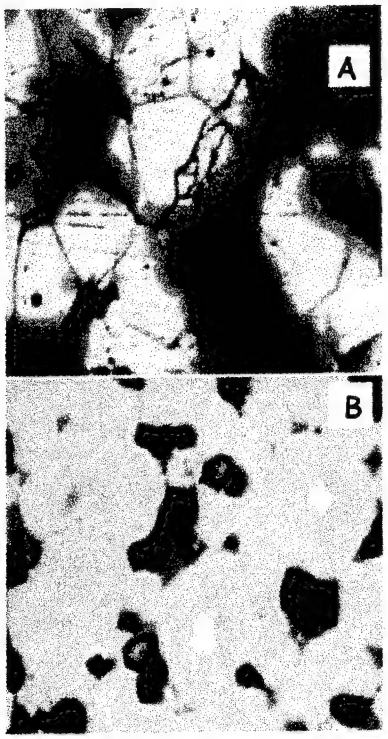

FIG. 1. Microstructures of $Fe_{17}Sm_2$ samples, with oxygen absorption at 200 °C (a) as-prepared, (b) TMA measured up to 700 °C.

nal microstructure. The powder particles in the TMA samples are now almost homogeneous [Fig. 1(B)]. This suggests that the heating allows a redistribution of oxygen in the sample, as expected for the case of formation of an oxygen solid solution. To verify this effect, we took the samples and heat treated them at 500 °C/40 h in argon atmosphere.

The microstructures of the heat-treated samples turned out to be very similar to the TMA ones. Thermomagnetic analysis of the heat-treated samples show only the presence of the oxygen-free phase, with no maximum around 500 °C, and the curves are now reversible.

We also obtained x-ray diffraction data for the as-prepared and heat-treated samples. The data show that the

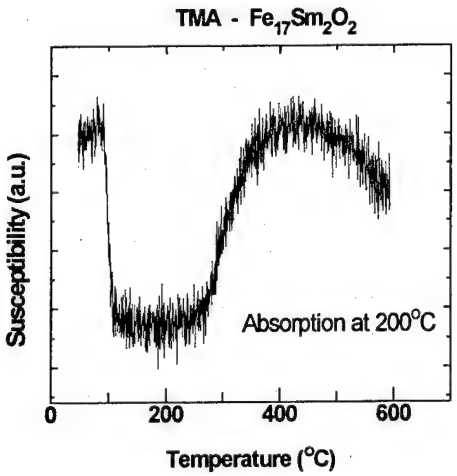

FIG. 2. TMA data for the $Fe_{17}Sm_2O_2$ sample, absorption at 200 °C.

as-prepared samples maintain the same diffraction patterns as the phase not oxidized; no change in peak positions or peak widths are observed, neither the presence of some extra phase. It seems that the oxygen has no noticeable effect in the lattice parameters. The data for the heat-treated samples show that these samples consist mainly of the 17:2 phase, pure Fe and probably Sm_2O_3. The x-ray data for the sequence of samples show that, with increasing oxygen content, the Fe amount increases and the $Fe_{17}R_2$ amount decreases. This is also confirmed by Mössbauer measurements.

These results led to the conclusion that holding these samples at high temperatures for long times, as during heat treatments, or for short times, as in a TMA measurement, brings out a decomposition of the phase into pure Fe and R_2O_3, which can be described by the reaction:

$$Fe_{17}R_2+3/2\ O_2 \rightarrow 17\ Fe+R_2O_3. \quad (1)$$

We note that in this reaction the number of oxygen atoms per formula unit of the original 17:2 phase is exactly 3. This is also the saturation number for the 200 °C absorption temperature. This observation rises the question: is the oxygen entering interstitially in the phase, or it reacts with the phase at once according to the above reaction? Three observations indicate that there is formation of an interstitial solid solution. First, the radical change in the microstructures after heating the samples. The samples become more or less homogeneous, and this requires that the oxygen is stored interstitially in the lattice of the phase, and, opposite to what happens in the nitrogen case, the oxygen must have high mobility, so that, during the heating, it is able to spread all over the grains, react with the phase and decompose it. The second observation is coming from the TMA curve. It shows a notable increase in the susceptibility, beginning at 300 °C. This has no parallel in the nitrogen case, and can be explained identifying the beginning of the increase in the TMA curves with the beginning of iron precipitation in very fine form in the microstructure. The susceptibility then increases until all oxygen reacts and the corresponding free iron precipitates. This is an irreversible process, and, accordingly, so are the TMA curves for the as prepared samples. The susceptibility decrease observed around 500 °C probably arises from the temperature variation of the Fe susceptibility, or from a phase that is a decomposition product, not yet identified. The uniformity of the observed heat-treated or TMA microstructures is attributed to this Fe and Sm_2O_3 precipitation in very fine scale. This same fine precipitation has been observed in the oxidation process for the $Fe_{14}Nd_2B$ phase.[6] These observations imply that if oxygen absorption is increasing the Curie temperature, as happens with the other interstitials (H, C, and N),[2] we can not see it because the very measuring process prevents us from obtaining its value.

The third observation comes from Mössbauer measurements, particularly clear for the case of Pr, in which case the unoxidized phase is paramagnetic at room temperature. The Mössbauer spectra was fitted using the doublet characteristic of the unoxidized phase, plus a broad hyperfine field distribution and a set of four sextets corresponding to an ordered phase (with spectral areas approximately proportional to 6:6:3:2). The existence of the hyperfine field distribution can

be best interpreted as the formation of an oxygen solid solution, distinct from the unoxidized phase. The hyperfine parameters obtained from fitting the four sextets, taking account of the iron present, show hyperfine fields of 35.5, 33.8, 32.0, and 38 T that can be associated with the $6f$, $6h$, $3d$, and $2c$ iron sites, respectively, using the hypothesis that we are dealing with a 17:2 phase. In the moment, there is no firm justification for this supposition, and the data can be interpreted also as belonging to a mixed oxide, as yet not identified.

IV. CONCLUSIONS

We can conclude that:

(1) The phases $Fe_{17}R_2$, R=Pr and Sm, can absorb oxygen from 200 °C up to 500 °C, with saturation values increasing with the absorption temperatures.

(2) At 200 °C, most probably the oxygen is absorbed interstitially, affecting the magnetic properties as do the other interstitials. At higher absorption temperatures, the original phase is profoundly altered already during the absorption process.

(3) For the 200 °C samples, heating as in heat treatments or TMA measurements homogenizes the microstructures and leads to a very fine scale precipitation of pure Fe and Sm_2O_3. This prevents the determination of the Curie temperature for the oxidized phase.

(4) Metallographic analysis, TMA, and Mössbauer spectroscopy measurements all point to the existence of an ordered interstitial phase.

Magneto-optical properties of (BiGdY) iron garnets for optical magnetic field sensors

O. Kamada
Department of Electronics, Polytechnic University, 4-1-1 Hashimotodai, Sagamihara, Kanagawa 229, Japan

The influence of the magnetization process of the stripe domain both on the linearity error and the temperature dependence of the sensitivity in $(BiGdY)_3Fe_5O_{12}$ films for optical magnetic field sensors are studied. By measuring the dc applied field dependence of the light beam diffraction angle by the periodic magnetic domain structure, the domain period and the reduced thickness τ were determined. The magnetization curves calculated for the measured τ parameter show good agreement with the experimental results on the output characteristics. The linearity error of the ac Faraday output were within $\pm 1\%$ in the external field ranging of 10–300 Oe. However, a large linearity error was observed in the small field range. It was also found that the sensitivity is not affected by the temperature dependence of the τ parameter. © *1996 American Institute of Physics.* [S0021-8979(96)28408-1]

I. INTRODUCTION

With recent developments in optical magnetic field (current) sensors based on Faraday effect, there has been considerable demand for applying these sensors to electric power systems such as power-delivery systems to measure current, and to monitor the condition of these lines.[1] Hence, high sensitivity and high accuracy in a wide magnetic field range are required. It is expected that rare-earth iron garnets, especially Bi-substituted rare-earth iron garnets [hereafter, referred as (BiR) IG] have high sensitivity constants because of a large Faraday rotation angle. But, recently, an attribution of Faraday loops to the light beam diffraction by the stripe magnetic domain structure of garnet films has been demonstrated.[2]

We have previously reported the experimental results on the temperature dependence of the sensitivity in detecting only the zeroth-order diffraction beam from (BiR) IG.[3] And, we have also reported on Gd-substituted (BiY) IG films with a minimal temperature dependence of the sensitivity.

In this work, the influence of the domain-wall-magnetization process both on the linearity error and the temperature dependence of sensitivity in magneto-optical (BiGdY) IG films are studied.

II. EXPERIMENTS

(BiGdY) IG films were grown on (111)-oriented $(GdCa)_3(MgZrGa)_5O_{12}$ substrates by means of a liquid-phase-epitaxial (LPE) dipping technique with a horizontal-rotation mode. A $PbO–Bi_2O_3–B_2O_3$ system was employed as a solvent and B_2O_3-rich melts were used to obtain highly Bi-substituted films.[4] The chemical composition of the prepared films was determined by electron-probe microanalysis.

The applied magnetic-field dependence of the stripe-domain period and its temperature dependence were measured from the first-order diffraction angle of the He–Ne laser beam to determine the reduced thickness τ which was introduced by Kooy and Enz[5] for the theoretical calculation of the magnetization curves. And, the linearity error measurements in the zeroth-order diffraction beam were made using 850 nm GaAlAs LED light which propagates parallel to the external dc or ac field.

III. RESULTS AND DISCUSSION

Figure 1 shows the schematic structure of the stripe domain assumed for the (111)-LPE-(BiGdY) IG film. The magnetization M_s inside the domain is indicated by arrows. The stripe domain acts as a binary magnetic grating[6] as shown in Fig. 1. In our case of the zeroth-order diffraction-beam detection, the Jones vector of the electric field of the output light wave according to the domain-wall displacement is given by

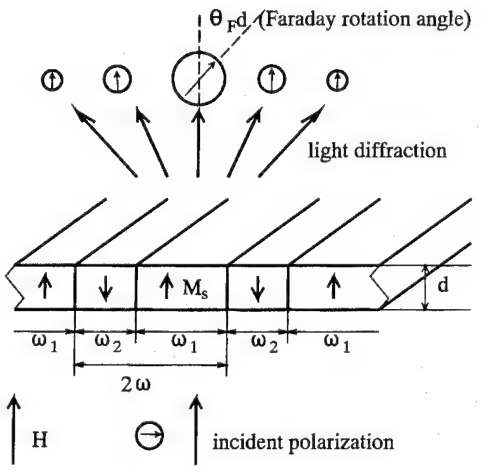

FIG. 1. Model of the stripe domain structure.

 0021-8979/96/79(8)/5976/3/$10.00

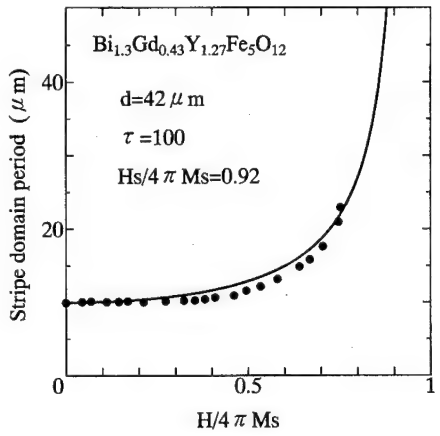

FIG. 2. Calculated curve and measurement results of the stripe domain period as dependent on the normalized external field.

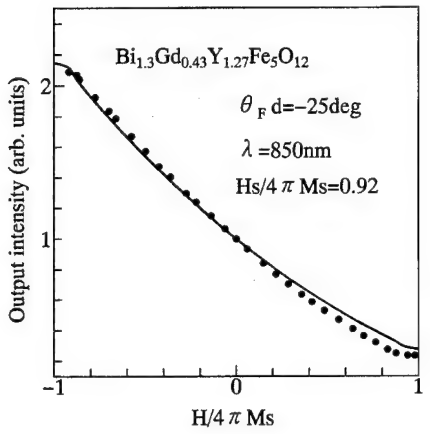

FIG. 4. Sensor output intensity vs normalized dc external field. (●) Show measured results and solid lines show calculated results by Eq. (1).

$$\begin{bmatrix} E_x \\ E_y \end{bmatrix} = \begin{bmatrix} \cos^2 45° & \cos 45° \sin 45° \\ \cos 45° \sin 45° & \sin^2 45° \end{bmatrix} \times \begin{bmatrix} E_0 \cos(\theta_F d) \\ E_0 (M/M_s) \sin(\theta_F d) \end{bmatrix}, \quad (1)$$

where, the action of the analyzer on the polarization state of the zeroth-order diffraction wave is described by 2×2 matrices. And in this case, the analyzer is at an angle of 45° with respect to the polarizer. The Faraday-output intensity, defined by the equation $p=1/2(|E_x|^2+|E_y|^2)$, is given by

$$P(H)/P(0)=[1+(M/M_s)\tan(\theta_F d)]^2, \quad (2)$$

where, $P(H)$ is normalized by $P(0)$. And M, M_s, θ_F, and d are the magnetic moment induced by the external magnetic field, the saturation magnetization, the Faraday-rotation angle, and the film thickness, respectively. The normalized magnetization of M/M_s in Eq. (2) is given by

$$k=M/M_s=(\omega_1-\omega_2)/(\omega_1+\omega_2), \quad (3)$$

where, ω_1 and ω_2 are widths of the domains, respectively, parallel and antiparallel to the direction of the external field H. The domain widths in arbitrary stage of magnetization can be determined from the equilibrium condition to minimize the total magnetic energy E for unit area of the film,[5] and E is

$$E=E_W+E_H+E_d, \quad (4)$$

where E_W, E_H, and E_d are the wall energy, the potential energy and the demagnetizing energy, respectively. Under these conditions, theoretical magnetization curves for the parameter of the reduced thickness τ can be obtained, and τ is defined by

$$\tau=\pi^2(1+\mu^{1/2})^{1/2}M_s d^{1/2}/(26)^{1/2}, \quad (5)$$

where σ is the specific wall energy.

The observed external field dependence of the domain periods are plotted in Fig. 2. The theoretical curve is obtained with the parameter values of $\tau=100\pm2$ which can be determined from the domain period at $H/4\pi M_s=0$. And to take account of the μ effect, $\mu^{1/2}=(1+2\pi M_s^2/K_u)^{1/2}=2.2$ for (BiGdY) IG was used, since the growth induced anisotropy K_u is about 4×10^4 erg/cm^3,[7] and $M_s=132$ Gauss. The calculated magnetization curves for $\tau=100$ are shown in Fig. 3, and the ratio of $H_s/4\pi M_s=0.92$ is obtained, where H_s is the saturation magnetic field. The cause of the deviation of

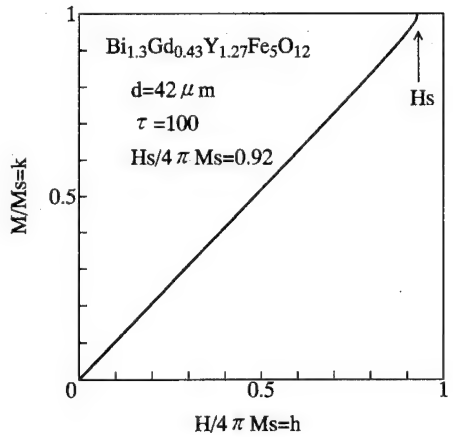

FIG. 3. Calculated magnetization curve for $\tau=100$.

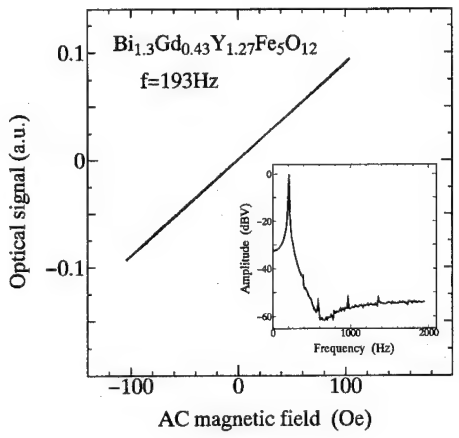

FIG. 5. Minor hysteresis loop. The insets show the result of the spectrum analysis.

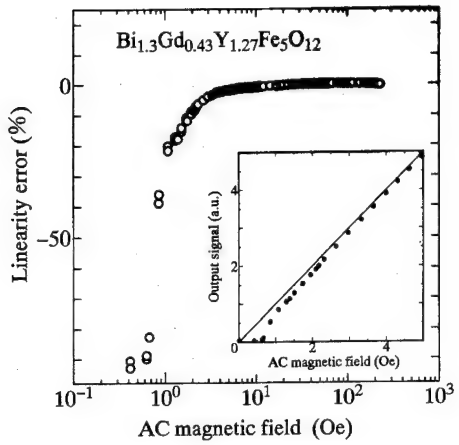

FIG. 6. Linearity error of the Farady output. The insets show the nonlinear ac output characteristics in the small external field region.

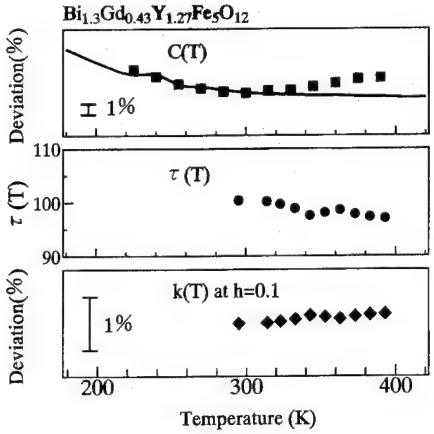

FIG. 7. Experimental results of the temperature dependence of sensitivity $C(T)$ and τ parameter. Calculated results of $k(T)$ variation related to $\tau(T)$ are also represented.

the experimental results from the calculated results of the domain period is expected to the influence of the small wall coercive force.

The output characteristics as a function of the applied dc field by Eq. (2) is analyzed. The calculated results by Eq. (2) are represented by a solid line in Fig. 4. The measured results are in good agreement with the calculated results and it is experimentally confirmed that the domain wall displacement is the dominant magnetization process in (BiGdY) IG film.

Figure 5 shows the minor hysteresis loop to evaluate the ac output linearity. A good linearity characteristics in (BiGdY) IG films is obtained, and it can also be found from the results of the spectrum analysis which shows the higher-order amplitude is less than −40 dB, as shown in the inset of Fig. 5. Figure 6 also shows the experimental results of the linearity error of less than ±1% over the applied field ranging from 10 Oe to 300 Oe. But a large linearity error at the small external field region is obtained. It is considered that the effect of the domain-wall coercive force of the order of 0.5 Oe appeared sensitively. So to explain this large nonlinearity phenomena quantitatively, it is necessary to calculate the magnetization curves and the minor loops[8,9] which takes the effect of the small wall coercive force into account. The present sensors for power-delivery systems, the higher field range than 10 Oe (for example, 15–150 Oe) is used, but improvement of the large linearity error in the lower field range is necessary to realize the wide range optical magnetic field sensors such as a optical wattmeter.

In previous paper,[3] the temperature dependence of sensitivity $C(T)$ were studied in terms of $\theta_F(T)$ and $M_s(T)$. The experimental results (■) and the calculated results (solid line) are shown in Fig. 7. However, the influence of the temperature dependence of $\tau(T)$ on $C(T)$ have not been taken into consideration. The measured results of $\tau(T)$ and the calculated results of the deviation of $k(T)$ at $h=0.1$ for the obtained $\tau(T)$ values are plotted in Fig. 7 too. From these results it can be found that $k(T)$ has very small temperature dependence within ±0.1% in the temperature ranging of 290–400 k, and the influence on $C(T)$ is very small.

IV. CONCLUSION

Bi-substituted rare-earth iron-garnet films, (BiGdY) IG for optical magnetic-field sensors were prepared by LPE method.

From the measurement of the applied-field dependence of the domain period, the reduced-thickness parameter, $\tau=100\pm2$ was obtained. Using this value of τ, the magnetization curves were calculated following the stripe-domain theory by Kooy and Enz. These curves show good agreement with the sensor output characteristics. However, in the weak external field region, a large linearity error was observed. It was estimated that the origin of this phenomena is the small coercive force, but more detailed investigations are required.

As another result, it was found that the sensitivity is not affected by the temperature dependence of the τ parameter.

The calculation of the contribution of the intraionic electric-dipole transitions between the $3d^8$ and $3d^7\,4p$ configurations of Ni^{2+} ions doped in barium ferrites to the Faraday effect is presented. It is shown that such transition is an important origin of the Ni contribution to the Faraday effect in the Ni-substituted barium ferrite. The energy difference between the mean energies of the $3d^8$ and $3d^7\,4p$ configurations is large. So the 496-nm wavelength (photon energy 2.5 eV) is far from the resonance frequencies. However, since the molecular field upon the Ni^{2+} ions is very large, the Faraday rotation at 496 nm produced by such transition is still large. Other possible origins are discussed briefly. © *1996 American Institute of Physics.* [S0021-8979(96)16108-5]

I. INTRODUCTION

With new techniques developed to prepare ferrite thin films,[1–3] magnetic oxides again become potential candidates for the magneto-optical (MO) recording material. Barium ferrite films have a marked uniaxial anisotropy and good squareness of in-plane hysteresis loop but the MO response remains quite poor. However it has been reported that the Co or Ni substitution in ferrites enhances the Kerr and Faraday rotations.[4–6] The enhancement factor of specific Faraday rotation (FR) at 496 nm wavelength is as large as 2×10^4 deg cm^{-1}/x for $Ba_{1-x}M_xFe_{12-x}Ni_xO_{19}$ films, where M is La or Pr which is substituted for Ba^{2+} ions for charge compensation and enhances no FR in the barium ferrite.[4]

As for the origin of the MO enhancement of the Ni substitution, to our knowledge, up to now there is still a lack of theoretical study. However, the origin of the MO enhancement of the Co^{2+} ions in ferrites has been discussed by some authors.[5–7] They attributed the MO enhancement of the Co^{2+} ions to the d–d electric dipole (ED) transitions. They think that a finite transition probability could be produced due to some reasons. First, the Co^{2+} ions in some ferrites have no center of symmetry. The odd-parity crystal potential terms mix higher-lying p orbitals into the d orbitals producing a finite transition probability. Second, the excited-state hybridization with ligands also produces a finite transition probability. Such transition is usually called a charge-transfer transition. However, it is worthwhile to examine if the intraionic ED transitions between the $3d^n$ and $3d^{n-1}4p$ configurations of the Ni^{2+} and Co^{2+} ions have large contribution to the MO effect in magnetic oxides containing cobalt or nickel. In this paper, the calculation of the contribution of such transition in the Ni^{2+} ions to the MO effect in Ni-substituted barium ferrite is presented.

II. THEORY AND CALCULATION

To calculate the contribution of the intraionic ED transitions between the ground and the parity allowed excited configurations to the MO effect, it is necessary to calculate the splitting of these configurations under the crystal electric field (CF) and superexchange interaction.

The Hamiltonian of the Ni^{2+} ion in the crystal is

$$H=H_0+H_{SO}+H_C+H_{ex}, \tag{1}$$

where H_{SO} is the spin-orbit interaction, H_0+H_{SO} is the Hamiltonian of a free Ni^{2+} ion, H_C is the CF Hamiltonian and H_{ex} is the superexchange interaction. H_C can be expressed as

$$H_C=\sum_i \sum_{kq} A_{kq} r_i^k Y_{kq}(\theta_i,\phi_i), \tag{2}$$

where A_{kq} is the CF parameter. In our calculation, the value of $\langle r^2\rangle_{3d}$, $\langle r^4\rangle_{3d}$, $\langle r^2\rangle_{4p}$ and $\langle r\rangle_{3d4p}$ are determined with the Slater radial wave function. The CF parameters are calculated with the point-charge model and only the contribution of the nearest neighboring O^{2-} ions is considered. In the barium ferrite, the Fe^{3+} ions occupy 2a, 2b, $4f_1$, $4f_2$, and $12k$ crystal sites. The nonzero parameters of the CF upon the Ni^{2+} ion substituting the Fe^{3+} ion at the 2b site are: $A_{20}\langle r^2\rangle_{3d}=-14966$ cm^{-1}, $A_{40}\langle r^4\rangle_{3d}=13197$ cm^{-1}, $A_{20}\langle r^2\rangle_{4p}=-66386$ cm^{-1}. Here the z axis is taken to be along the sixfold symmetric axis of the crystal. The CF-split energy levels and the corresponding wave functions of the ground configuration are obtained by solving the following secular equation,

$$\|\langle JJ_z|H_{SO}+H_C|J'J_z'\rangle-E^0\delta_{JJ'}\delta_{J_zJ_z'}\|=0. \tag{3}$$

 0021-8979/96/79(8)/5979/3/$10.00

TABLE I. The energies and the occupation probabilities at 300 K of the lowest four CF- and exchange-interaction-split levels of the $3d^8$ configuration for the Ni^{2+} ions at the 2b site.

Energy (cm^{-1})	−3948.3	−2963.7	−2909.2	−2897.0
Probability	0.976	0.009	0.007	0.006

The lowest two terms of the $3d^8$ configuration are ^3F and ^3P. The mean energy of the ^3P term is 15 936 cm^{-1} larger than that of the ^3F term. So, in solving Eq. (3), only the various multiplets of the ^3F term are included. The energies of the lowest five CF-split levels of this term for the Ni^{2+} ion at the 2b site are −3456, −2903.1, −2194.5, 246.8, 1340.8 cm^{-1}. Here the energy of the multiplet $^3F_4$ is taken to be zero. All these five levels are doubly degenerate.

The Zeeman splitting of the CF-split levels is calculated by solving the following secular equation:

$$\|\langle\psi_i|H_{SO}+H_C+H_{ex}|\psi_j\rangle-E\delta_{i,j}\|=0. \tag{4}$$

The molecular field acting on the Fe^{3+} ions in YIG estimated by Guillot *et al.* is 4000 kOe.[8] The Curie temperature of barium ferrite is higher than that of YIG. So the molecular field acting on the Ni^{2+} ions in the barium ferrite is taken to be 5000 kOe. Then $2\mu_B H_m$ is about 500 cm^{-1}. This is not small compared with the energy differences between the CF levels. Therefore, in general, the mixing of these levels by superexchange interaction is not negligible and it is considered by us. The energies of the lowest four CF- and exchange-interaction-split levels of the ground term of the Ni^{2+} ion at the 2b site are shown in Table I. The occupation probabilities of these levels at 300 K are shown in this table as well.

The $3d^7 4p$ configuration has many terms. Among them the terms allowed by the ED transition from $3d^8$: ^3F term are: $3d^7(^4F)4p$: ^3G, ^3F, ^3D; $3d^7(^4P)4p$: ^3D; $3d^7(^2P)4p$: ^3D; $3d^7(^2D1)4p$: ^3F, ^3D; $3d^7(^2D2)4p$: ^3F, ^3D; $3d^7(^2F)4p$: ^3G, ^3F, ^3D; $3d^7(^2G)4p$: ^3G, ^3F; $3d^7(^2H)4p$: ^3G. The lowest three terms are $3d^7(^4F)4p$: ^3G, ^3F, ^3D. Solving the following secular equation:

$$\|\langle JJ_z|H_0+H_{SO}+H_C|J'J'_z\rangle-E^0\delta_{JJ'}\delta_{J_zJ'_z}\|=0, \tag{5}$$

we have obtained the CF-split levels and the corresponding wave functions of these three terms. The differences between the mean energies of these terms are small, so in solving Eq. (5), the bra and ket include various states of these three terms. The values of the diagonal matrix elements $\langle JJ_z|H_0+H_{SO}|JJ_z\rangle$ in Eqs. (3) and (5) are taken from the book by Moore.[9] The energies of the lowest six CF-split levels of these terms are: 96 229, 96 380, 99 027, 99 030, 99 441, 99 699 cm^{-1}. Here the energy of the multiplet $3d^8$: $^3F_4$ is taken to be zero. For simplicity, the energies of all other terms are supposed to be 130 000 cm^{-1}. The CF splitting of these terms is neglected. Because the CF splitting is small compared with the difference between the mean energies of the $3d^8$ and $3d^7 4p$ configurations, the error due to the above approximation is small. The Zeeman splitting of the $3d^7 4p$ configuration is also neglected.

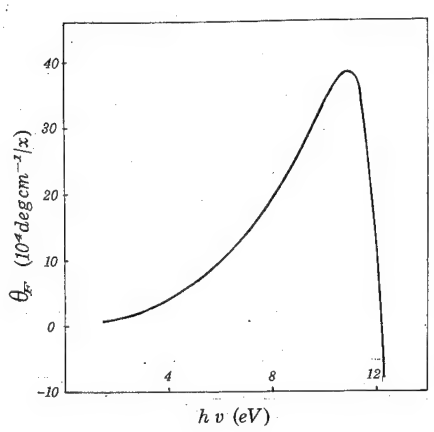

FIG. 1. The specific FR contributed by the Ni^{2+} ions at the 2b site in $Ba_{1-x}M_xFe_{12-x}Ni_xO_{19}$.

The FR per unit length of the medium caused by the ED transitions is (see Refs. 10 and 11 and the references therein)

$$\theta_F=\frac{N\pi(\bar{n}^2+2)^2}{9c\bar{n}\hbar}\times\sum_{ng}A_{ng}\frac{\omega^2(\omega_{ng}^2-\omega^2-\Gamma_{ng}^2)}{(\omega_{ng}^2-\omega^2+\Gamma_{ng}^2)^2+4\omega^2\Gamma_{ng}^2}\rho_g, \tag{6}$$

for each type of ion present in the material, where

$$A_{ng}=|\langle n|V_-|g\rangle|^2-|\langle n|V_+|g\rangle|^2. \tag{7}$$

In Eqs. (6) and (7), c is the velocity of the light in vacuum, ω the angular frequency of the light wave, $\bar{n}$ an average refractive index, for barium ferrite, $\bar{n}\approx 2.8$,[12] N the number of ions per unit volume, Γ_{ng} the half-widths of resonance lines, $|g\rangle$ the CF- and exchange-interaction-split $3d^8$ states with energy E_g, $|n\rangle$ the $3d^7 4p$ states with energy E_n, and $\hbar\omega_{ng}=E_n-E_g$. $V_\pm$ are the ED moment operators for right- and left-handed circularly polarized light, ρ_g is the occupation probability of the state $|g\rangle$. When $|\omega_{ng}^2-\omega^2|\gg\Gamma_{ng}^2$, Eq. (6) can be reduced to the following formula:[13]

$$\theta_F=\frac{N\pi(\bar{n}^2+2)^2}{9c\bar{n}\hbar}\sum_{ng}A_{ng}\frac{\omega^2}{\omega_{ng}^2-\omega^2}\rho_g \tag{8}$$

Both Eqs. (6) and (8) are accurate at low energies.

The calculated FR contributed by the Ni^{2+} ions at the 2b site at various photon energies is shown in Fig. 1. The FR at 496-nm wavelength is 1.53×10^4 deg cm^{-1}/x. The FR contributed by the Ni^{2+} ions at the $4f_1$ site is -1.4×10^4 deg cm^{-1}/x at 496 nm. When the Ni^{2+} ions are at the 2a or the $4f_2$ site, the enhancement factor is small. It should be noted that, in our calculation the values of $\langle r\rangle_{3d4p}$, $\langle r^2\rangle_{3d}$ etc. are obtained with the Slater radial wave function of the free Ni^{2+} ions. We think that the extension of the radial wave function of the Ni^{2+} ion in the crystal will make the actual enhancement factor larger than that given above. It is worthwhile to point out that the Slater radial wave function and the point-charge model were used to calculate the magnetocrystalline anisotropy of the barium ferrite[14,15] and Zn_2W ferrite.[16] As we have done in this paper, in calculating the CF parameters only the effect of the nearest neighbors was taken

into account. The calculated results can explain the main experimental results well. However the magnitude of the calculated magnetocrystalline constant K_1 is smaller than the measured one. This fact also makes us believe that the actual enhancement factor will be larger than the value given above. According to Machida *et al.*[3] and Gomi *et al.*,[4] the FR induced by a Fe^{3+} ion in the barium ferrite is much smaller than that by a Ni^{2+} ion at the 2b or $4f_1$ site. Therefore, in explaining the enhancement by Ni^{2+} substitution, it has been neglected to a first-order approximation.

III. CONCLUSION AND DISCUSSION

From our calculation, it is seen that the intraionic ED transition between the $3d^8$ and $3d^7 4p$ configurations is an important origin of the large MO enhancement of the Ni^{2+} ions in the barium ferrite when the photon energy is larger than about 1.5 eV. The Co^{2+} ions have similar characteristic as the Ni^{2+} ions, and the YIG and cobalt ferrite have similar characteristic as the barium ferrite. Therefore we think that the intraionic ED transition between the $3d^7$ and $3d^6 4p$ configurations may be also an important origin of the MO effect contributed by the Co^{2+} ions in such compounds in the wavelength region mentioned above. However, it is found that there is a resonance frequency at about 1500-nm wavelength for Co-substituted garnets[6] and a resonance frequency at about 900 nm for $Co_xCd_{1-x}Cr_2S_4$.[7] They cannot come from the origin mentioned above. Could they come from the $d-d$ transitions induced by the odd-parity crystal field? The environment of the 2b site in the barium ferrite has no center of symmetry. According to our calculation, the odd-parity CF upon the Ni^{2+} ions at the 2b site does produce MO resonance around 2.5 eV. However, the component of the $4p$ orbitals mixed into the d orbitals is so small that the maximum value of the FR near the resonance frequency is about 500 deg cm^{-1}/x. In our calculation the value of $\hbar\Gamma$ is taken to be 0.05 eV, which may be too small. The value of the FR near the resonance frequency depends on the value of $\hbar\Gamma$. So the value given above may be larger than the actual value. Therefore, the $d-d$ transitions induced by the odd-parity CF cannot explain the MO resonance phenomenon of the Co^{2+} ions in these compounds at long wavelength region. We think that it might come from the charge transfer between the Co^{2+} ions and the ligands.

As mentioned above, the Zeeman splitting of the excited configuration has been neglected. Therefore, when a plane-polarized electromagnetic wave propagates through the medium, the transition probabilities for the right- and left-handed circularly polarized light between the sublevels of a CF level of the ground configuration and the states of the excited configuration are the same. So there will be no Faraday effect if there is no Zeeman splitting of the CF levels of the ground configuration, but the Zeeman splitting makes the occupation probabilities of these sublevels different. This results in a so called "paramagnetic" type Faraday effect. The Zeeman splitting of the excited configuration will lead to a "diamagnetic" type Faraday effect. However, the energy differences between the CF-split $3d^7 4p$ states and the lowest $3d^8$ states are larger than 99 000 cm^{-1}, while the Zeeman splitting is less than 1000 cm^{-1}, so the diamagnetic type Faraday effect is very small and is neglected by us.

From the calculated results given above, it could be seen that the value of $\hbar\omega_{ng}$ is larger than 99 000 cm^{-1}, so the factor $\omega^2/(\omega_{ng}^2-\omega^2)$ is very small for the wavelengths near 496 nm. However, in barium ferrite, the molecular field upon the Ni^{2+} ions is so large that the occupation probability of the lowest CF- and exchange-interaction-split level of the $3d^8$ configuration is close to 1. Hence, the FR at 496-nm wavelength is still large. By the way, after the estimation of Dionne *et al.*,[17] the molecular field upon the Fe^{3+} ions in YIG is also so large that the occupation probability of the lowest CF- and exchange-interaction-split level is close to 1. Furthermore, for so large a Zeeman splitting, the calculation results do not depend seriously on the exact value of the molecular field. These facts make us believe that our main conclusion is reliable.

Second harmonic investigation of ac magnetized in-plane anisotropic garnet film

Sergey V. Lebedev
Laboratory of Applied Magneto-optics, Moscow Engineering Physics Institute, Kashirskoe shosse 31, 115409 Moscow, Russia

A magneto-optical method is applied to investigate the influence of external magnetizing on second harmonic signal of magnetic reversal of in-plane anisotropic epitaxial garnet film. The dependencies of the width, slope and amplitude of curves recorded in "amplitude-easy axis magnetic field strength" coordinates versus magnitude of ac longitudinal and dc transversal magnetic fields are obtained and analyzed. It is shown that the slope of transfer function reaches its maximum at 0.7–0.8 Oe ac magnetizing with very slow dependence from transversal magnetic field. The "amplitude vs dc transversal field" dependence appears to have two regions with rapid and slow signal changing corresponded to various magnetization mechanisms. © *1996 American Institute of Physics.* [S0021-8979(96)16208-1]

Thin epitaxial garnet films are the object of investigations during the past 25 years. However available scientific bibliography shows that the major part of investigations is devoted to the films with strong uniaxial anisotropy. As far as in-plane anisotropic garnet films are concerned, there is a sufficient number of articles dealing with their undoubtedly attractive applications—low magnetic fields and electrical currents measurement, nonreciprocal waveguide elements, and nondestructive inspection of various magnetic records. However we know of only a few investigations describing the magnetizing processes of in-plane anisotropic films in dc and ac magnetic fields, the influence of external magnetization on hysteresis loop, and the corresponding mechanisms of magnetic reversal.[1–4] It is noted that the corresponding phenomena in uniaxially anisotropic films are studied many times and in more detail.

The objective here is the investigation of influence of external magnetizing on a second harmonic signal of magnetic reversal of epitaxial garnet film with strong in-plane anisotropy. A high priority of this problem is stipulated on the one hand by complexity of magnetization processes taking place in garnet films with "easy axis in plane" anisotropy[4] as well as the necessity of obtaining additional fundamental information, and on the other hand—by near-term prospect to use them in sensors and fiber optic devices.

All experiments were carried out with previously described 5-μm-thick epitaxial $(BiLuCa)_3(FeGe)_5O_{12}$ film, grown on a (111)-oriented $Gd_3Ga_5O_{12}$ single-crystal substrate.[4] As is mentioned the film's anisotropy could be characterized more adequately as "easy axis in plane," when there are two mutually perpendicular easy and hard axes of magnetization with saturation fields difference at least by an order of magnitude (f.i. −1 and 10 Oe, respectively). The influence of residual cubic anisotropy results in the appearance of sloped domains.[2,4]

The external fields configuration includes dc transversal field H_h (0–10 Oe), directed along hard axis of magnetization, and a combination of ac field H_{ac} (300–2000 Hz, 0–3 Oe) and slowly changing dc field H_e (−10 to +10 Oe) directed along easy axis of magnetization, as indicated in Fig. 1. The second harmonic of magnetic reversal was recorded in a standard magneto-optical scheme of longitudinal hysteresis registration along the easy axis.[4] The garnet film was placed between two polarizers so that its plane was titled at an angle of 45° from the optical axis to provide the magneto-optical Faraday interaction of light with planar magnetization.

We have used as a light source a previously collimated near infrared LED. The linear output signal detection in balance photodiodes scheme[5] was provided using a 45° deflection of the main axis of the analyzer from that of the input polarizer. Thus the measured optical signal is strongly proportional to the garnet film magnetization averaged over the light aperture. The second harmonic of the magnetic reversal signal from the output of the lock-in amplifier was registered by a two-coordinate recorder with X input coupled to the output of a slow H_e sweeping generator.

Figure 2 shows the recorded amplitude of second harmonic signal as a function of the magnetic field H_e. This curve is universal only in external appearance for most ferro- and ferrimagnetic materials. Figure 3 demonstrates the ob-

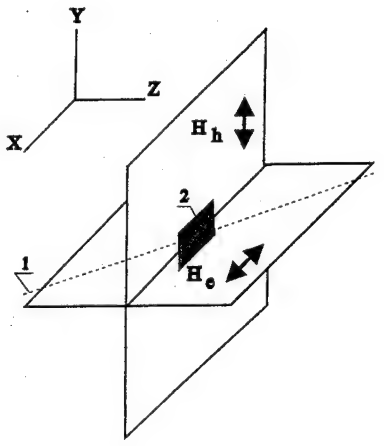

FIG. 1. The geometry of experiments: orientation of magnetic fields and of optical axis relative to garnet film plane: (1) the optical axis; (2) the garnet film.

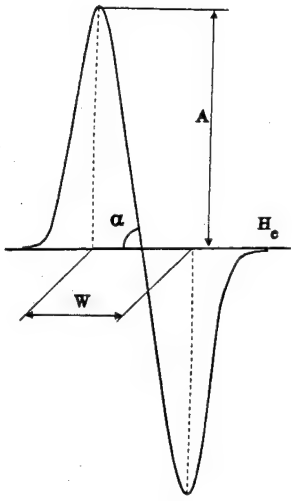

FIG. 2. Typical recorded curve of second harmonic signal.

tained dependencies of the width W (a), slope $Tg\alpha$ (b), and amplitude A (c) of recorded curve vs the amplitude H_{ac} of ac magnetizing along an easy axis corresponding to dc transversal magnetizing of 0, 0.7, and 1.4 Oe (the thin, middle-thick, and thick solid lines, respectively). The greatest peculiarities of these are:

(i) The width and amplitude of the second harmonic signal are monotonously increasing functions of the ac magnetizing field. Moreover the first ones appear to be a nearly linear function with no visible dependence from H_h so that Fig. 2(a) displays the results related only to 0 and 1.4 Oe dc magnetizing.

(ii) The $Tg\alpha$ dependence reaches its maximum at some value of H_{ac} around 0.7–0.8 Oe, slowly varying by changing of transversal field H_h. It is noted that the increase of H_{ac} is accompanied by the decrease of slope dependence from H_h.

Figure 4 shows the dependencies of A vs H_h measured at 0.4, 0.6, and 0.8 Oe of ac longitudinal magnetizing (the thick, middle-thick, and thin solid lines, respectively). Each curve has the central narrow maximum and the outlying wide and gradually decayed part. The smaller is the value of H_{ac}, the sharper is the changeover at 1.2–1.5 Oe from one part of the curve to another. The origin of this inflection may be the correspondent change in magnetization mechanism. The location of amplitude maximum of second harmonic signal in the H_e–H_h plane does not fall at great values of H_h outside the limits of the region of horizontal domains motion. However at low values of H_h there is a region where horizontal and sloped domains exist simultaneously. It may result in additional asymmetry of partial hysteresis loops and be responsible for more intensive amplitude increase.

As far as the frequency dependence of presented characteristics is concerned, the magneto-optical response decreases slowly while increasing the frequency of ac magnetizing above 3 kHz. It corresponds qualitatively to the results obtained earlier.[6]

We have used the in-plane anisotropic garnet films in the R&D of the self-calibrated dc current sensor.[7] The possibility of absolute zero determination in a well-known second har-

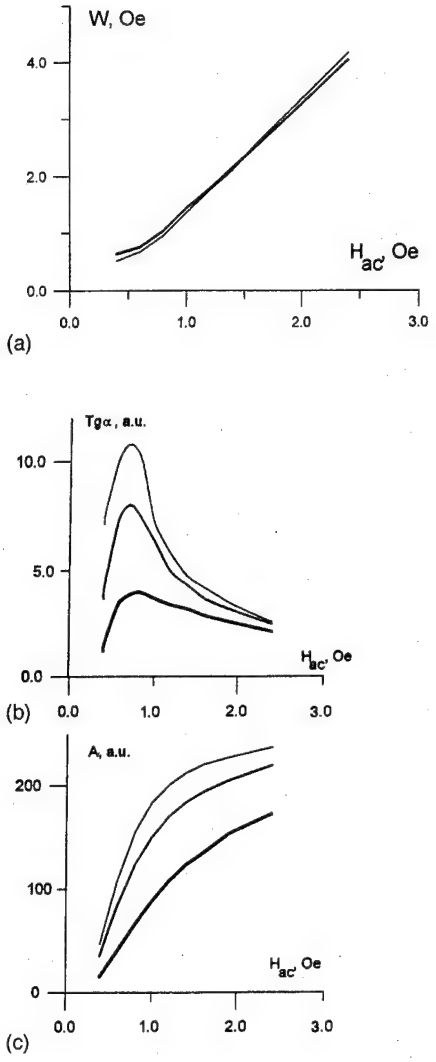

FIG. 3. The dependencies of width (a), slope (b), and amplitude (c) of second harmonic curves vs ac magnetic field oriented along easy axis of magnetization. The thin, middle-thick and thick solid lines correspond to dc transversal magnetizing of 0, 0.7, and 1.4 Oe, respectively.

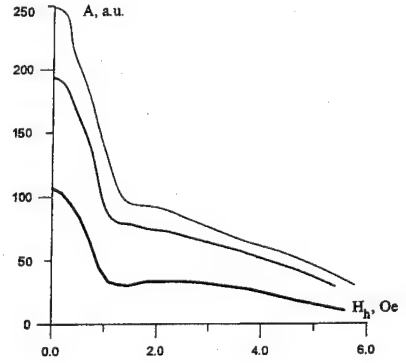

FIG. 4. The dependence of amplitude of second harmonic curves vs dc transversal magnetic field. The thick, middle-thick, and thin solid lines correspond to ac longitudinal magnetizing of 0.4, 0.6, and 0.8 Oe, respectively.

monic magnetometer scheme and the optimized external magnetization regime of our films allow us to increase enormously the sensitivity limit of the conventional magneto-optical sensor as well as to avoid the problems associated with zero drift—very serious ones for all known precise sensors.

Magneto-optical properties of Sc-substituted holmium iron garnet single crystals

J. Ostoréro
Laboratoire de Chimie Métallurgique et Spectroscopie des Terres Rares, CNRS, 92195 Meudon Cedex, France

M. Guillot
Laboratoire des Champs Magnétiques Intenses, CNRS/MPI, 38042 Grenoble Cedex, France

The Faraday rotation (FR) of scandium substituted holmium iron garnets single crystals $Ho_3Fe_{5-z}Sc_zO_{12}$ (z=0.35, 0.52, 0.56, and 0.73) has been investigated at 1152 nm wavelength in the 6 K $< T <$ $T_{Néel}$ temperature range and magnetic field up to 20 kOe applied along the [111] easy axis. At this wavelength, in a narrow concentration range ($0.5<z<0.6$), in addition to the classic magnetic compensation temperature T_{comp}, the spontaneous FR $\Phi_s(T, z=\text{Cte})$ curves present two magneto-optic (MO) compensation points $T^{MO}_{Comp}(1)$ and $T^{MO}_{Comp}(2)$ where the FR vanishes although the ferrite magnetization is different from 0. When $z>0.6$, only $T^{MO}_{Comp}(1)$ remains. These results, due to the influence of the diamagnetic dilution of the octahedral $[a]$ Fe^{3+} sublattice, are interpreted using the one ion FR model of Crossley *et al.* and the Dionne-refined Néel model of garnets. They give an indirect experimental confirmation of the temperature dependence of the MO electric dipole coefficient $C_e(\lambda=1152\text{ nm}, T)$, and of the preponderance of the $(d)-\{c\}$ magnetic interactions compared to the $[a]-\{c\}$ ones. © *1996 American Institute of Physics.* [S0021-8979(96)16308-8]

I. INTRODUCTION

Nonmagnetic substitutions in iron garnets are of great interest both for fundamental studies and applications in devices such as microwave and magneto-optic (MO) components. We presented recently the results concerning the MO properties of Al^{3+}-substituted holmium iron garnet (HoIG:Al) compounds.[1] Al^{3+} ions substitute to Fe^{3+} ions on both tetrahedral (d) and octahedral $[a]$ sites with a large tetrahedral preference.[2] In contrast Sc^{3+} ions substitute almost exclusively to Fe^{3+} on octahedral sites.[3,4] The purpose of this work is thus to study the influence of octahedral Sc substitution on the Faraday-rotation (FR) properties of $Ho_3Fe_{5-z}Sc_zO_{12}$ single crystals ($0.3<z<0.8$). Their formula can be written: $\{Ho_3\}$ $[Fe_{2-z}Sc_z]$ (Fe_3) O_{12} where $\{\}$ represents the rare earth dodecahedral c sublattice. The temperature variation of the magnetic properties of heavy-rare-earth iron garnets presents two different characteristic temperatures: $T_{Néel}$ and T_{comp}. $T_{Néel}$ corresponds to the temperature transition to the paramagnetic state governed mainly by the $Fe^{3+}-Fe^{3+}$ interactions.[5] In contrast, the magnetic compensation temperature T_{comp} strongly depends on the nature of the rare earth as the bulk magnetization $M_s=|(M_d-M_a)-M_c|$ vanishes whereas $M_{a,d,c}$ are different from zero (T_{comp}=137 K in pure HoIG[6]). At T_{comp} the FR changes its sign, keeping the same absolute value. In some ferrimagnetic garnets ($Gd_3Fe_5O_{12}$, for example), in addition to $T_{Néel}$ and T_{comp}, the temperature variation of the FR properties at a fixed wavelength (1152 nm) presents also a MO compensation point T^{MO}_{Comp} where the FR is zero although the ferrite magnetization is different from zero. To our knowledge, in the numerous literature devoted to the MO properties of ferrimagnetic garnets pure or substituted, the presence of at most one T^{MO}_{Comp} is known to occur. We present here the results of the MO properties of HoIG:Sc garnets single crystals with two different T^{MO}_{Comp} at 1152 nm wavelength for the same composition, giving a tentative interpretation based on the one ion FR model of Crossley *et al.*[7] and the Dionne-refined Néel magnetization model of garnets.[8,9]

II. EXPERIMENT

Using the method of flux growth under 10 bar of oxygen pressure, single crystals of composition $Ho_3Fe_{5-z}Sc_zO_{12}$ with z=0.35, 0.52, 0.56, and 0.73 were synthesized. The scandium content was determined by electron microprobe analysis to within ±2% accuracy. Polished platelets ~1 mm thick oriented perpendicular to the [111] axis were obtained from the "as grown" crystals. FR measurements were performed at temperatures between 6 and 600 K, under a magnetic field up to 20 kOe applied parallel to the [111] direction at a wavelength of 1152 nm using a modulation technique. This wavelength is situated in the IR band, in the transparency window of garnets, and the MO properties presented in this paper are mainly dispersive. The FR isotherms $\Phi(H)$ show a linear part when $H>4$ kOe for all compositions and temperatures. A least-squares fit of these isotherms using $\Phi=\Phi_s+\chi_F$ H gives the spontaneous FR $\Phi_s(T,z)$ and FR susceptibility $\chi_F(T,z)$. The experimental accuracy is estimated to ±2% for Φ and ±1% for Φ_s.

III. RESULTS AND DISCUSSION

The FR of a three sublattices rare earth iron garnet is given by Refs. 7, 10, and 11 (and references therein):

$$\Phi_s(\lambda,T)=\pm(A_e+A_m)|M_a|\mp(D_e+D_m)|M_d| \pm(C_e+C_m)|M_c|. \quad (1)$$

Upper (lower) signs are valid for $T<T_{comp}$ ($T>T_{comp}$). $A_{e,m}(\lambda)$, $D_{e,m}(\lambda)$, and $C_{e,m}(\lambda)$ are the respective MO electric "e" and magnetic "m" dipole coefficients of the $[a]$, (d), and $\{c\}$ sublattices with magnetizations $M_{a,d,c}(T)$. The first two terms of Eq. (1) are the contributions from the Fe^{3+} $[a]$

 0021-8979/96/79(8)/5985/3/$10.00

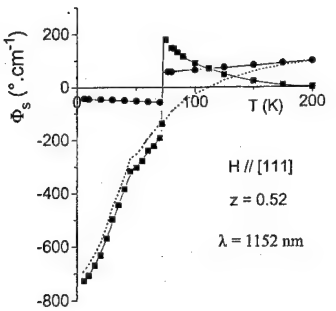

FIG. 1. Low temperature (T<200 K) dependence of $\Phi_{HoIG:Sc}$, z=0.52 (■), $\pm\Phi_{YIG:Sc}$ (●) of same Sc concentration, and Ho^{3+} contribution to FR Φ_{Ho} (dotted line) at 1152 nm wavelength.

and (d) sublattices which can also be deduced experimentally from the FR at the same wavelength of the corresponding YIG garnet of same composition:[1,10]

$$\Phi_{HoIG:Sc}=\mp\Phi_{YIG:Sc}\pm(C_e+C_m)|M_c|=\mp\Phi_{YIG:Sc}+\Phi_{Ho}, \quad (2)$$

where $\Phi_{Ho}(\lambda,T)$ is the Ho^{3+} contribution to the spontaneous FR. We plotted in Fig. 1 the temperature variation of $\Phi_s(z=0.52, \lambda=1152$ nm) when T<200 K and $H\|[111]$ for HoIG:Sc and YIG:Sc of same concentration. For HoIG:Sc, the characteristic magnetic compensation temperature T_{comp} is 72 K where Φ_s changes its sign. When $T\sim40$ K an inflection in the temperature variation curve is indicative of the onset of the umbrella spin structure in the Ho^{3+} sublattice.[12] The FR of YIG:Sc (z=0.52, λ=1152 nm), positive in the whole temperature range, is plotted in Fig. 1 with the appropriate sign to represent the Fe^{3+} contribution [Eq. (2)] along with the contribution of Ho^{3+} to FR $\Phi_{Ho}(z=0.52, \lambda=1152$ nm).

The high temperature part (100 K < T < $T_{Néel}$) of the FR of HoIG:Sc and YIG:Sc z=0.52 garnets crystals is plotted in Fig. 2. The behavior of Φ_s is complex and presents two characteristic temperatures $T^{MO}_{Comp}(1)$ and $T^{MO}_{Comp}(2)$, at which $\Phi_s(\lambda=1152$ nm) changes its sign whereas the bulk magnetization is different from zero. To our knowledge, this is the first time that such a behavior is reported. In order to confirm this situation, we plotted in Fig. 3 the high temperature (T >100 K) variation of Φ_s for different concentrations of the HoIG:Sc garnets. The presence of two MO compensation temperatures, at 1152 nm, is obtained only for z=0.52 and 0.56. At lower concentration (z=0.35) there is no MO compensation point but, instead, only an inflection point is observed. When the Sc concentration is higher (z=0.73), only the "low" MO compensation point remains. This is evidenced more clearly in Fig. 4 where we plotted the different characteristic temperatures of the HoIG:Sc system. By extrapolating the variation of $T^{MO}_{Comp}(1)$ and $T^{MO}_{Comp}(2)$, we note that $T^{MO}_{Comp}(2)$ is equal to $T_{Néel}$ for $z\sim0.6$. On the other hand, $T^{MO}_{Comp}(1)$ and $T^{MO}_{Comp}(2)$ merged together when $z\sim0.5$. Therefore, the limits of the Sc concentration zone where $\Phi_s(T)$ presents two MO compensation temperatures are $0.5<z<0.6$ (dashed area of Fig. 4). The existence of two MO compensation temperatures can be explained by the fact that the Sc substitution decreases at first the total Fe^{3+} contribution to

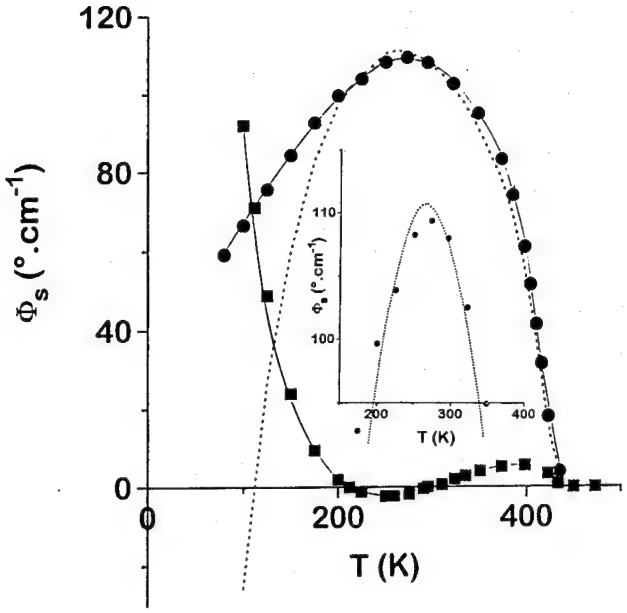

FIG. 2. High temperature (100 K < T < $T_{Néel}$) dependence of Φ_s (same legend as Fig. 1). Inset: magnification of the area where the contributions to FR of Ho^{3+} and that of Fe^{3+} intersect twice.

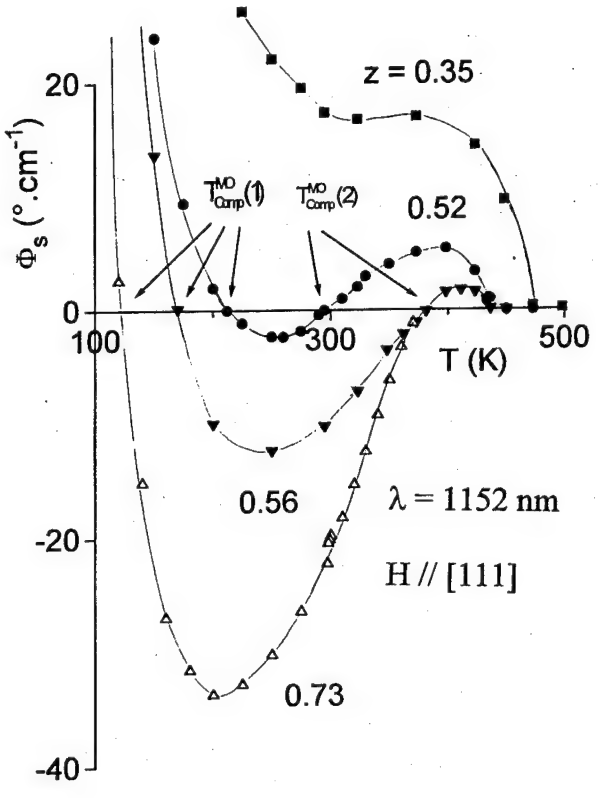

FIG. 3. Temperature dependence (T>100 K) of Φ_s for the different studied compositions at 1152 nm wavelength.

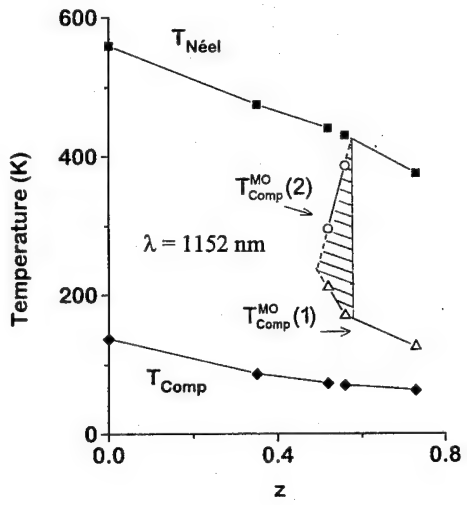

FIG. 4. Concentration dependence of the different characteristic temperatures of the MO properties of the HoIG:Sc system. The dashed area represents the existence zone for two MO compensation points at 1152 nm wavelength.

the FR of the garnet. The temperature variation of this contribution, as represented by the FR of YIG:Sc, presents a maximum in the vicinity of $T=250$ K (Fig. 2). At low temperature ($T<100$ K) the contribution of the Ho^{3+} sublattice is negative and preponderant for all the studied concentrations (Fig. 1). When $T>100$ K, the contributions of Ho^{3+} and Fe^{3+} are of the same magnitude order. In this temperature region, when the substitution is not too high ($z=0.35$), the contribution of Fe^{3+} is always dominant and there is no MO compensation point (Fig. 3). When z increases and $0.5<z<0.6$, the two contributions present a temperature range where they are very similar (Fig. 2) and crosses each other at two temperatures $T^{MO}_{Comp}(1)$ and $T^{MO}_{Comp}(2)$. A slight increase of the Sc concentration rate results principally in a decrease of the Fe^{3+} contributions, leaving the Ho^{3+} one nearly unchanged. As observed in Figs. 3 and 4, this leads to a larger value of the difference $T^{MO}_{Comp}(2)-T^{MO}_{Comp}(1)$: $T^{MO}_{Comp}(1)$ is shifted toward lower T, whereas $T^{MO}_{Comp}(2)$ is shifted toward $T_{Néel}$. At higher z ($z=0.73$), only $T^{MO}_{Comp}(1)$ is observed, shifted toward lower T (Figs. 3, 4).

At 1152 nm wavelength, the existence of two different T^{MO}_{Comp} leads thus to a more detailed analysis of the temperature behavior of the Ho contribution $\Phi_{Ho}=\pm(C_e+C_m)|M_c|$. According to Ref. 7, the coefficient C_m is given by $C_m=2\pi(\mu_B/c)ng_{Ho}$, where μ_B is the Bohr magneton and g_{Ho} the Landé factor of the Ho^{3+} ion. Assuming a refractive index $n=2.2$ and the same g_{Ho} factor as that of free Ho^{3+} ion, $C_m=5.72$ deg .$cm^{-1}.\mu_B^{-1}$.[6] As shown recently in HoIG:Al garnets,[1] $M_c(T,z)$ can be deduced using the Dionne-refined Néel model of ferrimagnetic garnets.[8,9] According to this model, the diamagnetic substitution in one sublattice induces a canting in the opposite sublattice which is taken into account through dilution functions applied to the molecular field coefficients (MFC) N_{ij} ($i, j=a,d,c$). As indicated previously, the $Fe^{3+}-Fe^{3+}$ interactions are well represented by those of YIG:Sc:[9]

$$N_{aa}(z)=N_{aa}(z=0),$$
$$N_{dd}(z)=N_{dd}(z=0)(1-0.43z), \tag{3}$$
$$N_{ad}(z)=N_{ad}(z=0)(1-0.125z).$$

In a first approximation, the MFC related to $Fe^{3+}-Ho^{3+}$ interactions were assumed to be the same as in pure HoIG:[1]

$$N_{ac}(z)=N_{ac}(z=0), \quad N_{dc}(z)=N_{dc}(z=0); \quad N_{cc}\sim 0. \tag{4}$$

The differences between calculated and experimental values of T_{comp} using this model and MFC of Eqs. (3), (4) are systematically greater than 20 K (well outside the experimental accuracy) due to an overevaluation of $M_c(T,z)$. A good agreement can be achieved using MFC of Eq. (4) as a function of z, either by increasing N_{ac} or decreasing N_{dc} when z increases. The first solution is not justified because the diamagnetic substitution cannot increase the exchange energy and only the second hypothesis,

$$N_{dc}(z)=N_{dc}(z=0)(1-\alpha z), \tag{5}$$

can be used. The value found for $\alpha=0.32$ is very similar to the coefficients in Eq. (3). This dilution function [Eq. (5)] indicates that Sc substitution in octahedral sites leads to canting in the tetrahedral sublattice which in turn influences the $Ho^{3+}-Fe^{3+}$ interactions. This confirms also that the magnetic rare earth$-Fe^{3+}$ interactions are mainly $(d)-\{c\}$.[5] In effect, in case of tetrahedral substitution (HoIG:Al), the influence of the canting in the $[a]$ sublattice should lead to a dilution function similar to Eq. (5) applied to the MFC N_{ac}, which is not the case.[1] This indicates that the $[a]-\{c\}$ interactions have much less influence on the magnetic properties than the corresponding ones $(d)-\{c\}$. Finally, it is to be noted that the temperature variation of $M_c(T)$ is a monotonous decreasing function. As shown in Fig. 2, the Ho contribution $\Phi_{Ho}(\lambda=1152$ nm, $T)=\pm(C_e+C_m)|M_c|$ presents a maximum. C_m being a constant, the MO electric dipole coefficient C_e must be a function of T. This confirms the hypothesis of the temperature dependence of the MO electric dipole coefficients in garnets at 1152 nm wavelength.[10]

Effect of structural irregularity on propagation properties of optical waves in discontinuous magneto-optical media with one-dimensional quasirandom array structures

Mitsuteru Inoue, Takeshi Yamamoto, Keiji Isamoto, and Toshitaka Fujii
Department of Electrical and Electronic Engineering, Toyohashi University of Technology, 1-1 Hibari-Ga-Oka, Tempaku, Toyohashi 441, Japan

To elucidate the effect of structural irregularity on propagation properties of optical waves in discontinuous magneto-optical media, theoretical analysis was carried out by employing random matrix technique and a model with one-dimensional quasirandom array structure. The analysis revealed that the effect of structural irregularity was so significant that the dispersion curves of optical waves varied considerably depending on the media structures. However, no matter how the medium structure varies irregularly, dispersion curves of waves always exist within the confines between those of the half (0···01···1) and the alternate (0101···01) structures. This fact suggests that the effect of structural irregularity becomes less significant when the discontinuous media have fine discrete structures, where the dispersion curves of the half and the alternate structures are very close.
 [S0021-8979(96)16408-4]

I. INTRODUCTION

Magneto-optical (MO) properties of discontinuous magnetic media are so unique that they are almost incomparable to those of continuous media. In fact, MO Faraday spectra (MO-FS) of uniformly dispersed or filament-like clustered cobalt particles in plastic films (polymethyl methacrylate) differ considerably from those of continuous media, and can widely be controlled by the concentration and aggregation states of the cobalt particles.[1,2] This suggests positively that the MO-FS can be manipulated artificially by introducing the discontinuous structures in magnetic media, though they are inherently material properties.

To explain the above experimental results theoretically, we analyzed the MO properties of magnetic media with one-dimensional periodic array structures.[3,4] We showed that optical waves in the media were modulated so as to satisfy boundary conditions imposed at every discontinuous plane, which resulted in the unique MO properties of the discontinuous media. However, the actual discontinuous media[1,2] are accompanied by a large number of clusters whose form and size vary irregularly, and thus their discrete structures are more complicated than that of the ideal periodic medium. Then, our previous analysis is still insufficient to elucidate the MO properties of such discontinuous media, because the optical waves will be also affected by the irregularity of the discrete structure.

In order to confirm this, we analyze optical waves in MO media with quasirandom discontinuous structures, and examine the effect of structural irregularity on the propagation characteristics of optical waves. To proceed with analysis, we use the "random matrix technique" which is considered to be an extended method of the matrix approach.[5] As a first step of the analysis, we ignored the change of material properties due to fining of the structures.

II. MODELING AND RANDOM MATRIX TECHNIQUE

Let us conceive a discontinuous magnetic media with quasirandom array structures which are built up as the following: First, as shown in Fig. 1(a), consider an infinitely wide MO medium with a finite thickness L which is composed of a one-dimensional array of virtual equivalent segments with width D. Each segment consists of N subsegments with widths d_i $(i=1,2,\ldots,N)$ which are generally assigned under the condition of $D=d_1+d_2+\cdots+d_N$. Supposing and simplifying our actual discontinuous media, we consider each subsegment is either magnetic material [specific dielectric tensor: $\tilde{\epsilon}_M(\lambda)$ at wavelength λ] with width d_M or air gap with width d_G [see Fig. 1(b)]. When we signify the magnetic material with "1" and the air gap with "0," sequential arrangement of the subsegments into one virtual segment is expressed by a binary number with N digits like "100101···01." This binary parameter of structure is obtained from a randomized integer generated by a computer. To specify the medium, packing density of the magnetic material in a medium (P_d) is defined by

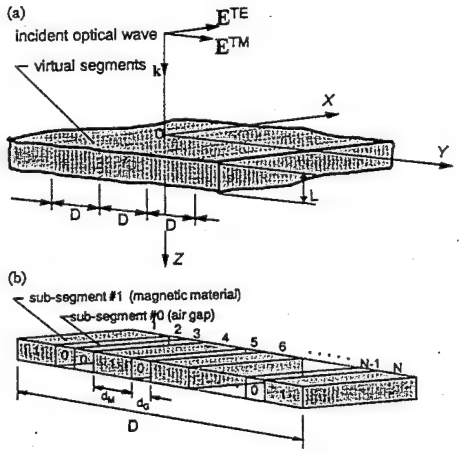

FIG. 1. Model of the discontinuous medium with quasirandom structure; (a) virtual segments in the medium and (b) subsegments in a virtual segment.

 0021-8979/96/79(8)/5988/3/$10.00

$P_d = D_M/D = N_M d_M/D$, where D_M and N_M are, respectively, the total width and the number of the magnetic materials in one virtual segment.

All magnetic materials in the medium are assumed to be identical to each other having magnetizations parallel to the propagation direction of optical waves (along the Z axis). When a linearly polarized (TE or TM) optical wave is incident normal to the top surface ($Z=0$) of the medium, fundamental equations of waves propagating in an ith subsegment are given by the Maxwell equations (1) and (2):

$$\nabla \times \mathbf{E}(Y,Z;t) = i\omega\mu_0 \mathbf{H}(Y,Z;t), \tag{1}$$

$$\nabla \times \mathbf{H}(Y,Z;t) = -i\omega\epsilon_0 \tilde{\epsilon}_i \mathbf{E}(Y,Z;t), \tag{2}$$

where we assumed that the optical wave had a plane wave form of $\exp[i\omega(n'Z/C_L - t)]$ with a complex refractive index $n' = n + i\kappa$ and an angular frequency ω. Equations (1) and (2) are arranged into the following matrix differential equation:

$$\frac{d}{dY}\mathbf{t}(Y) = \mathbf{A}_i(n',\omega)\cdot\mathbf{t}(Y), \tag{3}$$

in which $\mathbf{t}(Y) = (E_X, E_Z, H_X, H_Z)^t$ is the state vector and $\mathbf{A}_i(n',\omega)$ is the state matrix (4×4 complex matrix) of the ith subsegment whose explicit form is given in Ref. 4. Since the state matrix is a constant matrix with respect to Y, and the state vector is continuous at all discontinous interfaces between two neighboring subsegments, the state vector at $Y=D$ is given by

$$\mathbf{t}(D) = \Phi_N \cdot \Phi_{N-1} \cdots \Phi_2 \cdot \Phi_1 \cdot \mathbf{t}(0), \tag{4}$$

where $\Phi_i(n',\omega) = \exp\{\mathbf{A}_i(n',\omega)d_i\}$ is the transition matrix of the ith subsegment. Periodicity of the virtual segment with width D containing N subsegments imposes $\mathbf{t}(D) = \mathbf{t}(0)$, which yields the dispersion equation of waves with a 4×4 unit matrix $\mathbf{I}$:

$$\det(\Phi_N \cdot \Phi_{N-1} \cdots \Phi_2 \cdot \Phi_1 - \mathbf{I}) = 0. \tag{5}$$

Note that the transition matrices Φ_i in Eq. (5) are either of the magnetic material or air gap, and the dispersion equation is determined by the products of these matrices whose sequence corresponds to the random binary parameter of structure. The dispersion equation (5) was solved numerically using the combined technique of the steepest descent and the two-variable Newton-Raphson methods.[6]

III. RESULTS AND DISCUSSION

Numerical calculations were made using the same material parameters as used in the previous analysis, which were those of bismuth-substituted yttrium iron garnet ($Y_{0.25}Bi_{0.5}Fe_5O_{12}$, Bi:YIG hereafter).[7] As for structural parameters, we used $D=500$ nm, $N=2-50$, and $P_d=0-1.0$.

In the discontinuous medium with the one-dimensional periodic array structure, two fundamental eigenmodes of optical waves are R- and L-mode of waves,[3,4] which degenerate, respectively, into right and left circularly polarized optical waves when $D_M \gg \lambda$ (D_M, width of magnetic material; λ, wavelength of optical wave), while, when $D_M \ll \lambda$, they turn to TE wave (electric field **E**//X-axis) and TM wave (**E**//Y-axis), respectively. By solving Eq. (5), one finds that the R- and L-modes of waves are also the fundamental eigenwaves for the case of quasirandom array structure. Since the MO properties of the media are mainly prescribed by these waves, we discuss the dispersion characteristics of only these two waves, though the dispersion equation has a number of other solutions corresponding to their higher modes of waves.

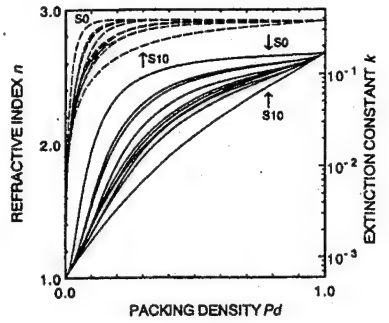

FIG. 2. Dispersion curves of R mode of optical waves in the quasirandom discontinuous media, where S0 and S10 denote the curves for the half and the alternate structures.

Figures 2 and 3 show, respectively, dispersion curves [refractive index n (solid curves) and extinction constants κ (broken curves) versus packing density $P_d = D_M/D$] of the R- and L-modes of waves in the discontinuous media with eleven types of discrete structures when $N=16$ and $\lambda=387.4$ nm. In the figures, curves labeled by S0 and S10 are special cases of periodic subsegment arrangements, where S0 is the curve of half structure of $(0000000011111111)_2=(255)_{10}$ while S10 is the curve of alternate structure of $(0101010101010101)_2=(21845)_{10}$. Subsegment arrangements of the other nine curves are expressed by 1804, 5787, 9195, 11096, 13089, 18571, 19620, 29854, and 54141 in decimal integers. It is seen that the values of n and κ of both waves are bounded between those of Bi:YIG (when $P_d \to 1.0$) and air gap (when $P_d \to 0.0$) irrespective of the medium structures. In this range, the dispersion curves vary depending strongly on the media structures, suggesting that the effect of structural irregularity is very large. However,

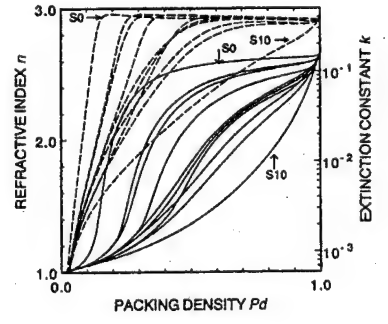

FIG. 3. Dispersion curves of L mode of optical waves in the quasirandom discontinuous media.

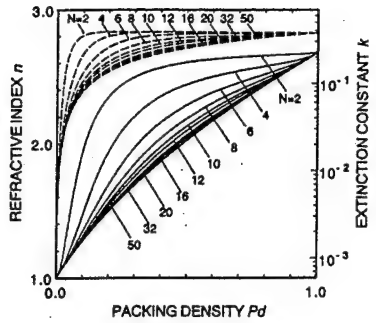

FIG. 4. Dispersion curves of R mode of optical waves in the quasirandom media with the alternate structures, where the number of the subsegments N is taken as a parameter.

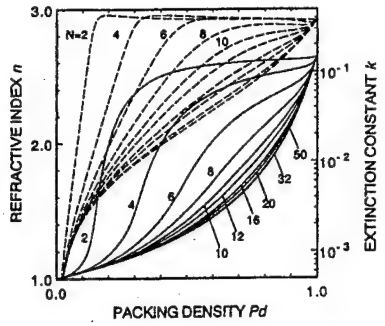

FIG. 5. Dispersion curves of L mode of optical waves in the quasirandom media with the alternate structures.

one should note that all dispersion curves of both waves exist within the confines between the dispersion curves of S0 and S10. This means that, no matter how the medium structure changes irregularly, the properties of optical waves are always within those of the half and alternate structures. Thus, when the dispersion curves of S0 and S10 are close to each other, the effect of structural irregularity should become less significant and can be ignored when describing the optical properties of the discrete media.

It is then worthwhile to examine the situation in which the dispersion curves of the half and the alternate structures are close. We can easily surmise that the dispersion curves of S10 will no longer be changed when the number of subsegments N is sufficiently large, because, for large N, the width of each subsegment becomes much smaller than the wavelength of optical waves. This is clearly shown in Figs. 4 and 5, where the dispersion curves for the R-mode (Fig. 4) and L-mode (Fig. 5) of waves in the discontinuous media with the alternate structures are depicted by taking the number of subsegments N as parameter. The dispersion curves for large N values are indeed almost identical (see the curves of $N=32$ and 50), where the discontinuous medium can be regarded as an effective continuous medium whose properties are solely designated by the packing density of magnetic material.

This indicates that, when the width of magnetic material in the half structure is approximately less than 5% of the wavelength of optical waves (here $\lambda=387.4$ nm), the discontinuous media with the half structure behave as if the effective continuous media. In this case, the dispersion curves of the half and the alternate structures are very close, and hence the effect of structural irregularity on the optical waves can no longer be remarkable.

IV. CONCLUSION

The analysis shows that the dispersion curves of waves vary considerably depending on the media structures. However, no matter how irregular the media structures are, dispersion curves of optical waves always exist within the region between those of the half and the alternate structures, and hence the more these dispersion curves approach each other, the less the dispersion curves change due to the structural irregularity. Provided that the maximum width of the magnetic material in the media is restricted approximately less than 5% of the wavelength of optical waves, the dispersion curves of the half and the alternate structures are almost identical and the effect of structural irregularity becomes negligible. This situation may correspond to our actual discontinuous media with uniformly dispersed cobalt particles ranging from 5 to 20 nm in diameter whose MO properties were evaluated within the wavelength interval between 400 and 900 nm.[1,2]

Our further calculations suggest that the present results are also applicable for describing the MO properties of the discontinuous media with filament-like clustered cobalt particles whose average size exceeds the limit mentioned above, which will be reported in detail elsewhere.

We report on the growth and magnetic characterization of epitaxial garnet thin films and heterostructures by pulsed laser deposition. Thin films and heterostructures consisting of yttrium iron garnet (YIG) interleaved with rare earth substituted bismuth iron garnet (BIG) have been deposited on single-crystal GGG substrates. These heterostructures exhibit strong polar magneto-optic Kerr effects with rotation angles of better than 5×10^4 °/cm at 533 nm. Microwave measurements at 10 GHz suggest that the Eu-substituted BIG layer has a preferred out-of-plane magnetization while the YIG layer is still magnetized in-plane. The implications of the magneto-optic and microwave results will be discussed in light of the heterostructure periodicity and film microstructure. © *1996 American Institute of Physics.* [S0021-8979(96)47708-4]

Mössbauer effect and electronic transport studies of icosahedral $Al_{50}Pd_{10}Mn_{25-x}Fe_xB_{15}$ alloys

M. Yewondwossen, J. E. Jagger, Z. Koziol, and R. A. Dunlap
Department of Physics, Dalhousie University, Halifax, Nova Scotia B3H 3J5, Canada

The temperature and applied magnetic field dependence of the resistivity of icosahedral $Al_{50}Pd_{10}Mn_{25-x}Fe_xB_{15}$ ($x=0$ and 5) alloys has been measured between 4.2 and 300 K. At low temperature, $T<30$ K, the resistivity showed a rapid decrease with increasing temperature and may be described by a combination of weak localization (WL) and magnetic scattering effects. At higher temperatures the resistivity is adequately described by the temperature dependence of the structural and magnetic effects as described by Boltzmann-type transport. The measured magnetoresistance of both samples is consistent with theoretical predictions based on WL. The room temperature Mössbauer effect spectrum of the $x=5$ sample showed a well resolved doublet with mean isomer shift (relative to room temperature α-Fe) and quadrupole splitting of +0.22 mm/s and 0.36 mm/s, respectively. These results indicate that the Fe probe nuclei do not carry a magnetic moment in these alloys. © *1996 American Institute of Physics.* [S0021-8979(96)16508-0]

I. INTRODUCTION

Quasicrystalline (QC) alloys which contain Mn have shown a wide variety of magnetic behavior and, in some cases have exhibited varying degrees of magnetic order. Typically, these magnetically ordered materials have been characterized by small Mn magnetic moments and low Curie temperatures. Recently, alloys which exhibit high Curie temperatures and substantial Mn moments have been reported[1–5] in the Al-Mn-Pd-B system. The availability of these materials allows for the investigation of the relationship of magnetic order and quasicrystallinity. In the present work we report on magnetotransport and Mössbauer effect studies of $Al_{50}Pd_{10}Mn_{25-x}Fe_xB_{15}$ alloys.

II. EXPERIMENTAL METHODS

Samples of $Al_{50}Pd_{10}Mn_{25-x}Fe_xB_{15}$ ($x=0$ and 5) were prepared by melt spinning. Resulting ribbons were shown to be single phase icosahedral quasicrystals by x-ray diffraction studies. The transverse magnetoresistance was measured at temperatures from 4.2 to 300 K in applied fields up to 5.5 T. The room temperature ^{57}Fe Mössbauer effect spectrum of the $x=5$ sample was obtained using a conventional constant acceleration drive system.

III. RESULTS AND DISCUSSION

The magnetoresistance data of $Al_{50}Pd_{10}Mn_{25-x}B_{15}Fe_x$ QC alloys ($x=0$, 5) are shown in Fig. 1. The most general expression for the magnetoresistance, $\Delta\rho(B)$, due to Fukuyama and Hoshino[6] which includes the effects of spin-orbit scattering, Zeeman splitting, and magnetic impurities is given by;

$$\frac{\Delta\rho}{\rho}=\rho A\sqrt{\frac{eB}{\hbar}}\left\{\frac{1}{2\sqrt{1-\gamma}}\left[f_3\left(\frac{B}{B_-}\right)-f_3\left(\frac{B}{B_+}\right)\right]-f_3\left(\frac{B}{B_2}\right)-\sqrt{\frac{4B_{so}}{3B}}\left(\frac{(\sqrt{t_+}-\sqrt{t_-})}{\sqrt{1-\gamma}}+\sqrt{t}-\sqrt{t+1}\right)\right\} \quad (1)$$

where

$$A=\frac{e^2}{2\pi^2\hbar},$$

$$\gamma=\left(\frac{3g^*\mu_B B}{8eD(B_{so}-B_s)}\right)^2,$$

$$B_\phi=B_i+2B_s,$$

$$B_2=B_i+\tfrac{2}{3}B_s+\tfrac{4}{3}B_{so},$$

$$t=\frac{3B_\phi}{4(B_{so}-B_s)},$$

$$B_\pm=B_\phi+\tfrac{2}{3}(B_{so}-B_s)(1\pm\sqrt{1-\gamma})+2B_s,$$

$$t_\pm=t+\tfrac{1}{2}(1\pm\sqrt{1-\gamma}),$$

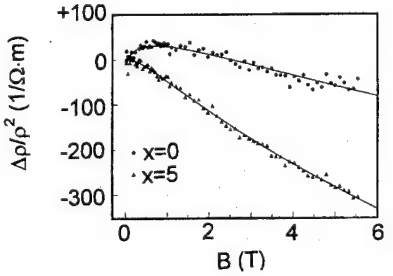

FIG. 1. The magnetoresistivity at 4.2 K of $Al_{50}Pd_{10}Mn_{25-x}B_{15}Fe_x$ plotted as a function of B. The solid lines are fits to WL theory.

 0021-8979/96/79(8)/5992/3/$10.00

TABLE I. Fitted parameters values for $Al_{70-x}Pd_{15}Mn_{15}B_x$.

Alloy (x)	$1/\tau_i$ ($\times 10^9\ s^{-1}$)	$1/\tau_{so}$ ($\times 10^9\ s^{-1}$)	$1/\tau_s$ ($\times 10^9\ s^{-1}$)	ρ(fitted) ($\mu\Omega$ cm)	ρ(exp) ($\mu\Omega$ cm)
0	5.4	10	0.7	870	1700
5	7.8	0.45	0.1	1200	1400

and D is the diffusion coefficient. The characteristic fields are related to electron scattering times through relations of the type

$$B_x=\frac{\hbar}{4eD\tau_x}, \tag{2}$$

where $x=i$, so, and s refer to the inelastic, spin-orbit, and magnetic spin-flip scattering times, respectively. The Kawabata function, $f_3(x)$,[7] has been written in the form proposed by Baxter *et al.*;[8]

$$f_3(x)=2\left(\sqrt{2+\frac{1}{x}}-\sqrt{\frac{1}{x}}\right)-\left[\left(\frac{1}{2}+\frac{1}{x}\right)^{-1/2}+\left(\frac{3}{2}+\frac{1}{x}\right)^{-1/2}\right]+\frac{1}{48}\left(2.03+\frac{1}{x}\right)^{-3/2}. \tag{3}$$

The magnetoresistance due to weak localization, $\Delta\rho_{WL}$, as given by Eq. (1), is negative in the case of weak spin-orbit scattering systems, i.e., $\tau_i<\tau_{so}$. In the case of strong spin-orbit scattering systems the magnetoresistance is positive and $\tau_i>\tau_{so}$.

The fitting procedure adopted for the samples studied is as follows. The WL contribution to the magnetoresistance is fitted with the temperature-dependent inelastic scattering time $\tau_i(T)$, and the temperature independent scattering times τ_{so} and τ_s as free parameters. The diffusion coefficient is taken to be 0.075 $cm^2\ s^{-1}$,[9] from literature values for similar quasicrystals. Quantum corrections to the resistivity predict $\Delta\rho/\rho\propto\rho$. Using ρ as a free parameter in the WL expression allows for a determination of the resistivity in a way that is independent of the sample geometry.[10]

The agreement between WL theory and the experimental data is good over the entire range of fields as illustrated by the fits shown in Fig. 1. The magnetoresistance of $x=0$ sample is positive in region $B<2.5$ T followed by a negative magnetoresistance in the remaining range of field. This feature reflects the moderate spin-orbit scattering case in which $\tau_i\approx\tau_{so}$. For the $x=5$, the magnetoresistance is totally negative and reflects the presence of weak spin-orbit scattering, $\tau_i<\tau_{so}$. The value of the fitted parameters are given in Table I.

The temperature dependence of the resistivity is illustrated in Fig. 2. The resistivity of the $Al_{70-x}Pd_{15}Mn_{15}B_x$ QC alloys is 1700 and 1400 $\mu\Omega$ cm at 4.2 K (for $x=0$ and 5, respectively). Various theories have been proposed to interpret the high values of the resistivity of QC's (e.g., Refs. 11–13). In general, two effects dominate $\rho(T)$ in QCs at low temperature; weak localization and magnetic scattering. The resistivity behavior at low temperature in $Al_{70-x}Pd_{15}Mn_{15}B_x$ is primarily due to magnetic scattering effects. This assertion may be illustrated as follows: The low temperature resistivity can be written as;

$$\rho(T)\approx\Delta\rho_{WL}(\tau_l(T),\tau_{so},\tau_s,D)+\rho_{Kondo}, \tag{4}$$

where $\Delta\rho_{WL}$ and ρ_{Kondo} are the WL and Kondo contributions, respectively. Using the scattering times described above the WL component may be subtracted from the resistivity data. The remaining data exhibit a $\ln(T)$ dependence for all the samples as is expected for Kondo-type scattering. At higher temperatures the resistivity is adequately described by the temperature dependence of Boltzmann-type transport.

The room temperature ^{57}Fe Mössbauer effect spectrum of icosahedral $Al_{50}Pd_{10}Mn_{20}Fe_5B_{15}$ is illustrated in Fig. 3. This spectrum shows a well defined doublet. The analysis of such spectra has been considered in detail by a number of authors (e.g., Refs. 14–16). In cases where the splitting is quadrupole in nature, spectra may be analyzed on the basis of a quadrupole distribution or a set of discrete splittings. Evidence seems to suggest that in related QC's two distinct classes of transition metal sites exist.[14,17,18] An analysis of

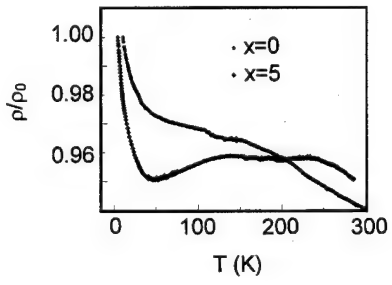

FIG. 2. Temperature dependence of the electrical resistivity normalized to the value at 4.2 K for $Al_{50}Pd_{10}Mn_{25-x}Fe_xB_{15}$ ($x=0$, 5).

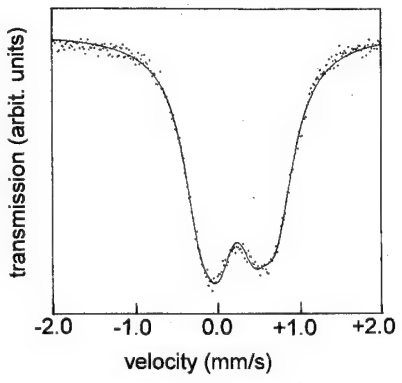

FIG. 3. Room temperature ^{57}Fe Mössbauer effect spectrum of icosahedral $Al_{50}Pd_{10}Mn_{20}Fe_5B_{15}$. The solid line is a fit to two symmetric doublets.

TABLE II. Room temperature ^{57}Fe Mössbauer effect parameters for the spectrum of icosahedral $Al_{50}Pd_{10}Mn_{20}Fe_5B_{15}$. Quadrupole splittings, Δ, and isomer shifts, δ, (relative to α-Fe) are given for the two doublets as described in the text. Mean parameter values are also given.

	Δ (mm/s)	δ (mm/s)
doublet No. 1	0.233	+0.219
doublet No. 2	0.493	+0.230
mean value	0.362	+0.224

Mössbauer spectra in terms of two discrete sites is illustrated in Fig. 3 and are summarized in Table II. In this case the two doublets have been chosen to have similar isomer shifts. Mean quadrupole parameters are consistent with Mössbauer effect results obtained for similar QCs. Spectra have also been fitted on the basis of a combined Zeeman and quadrupole interaction. The quality of fit for this analysis did not show any improvement over the previous analysis, suggesting that the Fe probe atoms do not carry magnetic moments in these alloys. There has been considerable work on Fe moment formation in QCs and evidence seems to suggest that Fe atoms prefer to reside in sites where a moment does not form.[14,19] The present measurements are consistent with this picture.

IV. CONCLUSIONS

The temperature and applied magnetic field dependence of the resistivity of icosahedral $Al_{50}Pd_{10}Mn_{25-x}Fe_xB_{15}$ ($x=0$ and 5) alloys has been measured. At low temperature results may be explained by a combination of weak localization and Kondo-type magnetic scattering effects. At higher temperatures the resistivity is adequately described by the temperature dependence of Boltzmann-type transport. The room temperature Mössbauer effect spectrum of the $x=5$ sample showed a well resolved doublet. A goodness-of-fit analysis indicated that the spectrum was appropriately described by a combination of two symmetric quadrupole doublets rather than an analysis based on the presence of a Zeeman splitting. This analysis suggests that the Fe probe atoms prefer to reside in sites where they do not carry a magnetic moment.

The magnetic susceptibility, magnetization and the temperature and field dependence of the Hall coefficient have been measured for the magnetically ordered icosahedral quasicrystals $Al_{70-x}Pd_{15}Mn_{15}B_x$ ($x=0,2,4,6,8,10$). The temperature dependence of the real and imaginary part of the complex ac susceptibility indicates re-entrant magnetic behavior and dc magnetization measurements are interpreted in the context of this behavior. The present Hall resistivity measurement shows the existence of both normal and anomalous Hall effects. The normal Hall coefficient is independent of temperature in all the alloys and changes from negative to positive with increasing boron concentration. This can be explained by the effects of $s-d$ hybridization. The anomalous Hall coefficient is also found to be temperature independent and has a compositional dependence correlated to the spin–orbit scattering rate. © *1996 American Institute of Physics.* [S0021-8979(96)12808-2]

I. INTRODUCTION

Since the first discovery of quasicrystals in Al–Mn alloys,[1] the electronic and magnetic properties of these materials have been studied extensively. Although early reports indicated that most quasicrystals are weakly magnetic,[2,3] some recently developed materials have shown strong magnetic behavior. Yokoyama *et al.*[4,5] have reported the synthesis and characterization of ferromagnetic $Al_{70-x}Pd_{15}Mn_{15}B_x$ icosahedral alloys. These alloys have Curie temperatures between 300–500 K and exhibit saturation magnetization up to 18 emu/g which disappears after crystallization. In the present work the Hall effect, magnetic susceptibility and magnetization of $Al_{70-x}Pd_{15}Mn_{15}B_x$ have been investigated and these complement our previous transport studies of this series.[6]

II. EXPERIMENTAL TECHNIQUES

Single phase icosahedral $Al_{70-x}Pd_{15}Mn_{15}B_x$ alloys were prepared in the form of ribbons by the melt spinning method.[7] The quasicrystalline nature of these samples was confirmed from x-ray diffraction patterns. The temperature dependent ac susceptibility was measured by a standard mutual inductance technique[8] at a frequency of 127 Hz in an ac magnetic field of ~80 A/m. dc magnetization measurements were carried out using a conventional superconducting quantum interference device (SQUID) magnetometer. Hall effect measurements were performed using a six-point dc technique in applied magnetic fields up to 4.4×10^6 A/m.

III. RESULTS AND DISCUSSION

Figure 1 shows the room temperature ac susceptibility of $Al_{70-x}Pd_{15}Mn_{15}B_x$ ($x=0-10$). The measured susceptibility increases with increasing x and is consistent with previous magnetization, nuclear magnetic resonance (NMR) and ferromagnetic resonance (FMR)[4,5,9] results for these alloys. This behavior can be described by the model in which the ferromagnetic coupling originates from the Mn–B bonding.[5]

A typical measurement of the real and imaginary parts of the ac susceptibility for the present alloys is shown in Fig. 2. These measurements show a knee in $\chi'(T)$ and, to a lesser extent, in $\chi''(T)$, for $6\leqslant x\leqslant 10$. No anomalous features have been observed for the susceptibility of samples with $x\leqslant 4$. Results may be compared with the previous data of Hattori *et al.*[10] which showed that the ac susceptibility of $Al_{70}Pd_{15}Mn_{15}$ showed a cusp at low temperature which was attributed to the existence of a reentrant spin glass (RSG) transition. There is some ambiguity in the interpretation of features in the ac susceptibility[10,11] which can arise from experimental conditions such as the exciting field frequency

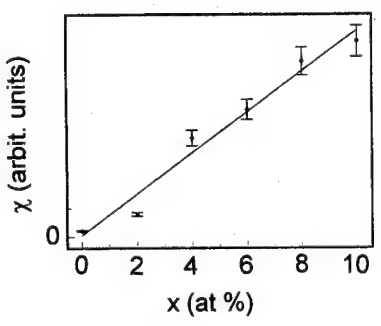

FIG. 1. The room temperature ac susceptibility of icosahedral $Al_{70-x}Pd_{15}Mn_{15}B_x$ alloys as a function of x.

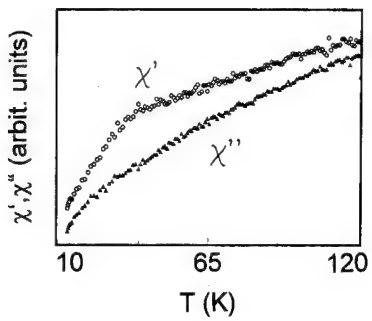

FIG. 2. The temperature dependence of zero-field cooled real and imaginary parts of the ac susceptibility for $Al_{60}Pd_{15}Mn_{15}B_{10}$.

and amplitude. The so-called Hopkinson peak[10] can obscure the characteristic behavior and, as a result, RSG features may be absent or may be shifted to a lower temperature. A comparison with magnetization data is often helpful in understanding the behavior of these materials. In most cases, the transition from ferromagnetism to the RSG state is defined by the onset of deviations from the plateau in the magnetization.[12] Results of these studies are illustrated in Fig. 3 for the present series of alloys. The knee associated with the RSG on lowering the temperature is clear for all alloys with $x \geq 2$. The observed temperature dependence is consistent with the behavior as described above.

In magnetically ordered materials both the ordinary Hall effect (OHE) and spontaneous Hall effect (SHE) are present. The latter is not restricted to ferromagnetic materials, but can appear in any material where strong magnetic interactions are present.[13] These two components combine to give the total Hall resistivity as (SI units):

$$\rho_H = R_0 B + R_s \mu_0 M \tag{1}$$

where B is related to the applied magnetic field by $B = \mu_0(H+M)$, M the magnetization and R_0 and R_s are the ordinary and spontaneous Hall coefficients, respectively.

The field dependence of the Hall resistivity $\rho_H(B)$ for $Al_{70-x}Pd_{15}Mn_{15}B_x$ is shown in Fig. 4. This behavior is virtually independent of temperature. The initial slope gives

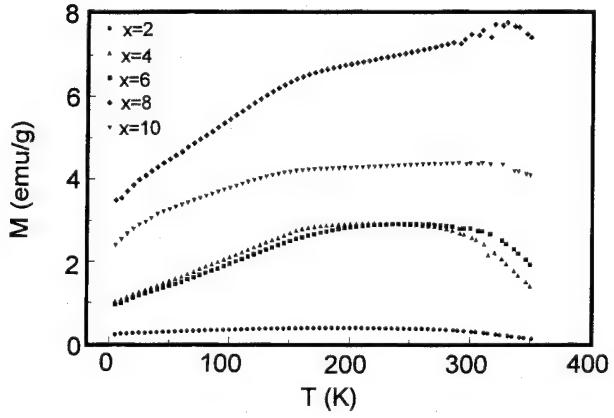

FIG. 3. Temperature dependence of the magnetization of $Al_{70-x}Pd_{15}Mn_{15}B_x$ as a function of x measured in an applied field of 8.0×10^3 A/m.

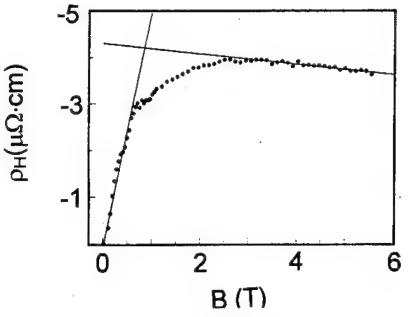

FIG. 4. Hall resistivity as function of field for $Al_{62}Pd_{15}Mn_{15}B_8$ at 4.2 K.

$$R_H = \left(\frac{\partial \rho_H}{\partial B}\right)_{B\to 0} \cong R_s \tag{2}$$

and the slope at high fields, gives:[14]

$$R_H = \left(\frac{\partial \rho_H}{\partial B}\right)_{B\to \infty} \cong R_0 . \tag{3}$$

Figure 5 shows that R_0 changes sign as a function of x. This behavior can be explained in terms of the effect of $s-d$ hybridization. This mechanism results from a shift of the Fermi energy and has been used to explain Hall effect results in amorphous alloys as it gives rise to regions of negative group velocity leading to positive R_0. In the present alloys the substitution of B for Al causes the Fermi level to increase as a result of a reduction in the unit cell volume[7] giving rise to the observed behavior.

In disordered alloys the SHE coefficient may be related to the temperature dependent resistivity, $\rho(T)$, as:

$$R_s(T) = a\rho(T) + b\rho^2(T) \tag{4}$$

where the first term results from quasiclassical skew scattering and the second term results from the quantum mechanical side jump.[13,15] In amorphous alloys, because of the large number of scattering centers, the quadratic term is believed to dominate. In the present alloys R_s is constant in temperature while $\rho(T)$ changes by as much as about 20%.[7] Therefore, at least to first order, there is no measurable correlation between R_s and ρ. This has been observed in other systems and has been explained by different scattering mechanisms for ρ and ρ_H.[16] The x dependence of R_s is shown in Fig. 6. R_s is negative for all alloys and shows a systematic change

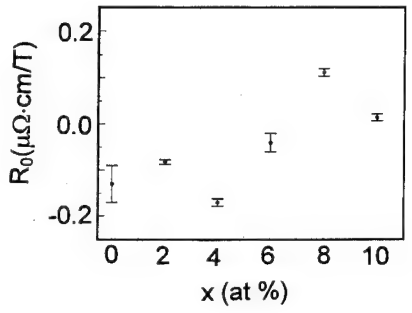

FIG. 5. The ordinary Hall coefficient of $Al_{70-x}Pd_{15}Mn_{15}B_x$ as a function of x at 4.2 K.

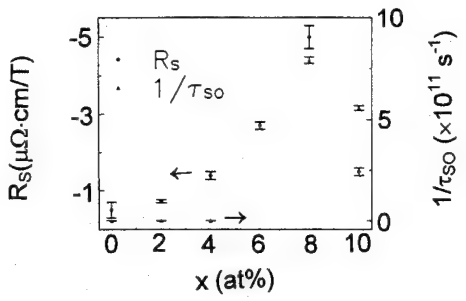

FIG. 6. The spontaneous Hall coefficient and spin–orbit scattering rate of $Al_{70-x}Pd_{15}Mn_{15}B_x$ as a function of x at 4.2 K.

with x. These results can be explained in terms of spin–orbit interactions. In Fig. 6 R_s is plotted along with the spin–orbit scattering rate as reported previously.[6,7] The magnitude of R_s increases with the scattering rate showing that the spin–orbit interaction is indeed the important contributor to the Hall resistivity although the mechanism by which the spin–orbit interaction influences the Hall resistivity is not obvious.

IV. CONCLUSIONS

Magnetic studies of icosahedral $Al_{70-x}Pd_{15}Mn_{15}B_x$ (x =0,2,4,6,8,10) as presented here indicate that these materials are ferromagnetically ordered and show a re-entrant spin glass transition at low temperature. The dc magnetization results indicate a higher transition temperature as expected on the basis of the effects of the Hopkinson peak on ac susceptibility data. The interpretation of these results is consistent with previous magnetic,[4] NMR,[5] and FMR[9] studies.

The data presented show that the Hall resistivity ρ_H is the result of two contributions; the normal term R_0B, due to the Lorentz force and anomalous term $\mu_0 M_s R_s$ due to the spin–orbit interaction. R_0 is independent of temperature but changes sign as a function of x and can be explained by the effects of $s-d$ hybridization. R_s is also found to be temperature independent and suggests that the scattering mechanisms responsible for $R_s(T)$ and $\rho(T)$ are different. The compositional dependence of R_s is similar to that of the spin–orbit scattering rate and indicates that this is the responsible interaction for the spontaneous Hall behavior in these materials.

Structural, magnetic, and magnetocaloric properties of $(Hf_{0.83}Ta_{0.17})Fe_{2+x}$ materials

J. F. Herbst and C. D. Fuerst

We have investigated the sensitivity of structural, magnetic, and magnetocaloric properties of $(Hf_{0.83}Ta_{0.17})Fe_{2+x}$ alloys ($x=-0.18$, -0.09, -0.02, 0.00, 0.09, 0.26) to Fe content. As-cast samples for all x consist essentially exclusively of hexagonal $MgZn_2$-type material. Via magnetization and differential scanning calorimetry measurements we find that all the alloys except $x=0.26$ feature both a ferromagnetic→antiferromagnetic (FM→AFM) transition at temperature T_0 and a Néel transition. The most abrupt FM→AFM transition occurs in the $x=-0.02$ material which also exhibits the lowest T_0 and largest low-temperature moment. We report a magnetocaloric property, the field-induced entropy change ΔS, for the $x=0.00$ and $x=\pm 0.09$ alloys. © *1996 American Institute of Physics.* [S0021-8979(96)12908-9]

I. INTRODUCTION

Nishihara and Yamaguchi have reported[1] the occurrence of a first order ferromagnetic→antiferromagnetic (FM→AFM) transition with increasing temperature T in the pseudobinary $Hf_{1-y}Ta_yFe_2$ systems having tantalum concentrations in the $0.1<y<0.3$ interval. A reversed (AFM→FM), but otherwise similar first order transition takes place as T increases near room temperature in Fe–Rh alloys, which have been suggested as candidate working materials for magnetic refrigeration.[2] In both systems the FM↔AFM transition is evidently sensitive to preparation conditions as well as composition. Annealed $Hf_{1-y}Ta_yFe_{1.99}$ materials were investigated in Ref. 1, while as-cast $Hf_{0.8}Ta_{0.2}Fe_{1.97}$ was employed in a recent study[3] of thermal and transport properties by Wada, Shimamura, and Shiga, who observed a sharper transition in as-cast, as compared with annealed, samples. Here we explore the sensitivity of the structural and magnetic properties to departures from stoichiometry by focusing on a series of samples with fixed Hf:Ta concentration ratio. For several alloys we also report determination of a magnetocaloric property, the isothermal field-induced entropy change ΔS.

II. SAMPLE PREPARATION AND STRUCTURAL CHARACTERIZATION

Ingots having nominal compositions specified by $(Hf_{0.83}Ta_{0.17})Fe_{2+x}$ with $x=-0.18$, -0.09, -0.02, 0.00, 0.09, and 0.26 were prepared by induction melting elemental constituents in BN crucibles under argon. The purity of the iron and tantalum employed was 99.999% and 99.9%, respectively; Zr was the primary contaminant of the hafnium, at a level of 3 at. % for all samples except $x=0.00$, for which it was 5 at. %. Each sample was furnace cooled (~3 min) and not subjected to any additional heat treatment. Phase occurrence and composition were established by x-ray powder diffraction (XRD) measurements and electron beam microprobe (EBM) analyses.

For each sample XRD indicated that the major phase is characterized by the hexagonal $MgZn_2$-type structure (C14; space group $P6_3/mmc$) featuring one Mg site ($4f$) and two Zn sites ($2a$,$6h$). Figure 1(a) displays the pattern observed for the most contaminated material, the $x=-0.18$ specimen, and Fig. 1(b) shows the pattern calculated for $(Hf_{0.83}Ta_{0.17})Fe_2$. It is clear that the sample consists principally of $MgZn_2$-type material; the asterisks indicate the only identifiable impurities, HfN and ZrN, which the EBM results corroborate. Even smaller amounts of nitride impurities were found in the $x=-0.02$, $x=0.09$, and $x=0.26$ samples, and no secondary phases were detected in the $x=-0.09$ and $x=0.00$ materials. The x-ray linewidths and relative intensities exhibited some sample-to-sample variation suggestive of changes

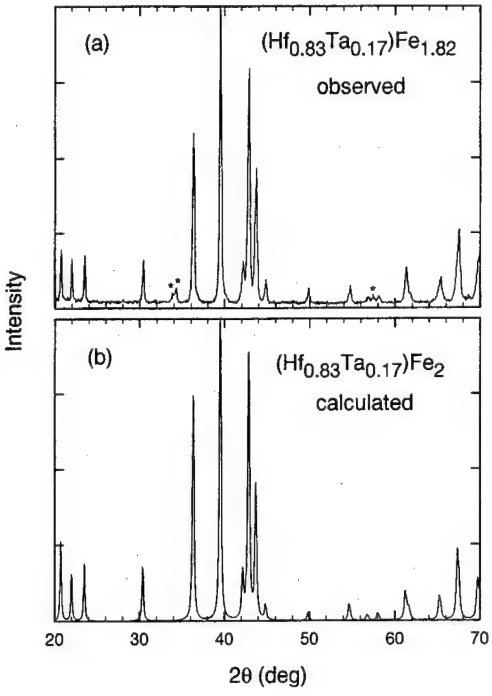

FIG. 1. (a) Cu K_α x-ray pattern observed for C14 $(Hf_{0.83}Ta_{0.17})Fe_{1.82}$ ($x=-0.18$); (b) pattern calculated for $(Hf_{0.83}Ta_{0.17})Fe_2$ using the lattice constants inferred from (a).

in effective grain size and at most modest preferred orientation effects.

While the XRD results demonstrate formation of a major C14-type phase over the entire $-0.18 \leq x \leq 0.26$ interval studied here, significant differences between the nominal ingot composition and the actual composition of the major phase in the as-cast samples were revealed by the microprobe work. The second and third rows of Table I specify x' and y' for the $(Hf_{1-y'}Ta_{y'})Fe_{2+x'}$ composition of the principal phase as determined by the EBM analyses. The y' values deviate from the nominal 0.17 Ta content by as much as 12%, outside the ~3% EBM composition accuracy. Furthermore, it is evident that x' undergoes considerably less excursion than x, especially on the Fe-poor side where x' reaches its lowest value, $-0.05 \sim 0$, for the $x=-0.18$ material. For all other compositions x' is positive. Despite the narrower range of x', the EBM results confirm that C14-type material forms in a rather broad homogeneity region. Moreover, the $x' \sim 0$ lower limit of the x' interval indicates that the solubility of Hf and Ta on the $2a$ and $6h$ iron sites is negligible compared with the solubility of Fe on the $4f$ sites. This is in qualitative accord with the fact that the metallic volumes of Hf and Ta, 22.4 and 18.0 Å^3, respectively, are both much larger than that of Fe, 11.8 Å^3.

Lattice parameters a and c determined from Rietveld refinements of the XRD data are included in Table I, as are the unit cell volumes V and the c/a ratios. In general a, c, and V decline with increasing x, aside from a slight deviation for $x=0.00$. The overall trend for V to decrease with Fe content suggests that excess, hyperstoichiometric iron enters substitutionally on the (Hf,Ta) $4f$ sublattice rather than interstitially. The c/a ratio decreases on both sides of a plateau at $x=-0.02$ and $x=0.00$. All the c/a values, however, are remarkably near the ideal ratio $(8/3)^{1/2}=1.6330$ corresponding to the hexagonal closest-packing of spheres; the maximum departure is 0.2%.

III. MAGNETIC, CALORIMETRIC, AND MAGNETOCALORIC RESULTS

Figure 2 displays magnetization versus temperature curves measured in a maximum applied field of 9 kOe, which in each case was sufficient to saturate the magnetization. The low temperature values M(10 K) are listed in Table I, as are the magnetic moments per Fe atom, μ_{Fe}, determined using the x' and y' values. M(10 K) spans a substantial range from 46.1 emu/g to 55.7 emu/g and shows no simple relation to the Fe content. For comparison, the magnetization of FeRh alloys is ~130–140 emu/g at low temperature for compositions near the equiatomic stoichiometry.[4,5] It is evident from Fig. 2 that $M(T)$ varies dramatically with x. The sharpest variation occurs in the $x=-0.02$ material at a temperature $T_0 \sim 210$ K which we identify with an FM→AFM transition. This result is in agreement with the previous finding[3] that the most abrupt transitions occur in as-cast samples prepared from slightly Fe-deficient starting compositions.

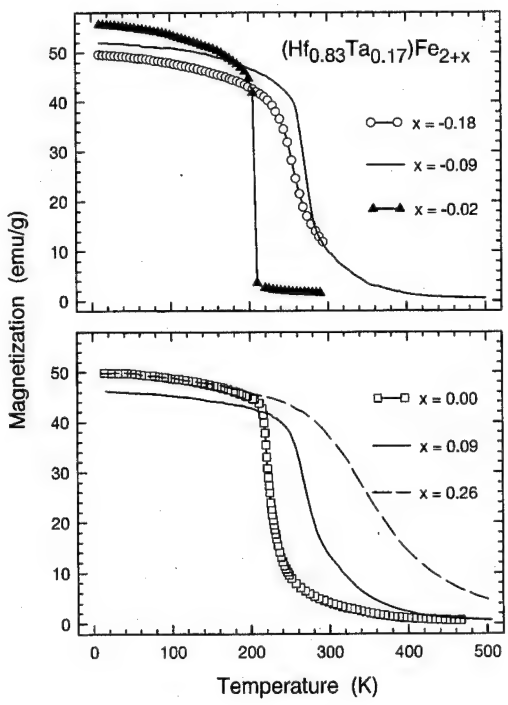

FIG. 2. Magnetization vs temperature for as-cast $(Hf_{0.83}Ta_{0.17})Fe_{2+x}$ materials.

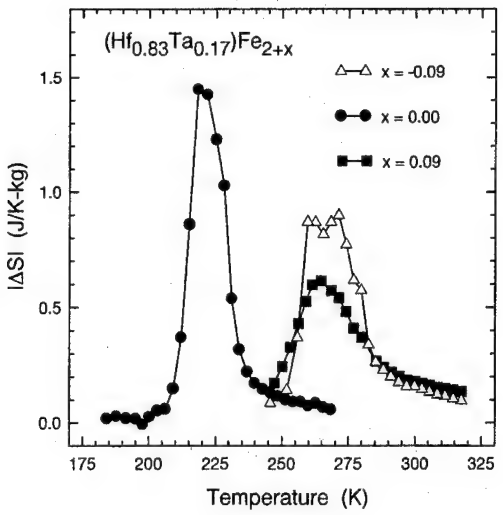

FIG. 3. Entropy change $|\Delta S|$ of $(Hf_{0.83}Ta_{0.17})Fe_{2+x}$ materials after application or removal of a 9 kOe magnetic field.

We identified other FM→AFM, Curie (FM→paramagnetic), and Néel (AFM→paramagnetic) transitions in these samples with the help of differential scanning calorimetry (DSC) measurements performed in the $T>225$ K range; the corresponding transition temperatures, T_0, T_C, and T_N, respectively, are given in Table I. The DSC structures to which we assigned T_C and T_N were characteristically asymmetric, while each peak identified with a FM→AFM transition was considerably more symmetric. We would have been reluctant to make this assignment using the DSC data alone, but our magnetization measurements and the magnetocaloric results derived from them (Fig. 3) make for consistent and credible identification.

Aside from the $x=0.26$ material, each sample is characterized by both a FM→AFM and a Néel transition, with the associated temperatures falling into two distinct groups. For $x=-0.18$ and $x=\pm 0.09$, $T_0\sim 260$–270 K and $T_N\sim 320$ K, while for $x=-0.02$ and $x=0.00$, $T_0\sim 210$–230 K and $T_N\sim 340$ K. It is interesting to note that the $x=-0.02$ material exhibiting the most abrupt change in $M(T)$ and T_0 has the largest low-temperature moment, lowest T_0, and largest (T_N-T_0) difference. Only one, asymmetric DSC peak was observed for the Fe-richest sample, $x=0.26$; together with the magnetization curve (Fig. 2), this indicates that the material is ferromagnetic over the entire ordered temperature range.

To make a preliminary assessment of magnetocaloric effects in these systems we determined the field-induced entropy change ΔS for three of the samples. Using the Maxwell relation $(\partial S/\partial H)_T=(\partial M/\partial T)_H$, which implies

$$\Delta S=\int_0^H\left[\frac{\partial M(H',T)}{\partial T}\right]_{H'}dH', \tag{1}$$

we calculated ΔS from magnetization data acquired as a function of both applied field H and temperature T. Figure 3 displays $|\Delta S|$, corresponding to application or removal of a 9 kOe field, as a function of T for the $x=0.00$ and $x=\pm 0.09$ materials. The maximum entropy change $|\Delta S_{\max}|$ extends from ~0.6 J/K kg to ~1.5 J/K kg and in each case occurs slightly below the T_0 value listed in Table I. The sharpness of the transition in the $x=-0.02$ sample precluded an accurate determination of $|\Delta S|$, although we estimate that the peak value exceeds 20 J/K kg. For comparison purposes we note that, in a 9 kOe field and at temperatures in the vicinity of ambient, $|\Delta S_{\max}|\sim 3$ J/K kg for both Gd (Ref. 6) and annealed $Fe_{49}Rh_{51}$ (Ref. 2), while quenched $Fe_{49}Rh_{51}$ features $|\Delta S_{\max}|$ as large as ~17 J/K kg (Ref. 2).

IV. SUMMARY

We have shown that the magnetic and magnetocaloric properties of $MgZn_2$-type $(Hf_{0.83}Ta_{0.17})Fe_{2+x}$ as-cast alloys are highly sensitive to the Fe level. A FM→AFM transition occurs over a broad range of x and temperature and is most abrupt in materials having slightly substoichiometric Fe content. Magnetocaloric effects in these systems merit further investigation in view of the fact that the effects of preparation conditions as well as composition are still incompletely known.

Magnetic properties of a high T_c superconductivity related system $Y_{1-x}Pr_xBa_2Fe_3O_8$

We studied Pr substitution for Y in a 123 high T_c superconductor related system, $Y_{1-x}Pr_xBa_2Fe_3O_8$ using of x-ray diffraction, magnetization, and ^{57}Fe transmission Mössbauer spectroscopy. The Fe sublattices are magnetically ordered through the whole system. The Pr substitution, however, suppressed the Fe ordering temperature. The low temperature susceptibility across the system increases with increased Pr concentration x, and an additional antiferromagnetic ordering at 24 K is observed for $x=1$, indicating a possible Pr ordering. The averaged magnetic hyperfine field at Fe sites measured at 15 K is also reduced as x increases. The dramatic effect of Pr substitution for Y in this system, which is not observed in studies of Y substitution by other rare-earth elements, is interpreted as the effect of the hybridization between the Pr 4-f electrons and the electrons in the $Fe(2)O_2$ layers, similar to the Pr hybridization in $Y_{1-x}Pr_xBa_2Cu_3O_{7-y}$ system. [S0021-8979(96)16608-7]

The substitution effect has been extensively studied since the 123 high T_c superconductor material $YBa_2Cu_3O_{7-x}$ was discovered. The study of the substitution of Y with most of the rare-earth elements of different concentrations up to 100% shows no or little effect on the superconducting behavior of the material, except with Pr, which suppresses the superconducting transition temperature, T_c, to zero at a concentration around 50%.[3] Among the models that explain the suppression of T_c along with other unusual features of the Pr substituted 123 compounds are the hole filling mechanism, which requires tetravalent or mixed valent Pr,[4,1] and the mechanism of hybridization between the 4f-electrons of Pr^{3+} and the electrons in the adjacent $Cu(2)O_2$ planes.[5,6,1] Both models are well supported by a large amount of experimental and theoretical data. But the nature of the Pr valence is still inconclusive.[7] The partial replacement of Cu atoms with other transition metals suggests that the two-dimensional $Cu(2)O_2$ layers play a more important role than the Cu(1) chains in the superconducting process.[8,9] It has been thought that the information about the Cu-free 123 compounds could be very important to the full understanding of the 123 high T_c superconductivity, yet relatively few studies on the complete substitution of Cu have been reported in the literature.[10–13] One of the interesting Cu-free compounds is $YBa_2Fe_3O_8$. The neutron diffraction study[1] showed that the crystal structure of the compound is tetragonal with the symmetry of space group p4/mmm. This structure is very similar to the 123 high T_c superconductors, except that the oxygen sites in the Cu(2)-chain layers are fully occupied. The same study also showed that the Fe moments are coupled antiferromagnetically both within each FeO_2 layers and along the C axis. The Fe ions at two inequivalent sites, Fe(1) and Fe(2), are interpreted to have same values of the valence and the magnetic moment. The Mössbauer studies on $YBa_2Fe_3O_8$[2,13] showed that the spectrum can be fitted as two sets of subspectra corresponding to Fe(1) and Fe(2). However these two subspectra have the same hyperfine field, and differ only in their quadrupole interactions. It has also been reported[13] that the substitution of Y by a number of rare-earth elements (Ho, Eu, and Er) has essentially no effect on the Fe antiferromagnetic ordering.

In order to further investigate the Cu-free 123 compounds and the nature of the Pr substitution effect, we studied the magnetic properties of $Y_{1-x}Pr_xBa_2Fe_3O_8$ system by means of dc magnetization measurement and ^{57}Fe Mössbauer experiment. Our study yielded more detailed information at the two different Fe sites. And more importantly, we observed that the Pr substitution has a dramatic effect on the magnetic behavior of the system.

Polycrystalline samples of $Y_{1-x}Pr_xBa_2Fe_3O_8$ for $x=0$, 0.25, 0.50, 0.75, and 1.0 were synthesized by coprecipitation mixing and solid-state sintering techniques. The stoichiometric amounts of 99.9% purity materials $BaCO_3$, Fe metal, Y_2O_3, and $Pr(CH_3COO)_3$ were dissolved in dilute nitric acid to form a stock solution with appropriate cation proportions. The solution was then added to a fast stirring concentrated solution containing Na_2CO_3 and NaOH with 25% of solvent ethyl alcohol to force the metallic ions to coprecipitate as insoluble carbonates. A better mixing at a microscopic level is therefore achieved without mechanical grinding and shaking. The gel-like precipitates were filtered, washed with mixture of distilled water and ethanol, and dried in an oven at 120 °C for a day. Finally, the dried precursors were fired in tube furnaces at 950 °C with oxygen flow for about 10 days.

The sample purity and their crystal structures were determined by powder x-ray diffraction measurements using a Regaku Diffractometer. A Quantum Design SQUID was used to measure the magnetic susceptibility for 5 K$\leqslant T\leqslant$400 K and the isothermal magnetization. In these measurements, the samples were first cooled to the lowest temperature in zero field. The field was then applied and the temperature was increased. The ^{57}Fe transmission Mössbauer spectra

were measured for 15 K$\leqslant T\leqslant$298 K using a conventional constant acceleration Mössbauer spectrometer with a closed cycle refrigerator. A ^{57}Co:Rh source of 25 mCi was used in the Mössbauer measurements.

Powder x-ray diffraction studies showed clean patterns for all samples with no detectable secondary phase formation. All phases in the system formed a tetragonal crystal structure with space group P4/mmm, which is as reported by other groups for $YBa_2Cu_3O_8$.[1,2] The measured lattice parameters at room temperature are $a=3.916$ Å and $c=11.798$ Å for $YBa_2Fe_3O_8$, and, $a=3.940$ Å and $c=11.817$ Å for $PrBa_2Fe_3O_8$. Across the system the lattice parameters monotonically increase as x increases, but the trend deviates from the Vegard's Law.

Figure 1 shows the temperature dependence of the magnetic susceptibility of $Y_{1-x}Pr_xBa_2Fe_3O_8$, $\chi(T)$, measured in a field of 1 kG. The susceptibility behaves similar to the Curie-Weiss magnetism above $T=50$ K. Below 50 K, for the $PrBa_2Fe_3O_8$ sample, i.e., $x=1$, the susceptibility showed a clear cusp at $T=24$ K, indicating an antiferromagnetic ordering. This ordering is likely originating from Pr moments, which is similar to the Pr ordering in $PrBa_2Cu_3O_7$ at $T=17$ K.[5,1] Shown in the insert of Fig. 1 is the $\chi(T)$ of $PrBa_2Fe_3O_8$ at different fields. The cusp, which determines the Neel temperature, T_N, is shifted to lower temperatures as the applied field increases and disappears when the field is larger than 11 kG. The field dependence of T_N is shown in the insert of Fig. 2.

The isothermal magnetization of $PrBa_2Fe_3O_8$ up to 5.4 tesla at various temperatures is shown in Fig. 2. We also plot M(H) for $YBa_2Fe_3O_8$ (data from Ref. 13), which is linear in H, in the same scale for comparison. The deviation of M(H) of $PrBa_2Fe_3O_8$ from the linear dependence suggests a canted magnetic structure of the Fe sublattices. Such a canted structure is expected to be more complicated than the antiferromagnetic structure in $YBa_2Fe_3O_8$, which was determined by the powder neutron diffraction experiment.[1] The difference in the magnetic structures of $PrBa_2Fe_3O_8$ and $YBa_2Fe_3O_8$ might be caused by the effect of hybridization between Pr f-electrons and the Fe(2)O_2 layers.

The room temperature ^{57}Fe Mössbauer spectra of $Y_{1-x}Pr_xBa_2Fe_3O_8$ are presented in Fig. 3. The spectra for $x\leqslant 0.50$ can be very well fitted into a combination of two sextuplets with the intensity ratio 1:2, plus a quadrupole doublet near the center of the spectra, which counts less than 3% of total intensity. The two sextuplets correspond to the two crystallographically inequivalent lattice sites, Fe(1), with an octahedral coordination, and Fe(2), with a square-pyramidal coordination. The additional quadrupole doublet may indicate a small amount of impurity phases in the samples. An important feature shown in this figure is that the spectra of $x=0.75$ and $x=1.0$ samples are significantly different from the spectrum of $YBa_2Fe_3O_8$. Specifically, we did not observe any hyperfine splitting in these two samples. This clearly indicates that the substitution of Y by Pr significantly changes the electronic and magnetic structure of the system. Such an effect, however, was not observed in the substitution of Y by other rare-earth elements, such as Eu, Ho, and Er.[2] In the case of superconducting 123 system, Pr is special because it suppresses T_c when substituted in $YBa_2Cu_3O_7$, while the substitution of other rare-earth elements does not. In our case Pr again singles itself out by affecting the magnetic properties of $YBa_2Fe_3O_8$ by its substitution.

Finally, in Fig. 4 we plot the Mössbauer spectra of $Y_{1-x}Pr_xBa_2Fe_3O_8$ measured at $T=15$ K. The spectra for samples of $x=0.0$ and 0.25 are similar to the room tempera-

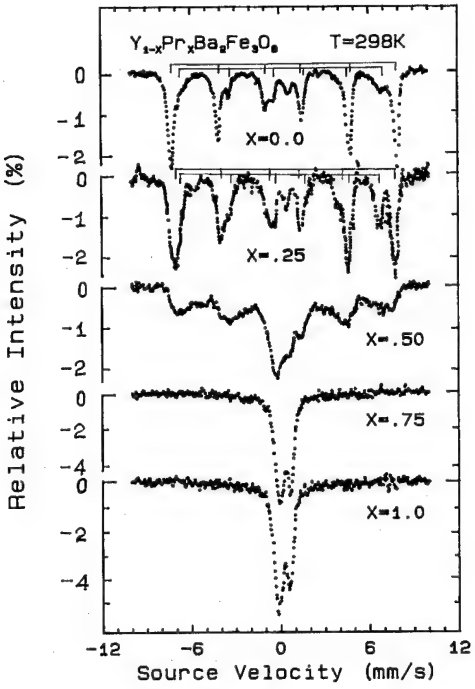

FIG. 3. Mössbauer spectra of $Y_{1-x}Pr_xBa_2Fe_3O_8$, for $x=0.0$, 0.25, 0.50, 0.75, and 1.0, measured at room temperature.

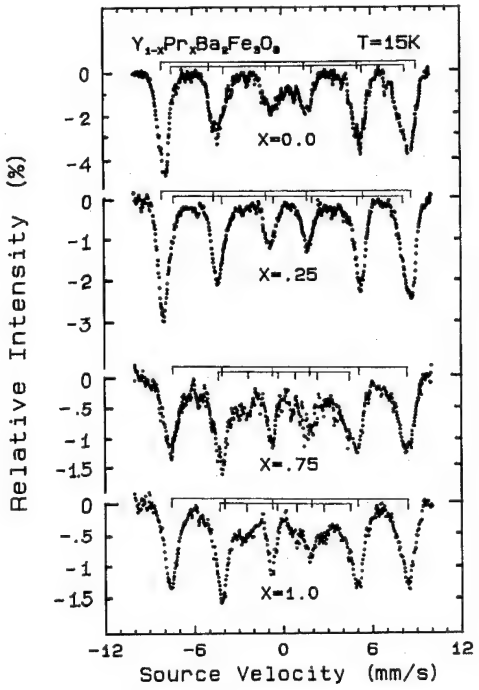

FIG. 4. Mössbauer spectra of $Y_{1-x}Pr_xBa_2Fe_3O_8$, for $x=0.0$, 0.25, 0.75, and 1.0, measured at 15 K.

ture spectra but with larger hyperfine splitting. The spectra of $x=0.75$ and $x=1.0$ samples showed that the Fe(1) and Fe(2) sublattices are magnetically ordered. The averaged hyperfine field reduces its value as x increases. The temperature dependent Mössbauer study on $PrBa_2Fe_3O_8$ indicated that the magnetic ordering temperature is somewhere between 250 K and room temperature. However, we did not see any noticeable anomaly in the susceptibility data. The reduction of the average hyperfine field can be interpreted as the effect of the hybridization between the Pr 4*f*-electrons and the Fe(2)O_2 layers. Fitting our Mössbauer data yielded two well-defined parameter sets of isomer shift, quadrupole splitting, and magnetic hyperfine field for all the spectra measured below the magnetic ordering temperature. We find these two sets of parameters are significantly different. This difference is not only due to the Pr substitutions. Even for $YBa_2Fe_3O_8$, the magnetic hyperfine fields at Fe(1) and Fe(2) sites are 428.1 and 471.9 kG at room temperature, and, 496.7 and 523.8 kG at $T=15$ K. This result, along with the result of different isomer shift parameters, clearly indicates that the electronic valence states and the magnetic moments of the Fe ions at the two sites are different. Our result disagrees with the previously reported results[1,2] on $YBa_2Fe_3O_8$, i.e., that the ions at the two different sites have the same electronic valence and the same magnitude of the magnetic moments.

Further studies including the high temperature susceptibility, the specific heat, and the electrical resistivity measurements are being conducted and will be reported later. Neutron study and other complement measurements are required to fully understand this system regarding its magnetic structure.

The authors would like to acknowledge the Center for Materials Research at Temple University for supporting this research. T. Yuen would like to express her appreciation to Dr. C. L. Lin, for his technical help and many valuable discussions.

Observation of independent iron and rare-earth ordering in RFe_6Ge_6 (R= Y, Gd–Lu) compounds

D. H. Ryan[a] and J. M. Cadogan
School of Physics, The University of New South Wales, Sydney NSW 2052, Australia

Mössbauer and magnetization measurements have been used to study magnetic ordering in RFe_6Ge_6 alloys. The iron sublattice orders antiferromagnetically and T_N remains essentially constant across the series at ~480 K with no evidence of a net magnetization in any of the alloys. For R=Gd–Er, the rare-earth sublattice orders ferromagnetically with T_c's that descend from 30 K at Gd to 3 K at Er. This order is established without affecting the order on the iron sublattice. The large difference in ordering temperatures and the unrelated magnetic structures adopted by the two sublattices indicate that the iron and rare-earth moments are effectively isolated from each other and that they order independently. © *1996 American Institute of Physics.* [S0021-8979(96)13008-3]

INTRODUCTION

Earlier work on RFe_6Ge_6 alloys has shown that they order antiferromagnetically below about 480 K, and that T_N (Ref. 1) is insensitive to the rare-earth element present in the alloy. Furthermore, the hyperfine field at the iron sites, B_{hf}, does not change when Gd or Tb is substituted for Y, nor is any net magnetization observed following these substitutions.[2] These results suggest that either the rare-earth sublattice also orders antiferromagnetically, or that it does not order at all.

In order to investigate this alloy series in more detail, we have extended our previous study[2] to include all of the heavy rare earths. We have used Mössbauer spectroscopy to probe, the effects of the rare-earth substitutions on a microscopic scale, and low-temperature susceptibility and magnetization measurements, to look for evidence of magnetic order at the rare-earth sites.

EXPERIMENTAL METHODS

The alloys were prepared by arc-melting stoichiometric ratios of the pure elements (Fe: 99.95%, Ge: 99.999%, and rare-earths: 99.9% pure) under Ti-gettered argon to yield ~2 g ingots. To allow for the inevitable loss of Tm and Yb by evaporation during arc melting, excess Tm (10%) and Yb (25%) was added to the starting mixture. Room temperature Mössbauer spectroscopy showed both the magnetic pattern of the 1–6–6 phase with typically a 10%–20% contamination from the nonmagnetic, tetragonal 1–2–2 phase.[3] Annealing at 900 °C for two weeks sealed under vacuum in quartz tubes yielded single-phase 1–6–6 alloys.

Powder x-ray diffraction patterns were obtained using Cu–K_α radiation on an automated Nicolet–Stoe diffractometer. The structures of the annealed alloys were found to be in agreement with those reported by Venturini *et al.*,[1] with the exception of the Gd alloy where we found no evidence for the superlattice structure and Pnma space group they reported. Our $GdFe_6Ge_6$ alloy showed the much simpler hexagonal P6/mmm structure found also in the Yb and Lu alloys.

Mössbauer spectra were obtained at room temperature in transmission geometry on a conventional constant-acceleration drive using a 1 GBq ^{57}CoRh source. The instrument was calibrated with a natural iron foil and all isomer shifts are given relative to that standard. 60–80 mg samples were hand ground and dispersed in graphite. Resonant absorptions of 7%–10% were obtained.

Thermogravimetric analysis was carried out on a Perkin–Elmer TGA-7 in a small field gradient to look for evidence of ferromagnetic or ferrimagnetic ordering. The Néel temperatures of the alloys were measured on a Perkin–Elmer DSC-7, using the heat capacity peak at T_N as the signature of ordering. Both systems were calibrated using standard alumel and nickel samples. A LakeShore susceptibility system with a closed-cycle refrigerator was used to record χ_{ac} vs T down to 12 K. Magnetization measurements were carried out on a Quantum Design SQUID down to 2 K in fields of up to 5 T.

RESULTS AND DISCUSSION

The room temperature Mössbauer spectra of the annealed samples (Fig. 1) show a magnetically ordered, six-line pattern with a splitting of ~15 T, half that found in α-Fe, suggesting an iron moment of about 1 μ_B. There is no evidence of either magnetic or nonmagnetic contaminants. Thermogravimetric analysis (TGA) measurements showed no sign of either ferromagnetic or ferrimagnetic order between 300 and 600 K. Given the obvious magnetic order on the iron sites observed by Mössbauer spectroscopy, we conclude, as before,[1,2] that the ordering in all of these alloys is antiferromagnetic. The Mössbauer parameters for the alloys studied here are summarized in Fig. 2. The three crystal structures adopted by the alloys in this series are closely related and is it clear from the absence of any jumps in the hyperfine parameters that the local environment of the iron remains essentially unchanged as the structure passes from Cmcm (Y–Ho) through Immm (Er,Tm) to P6/mmm (Yb,Lu). Furthermore, the easy axis of magnetization must remain in the basal plane at room temperature in all of the alloys since the quadrupole splitting is essentially constant across the series.

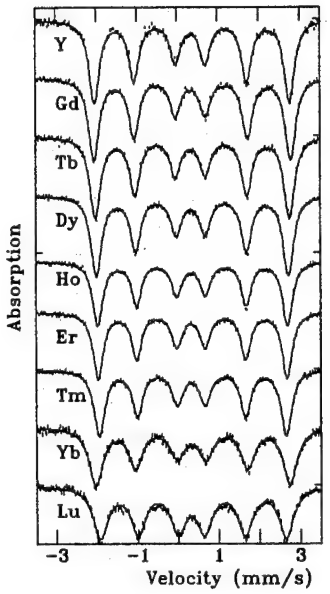

FIG. 1. Room temperature Mössbauer spectra of the annealed RFe_6Ge_6 alloys. Solid lines are fits assuming a single, magnetically ordered iron site.

The most surprising feature of this system is the fact that both the hyperfine field at the iron nucleus (B_{hf}, Fig. 2) and T_N (Fig. 3) are essentially independent of the rare-earth present. Apart from a gradual decline in B_{hf} (5%) and T_N (2%) there appears to be no significant change in the magnetic properties on going from Gd to Lu. These results suggest that the rare-earth sublattice does not order with the iron at 480 K, furthermore, an earlier study[1] found no evidence of

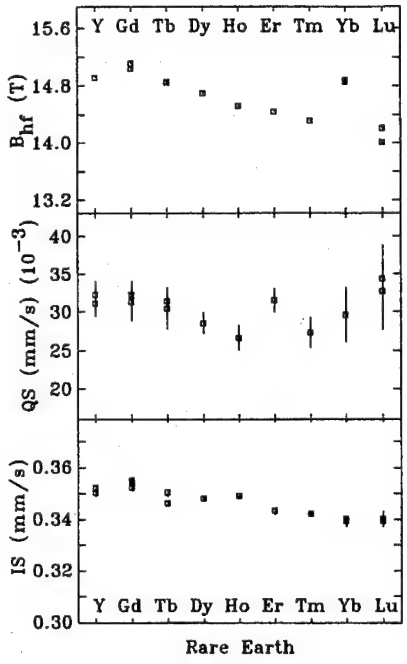

FIG. 2. Summary of fitted hyperfine parameters at room temperature for all of the RFe_6Ge_6 alloys studied here. Error bars are derived from statistical uncertainties. Values obtained from samples before and after annealing are shown in several cases, and agree within error. Data on two Gd alloys are included as a consistency check.

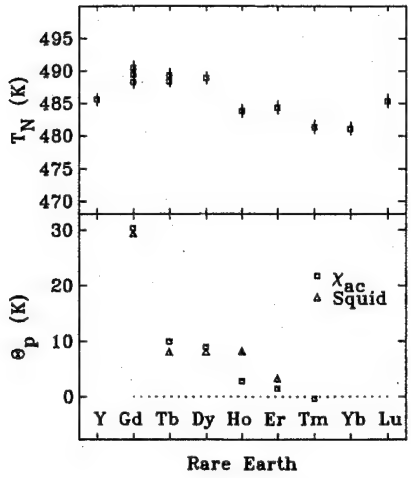

FIG. 3. Top: Néel temperature of the Fe sublattice, derived from DSC measurements. Bottom: Curie–Weiss temperatures for the rare-earth sublattice obtained from fits to χ_{ac} vs T above 12 K, or SQUID data down to 2 K.

rare-earth ordering down to 90 K. One possible explanation for this behavior could lie in the magnetic structure of the iron sublattice. The ordered state of the binary FeGe compound, from which the 1–6–6 alloys studied here are derived, consists of ferromagnetic Fe planes coupled antiferromagnetically to each other.[4] The 1–6–6 structures are formed by placing rare-earth atoms between the iron planes, and if the magnetic structure of the parent FeGe compound is retained, there could be a net cancellation of the Fe–R exchange at the rare-earth sites, effectively isolating them from the ordering of the iron moments. Since the rare-earth moments do order in RFe_2Ge_2 where the iron atoms carry no moment,[5] it seems reasonable to expect order to develop on the rare-earth sublattice at low enough temperatures. Figure 3 shows paramagnetic ordering temperatures (θ_p) derived from Curie–Weiss fits to χ_{ac} data measured down to 12 K. Except for the case of $GdFe_6Ge_6$, all of the extrapolated ordering temperatures lie below the limit of the closed-cycle refrigerator, while the value for the Tm alloy is in fact slightly negative. θ_p scales approximately with the deGennes factor for the rare-earths, except for the case of the Tb alloy, where θ_p is too low.

Our data for $GdFe_6Ge_6$ suggest that it orders ferromagnetically at 30.5±0.2 K, giving a large susceptibility that saturates below T_c. This may not be the first observation of ordering in $GdFe_6Ge_6$, as an earlier study of $GdFe_2Ge_2$ showed a susceptibility feature close to this temperature in an off-stoichiometry sample which may have contained some 1–6–6 as an impurity, although no details about phase purity were given.[6] In order to confirm our view of the magnetic structure of the Gd compound, and to determine ordering temperatures for some of the other alloys, we also carried out measurements on a SQUID magnetometer that could be operated down to 2 K. Ordering temperatures, taken from the kink in a plot of $1/\chi$ vs T, are also shown on Fig. 3. These are in agreement with the values extrapolated from 12 K except in the case of the Ho alloy whose ordering temperature is somewhat higher than expected. The magnetization at 2 K, converted to μ_B per formula unit, is shown in Fig. 4

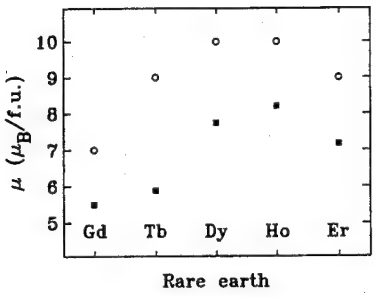

FIG. 4. Ordered moment per formula unit at 2 K (solid symbols) compared with gJ for the corresponding free ion (open symbols) for the RFe_6Ge_6 alloys that ordered above 2 K.

along with values of gJ for each of the rare-earths. A difference of about $2\mu_B$ is apparent in each case. Some of this is clearly due to the measurements being carried out rather closer to T_c than ideal, and a further contribution can be attributed to a failure to saturate the magnetization in 5 T for all of the samples other than $GdFe_6Ge_6$. The origin of the discrepancy remains a problem for the Gd alloy, which was measured at 0.15 T_c and had saturated. Two simple explanations would be either a noncollinear ordering of the Gd sublattice, or an Fe–Gd interaction that modifies the antiferromagnetic order on the Fe sublattice so as to yield a net magnetization directed against that of the Gd sublattice. The high capture cross-section of Gd makes neutron diffraction essentially impossible and so direct structural measurements are not available. Preliminary ^{155}Gd and ^{57}Fe Mössbauer measurements at low temperatures have confirmed that the Gd moments do order at 30 K and that the iron sublattice does not appear to be affected in any way by this ordering.[7]

CONCLUSIONS

Mössbauer and magnetization measurements on RFe_6Ge_6 alloys with $R=Y$, Gd–Lu, indicate that the antiferromagnetic ordering of the iron sublattice at $T_N \sim 480$ K, is unaffected by changes to the rare-earth element present. Furthermore, the rare-earth sublattice orders ferromagnetically at much lower temperatures, ranging from 30 K for the Gd alloy, to 3 K in the case of Er, without affecting the order on the iron sublattice. The difference in ordering temperature between the iron and rare-earth sublattices, which is never less than a factor of 10, coupled with the unrelated magnetic structures adopted, indicates that the two magnetic species order independently, and that the Fe–R exchange is essentially zero.

Cobalt-doped carbon nanotubes: Preparation, texture, and magnetic properties

K. Lafdi, A. Chin, N. Ali, and J. F. Despres
Southern Illinois University at Carbondale, Carbondale, Illinois 62901, and Laboratoire M. Mathieu, 2 av. du President P. Angot 64000 Pau, France

The nested carbon nanotubes discovered by Ijima and co-workers as a by-product of fullerene production extended the dimension and geometries of fullerenes into the domain of nanoparticles. These nanotubes are fiberlike structures consisting of concentric graphite sheets nested along the axis extending as long as several micrometers, and diameters of these nanotubes are limited to less than 100 nm. In this paper we report preparation, structural and magnetic properties of cobalt-doped carbon nanotubes. We observed a tubular structure made of coaxial graphite sheets. The inside, of these carbon nanotubes, was filled with cobalt particles. The magnetic properties of the Co-doped nanotubes were measured using a SQUID magnetometer. The undoped (pure) carbon nanotubes exhibit diamagnetic behavior. The Co-doped nanotubes exhibit superparamagnetic behavior with saturation of magnetization at about 0.5 T and coercive field of 750 G. © *1996 American Institute of Physics.* [S0021-8979(96)00908-1]

I. INTRODUCTION

The nested carbon nanotubes discovered by Ijima[1,2] as a by-product of fullerene production extended the dimension and geometries of fullerenes into the domain of nanoparticles and perhaps, to nanowires. Structurally engineered materials with nanometer-sized entities, such as superlattices and granular solids, etc., have attracted much attention in recent years because of their distinctive properties and potential for technological applications. Interest in the unique electrical and thermal properties of these nanotube structures is a result of several theoretical calculations which suggest that the structures might have either metallic or semiconductor properties.[3–6] These nanotubes are fiberlike structures consisting of concentric graphite sheets nested along the axis and extending as long as several micrometers.[1] This type of tubular filament or carbon shell, containing a metal microcrystal less than 100 nm in size, is made by a catalytic reaction.[2,7]

The work of Audier *et al.*[7] emphasizes the role of crystallographic orientation of the metal crystal upon the growth and degree of graphitization of carbon filaments. The objectives of the present study are to fabricate doped carbon nanotubes, to examine the magnetic properties, and to emphasize the textural approach when attempting to understand the observed enhanced magnetic properties of these materials.

II. EXPERIMENTAL AND RESULTS

First, a graphite rod doped with cobalt was prepared by mixing "anisotropic" pitch with colloidal cobalt. This mixture produces a homogeneous, two phase dispersed system (sol-gel). After hot pressing, pyrolysis, stabilization, and carbonization, a doped graphite rod is obtained. This rod was used as the anode in an arc discharge process. The Kratschmer–Huffman method was used to prepare nanotubes.[8] During this process the doped graphite evaporates at the anode and a carbon deposit (slag) is formed on the cathode. Samples from the slag collected from the dc electric discharge process were examined using transmission electron microscopy (TEM). We observed a tubular structure made of coaxial graphite sheets. These carbon nanotubes are filled with particles of cobalt. Two samples were made using the arc discharge method. Sample A was produced using pure carbon rods; B was made using cobalt-doped carbon rods. TEM characterization using lattice fringe (LF002) mode shows that the pure carbon nanotubes without cobalt contain several tubes of 100 nm in diameter and about 1 μm in length. The tube walls consist of at least three or four layers of graphite and resemble the construction of a cardboard tube [Fig. 1(a)]. Sample B, however, as Fig. 1(b) shows, consists of nanotubes containing cobalt particles. The doped carbon nanotube yield seems to be directly related to the homogeneity of the pitch/cobalt powder mixture and the density of the electrode during the fabrication process. In comparison to the catalysis method,[3] the arc discharge process allows us to produce a higher yield of doped carbon nanotubes. The maximum yield obtained is 18%. The magnetization was measured using a SQUID magnetometer (Quantum Design, Inc.) with an applied magnetic field $-2\ \mathrm{T} \leqslant H \leqslant 2\ \mathrm{T}$ in steps of 0.05 T at 10 K. In order to observe clearly the remanence and the coercive field, the measurement step was 0.002 T within 0.05 T range. Figure 2 show the magnetization versus applied magnetic field. It is evident that for pure nanotubes, sample A, the magnetic behavior is diamagnetic with negative magnetic susceptibility. For pure Co powder (sample C), the magnetization curve shows ferromagnetic behavior with hysteresis loop (Fig. 3). The Co powder and carbon nanotube mixture (sample D) show ferromagnetic behavior at low-field range (Fig. 4), however the behavior of sample D changes into diamagnetic behavior with negative magnetic

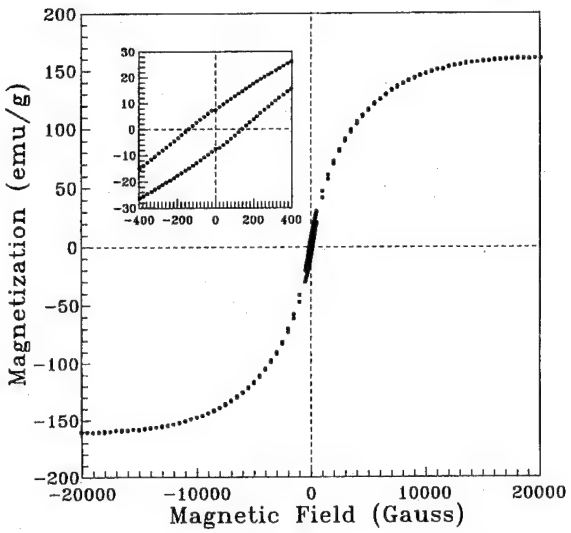

FIG. 3. Magnetization of pure 300 mesh cobalt powder at 10 K.

susceptibility after 1.7 T (inset of Fig. 4). For Co-"doped" nanotube, its magnetization curve shows typical ferromagnetic behavior (Fig. 5) and has a higher coercive force than that of pure Co powder. The values of saturation magnetization, remanence, coercive field, and saturation field of all the specimens are listed in Table 1.

The cobalt-doped nanotubes, sample B, exhibit saturation in magnetization versus field data. This material saturated at about 0.5 T which is approximately half the value exhibited by bulk cobalt.[1] The coercivity of the doped nanotubes was around 0.075 T.

The pure carbon nanotube sample exhibits diamagnetism as one may expect. For the Co powder, the magnetization data show magnetic properties similar to bulk Co. The sample D, which is a mixture of Co powder and pure carbon nanotube, shows the tendency of magnetization saturation up to 1 T (Fig. 4). However, above 1 T one observed a linear decrease in magnetization with increasing applied magnetic

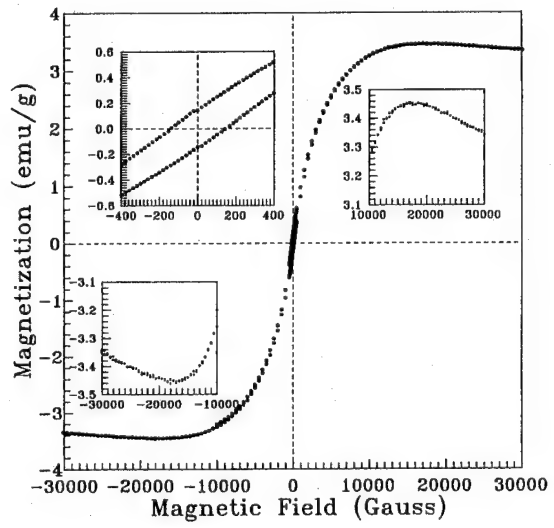

FIG. 4. Magnetization of carbon nanotube and cobalt powder mixture at 10 K.

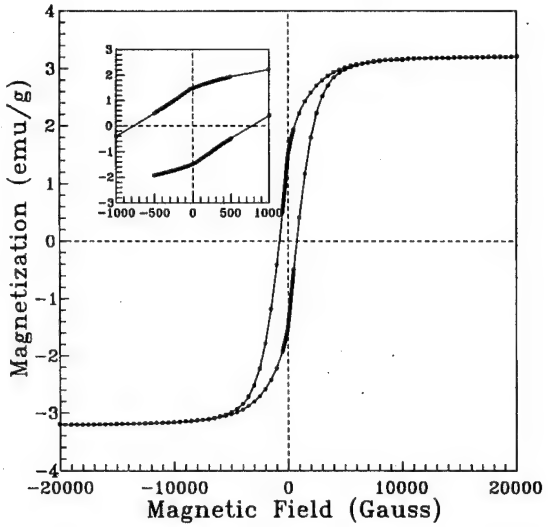

FIG. 5. Magnetization of cobalt-doped carbon nanotube at 10 K.

field. This behavior of magnetization (Fig. 4) can be explained by additive effect of ferromagnetic saturation of Co magnetization and diamagnetic decrease in the magnetization of pure carbon nanotubes with increasing field. The Co-doped nanotube samples show saturation of magnetization much faster (at -0.5 T) compared to pure Co powder sample (at -1.7 T). In addition we also observe that the coercive field also increases by a factor of more than five. It is estimated that in the Co-doped nanotube samples the size of Co particles inside nanotubes ranges from 7 to 50 nm. The magnetic properties of Co-doped nanotube exhibit most likely superparamagnetic behavior.

III. DISCUSSION AND CONCLUSION

In summary, the TEM results show clearly that the structure of cobalt-doped carbon nanotubes is similar to that exhibited by pure carbon nanotubes. Also, the Kratschmer–Huffman method produces a higher yield of doped carbon nanotubes than catalysis, but with smaller lengths and diameters.[7] In this work, we observe that the magnetic properties of pure carbon nanotube are diamagnetic, cobalt powder are ferromagnetic, like bulk cobalt, and the magnetic behaviors of the mixture has the results of additive effect. For Co-doped nanotubes the magnetization increases rapidly at low fields, the magnetization saturates faster at lower field and there is no diamagnetic behavior after the saturation. These intriguing magnetic properties are most likely related to the low dimensionality of the cobalt entities. The magnetic properties of cobalt particles can be significantly altered by the nanometric size, their specific surface area and the tubular shape of doped carbon materials. The carbon nanotubes possibly cause the easy magnetization direction of Co particles in the nanotube to align well along the tube axis and lead to fast saturation of the magnetization.

TABLE I. Values of saturation magnetization, remanence, coercive field, and saturation field for all specimens.

Sample name	A (pure C nanotube)	C (Co powder)	D (Co powder and pure C nanotube)	B (Co-doped nanotube)

Magnetic properties of nanosized wires

J. Meier, B. Doudin, and J.-Ph. Ansermet
Institut de Physique Expérimentale, Ecole Polytechnique Fédérale de Lausanne, 1015 Lausanne, Switzerland

Assemblies of ferromagnetic cylinders made of Ni with diameters ranging from 35 to 250 nm were produced by electrodeposition in nanoporous membranes. The large coercive fields of Ni nanowires at low temperature could be accounted for by the curling mode of magnetization reversal, taking into account the distributions of wire diameters and orientations. The coercive field of the nanowires of the smaller diameter range decreased from 1500 Oe at 20 K to 200 Oe at 300 K nearly linearly.
 [S0021-8979(96)40808-X]

I. INTRODUCTION

Characterization and understanding of the magnetic properties of small particles have been a challenge for decades and prompted intense research activity, motivated in particular by applications in magnetic recording technology. Some simple problems remain unclear.[1] For example, the reversal mode of the magnetization of a perfect cylinder is still the subject of theoretical predictions.[2] Comparison with experiments most often suffered from the difficulty of producing samples with well characterized morphologies. Furthermore, the limited sensitivity of magnetic measurements necessitates the study of a large number of particles. Consequently samples present a dispersion in morphological features. We prepared well defined and reproducible assemblies of ferromagnetic cylinders by electrodepositing ferromagnetic metals in the cylindrical pores of polycarbonate track-etched (PCTE) membranes of thicknesses between 6 and 10 μm. This method made possible the production of wires as small as 30 nm in diameter. One advantage of this technique is the possibility of changing the composition of the deposit, allowing the comparison of the magnetic properties of various materials in exactly the same morphology. We could also extend the technique to the synthesis of wires with alternating metals, thus opening the study to magnetic grains with controlled shape and separation.[3] The technique of making small wires with diameters under 100 nm has been extensively studied for the case of aluminum oxide porous membranes (alumite).[4–6] Alumite can have a pore density as high as 10^{11} pores/cm^2. It has been shown that magnetostatic interactions among the wires cannot be neglected.[6,7] In contrast, the highest pore density of commercially available PCTE is 6×10^8 pores/cm^2 and lower densities can be produced. In this study, we found that the coercive field of nanowires depended on the diameter like in the manner expected of acicular particles or wires, and showed how the distribution of pore orientation of commercially available PCTE change the average magnetic properties of filled membranes.

II. SAMPLE PREPARATION

We used commercially available nanoporous PCTE membranes.[8] Experimental details on growth and morphological characterization of nanowires have been published.[9] The technique of elctrodeposition in such nanoporous templates has been recently reviewed[10] and initial results about Co and Ni wires have been reported.[11,12]

III. RESULTS AND DISCUSSION

We used a commercial superconducting quantum interference device (SQUID) magnetometer to measure between 2 and 400 K the magnetic moments of discs of 3 mm in diameter which were cut out of Ni-filled membranes and contained about 1 μg of Ni. The hysteresis curves were measured with the applied field perpendicular or parallel to the membrane plane (Fig. 1). The anisotropy of the sample ap-

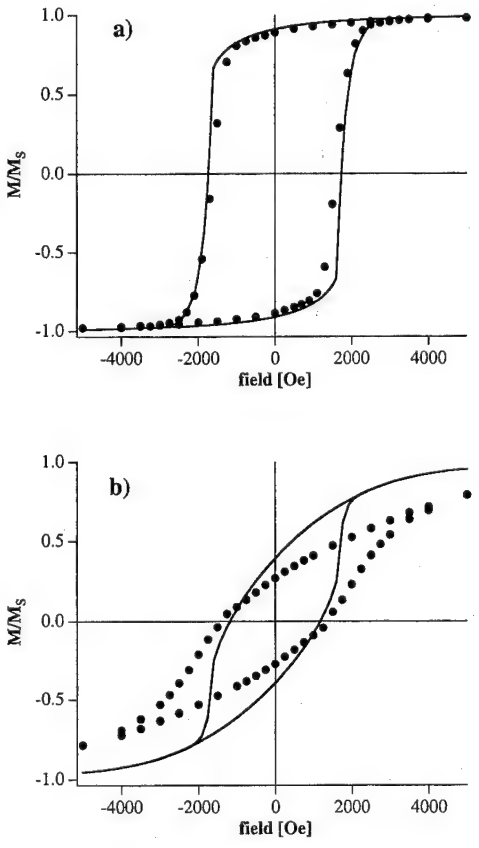

FIG. 1. Hysteresis loops for an assembly of Ni nanowires with a mean diameter of 53 nm at 5 K (dots). The continuous line is the prediction of the Stoner–Wohlfarth model. The wires were oriented predominantly parallel (a) or perpendicular (b) to the applied field.

 0021-8979/96/79(8)/6010/3/$10.00

peared clearly. The data can be easily understood in terms of the alignment of the wires. We calculated the hysteresis curves for the Stoner–Wohlfarth (SW) model of uniform rotation with a uniaxial magnetic anisotropy[13] which was taken to be the shape anisotropy only. We took into account the fact that the wires were not perfectly aligned perpendicularly to the membrane by assuming a uniform probability distribution $p(\alpha)$ of the angle α between the wire axis and the normal to the plane of the membrane, ranging from 0 to α_m

$$p(\alpha)d\alpha = \frac{1}{1-\cos\ \alpha_m} \sin\ \alpha d\alpha. \tag{1}$$

The value of the maximum angle α_m of 34° was provided by the manufacturer. The hysteresis curves (Fig. 1) were calculated as weighted averages of the prediction of the SW model for the magnetization for all possible orientations of the wires with respect to the applied field.

The influence of the neighboring wires could be estimated as an additional demagnetizing field. In the case where the membrane was perpendicular to the field, it was estimated as the field produced by a uniform film with the same magnetization as that of the filled membranes

$$H_D = 4\pi M p\,, \tag{2}$$

where M is the average magnetization and p is the porosity of the membrane. As the highest density which is commercially available is limited to 6×10^8 pores/cm^2, the porosity was limited to a few percents. For the sample of Fig. 1, the maximum value of H_D was 85 Oe only. In the case where the membrane was parallel to the field [Fig. 1(b)], the demagnetizing field of a uniform membrane would vanish. The discrepancy between the data and the (SW) model indicates that, in this direction, the magnetostatic interactions among neighboring wires cannot be neglected. Hence the angular distribution of wire orientations accounts correctly for the observed slopes of the hysteresis curve in the orientation of the membranes which corresponds to the greatest alignment of the wires with the field.

The dependence of the coercive field on the average diameter of the Ni wires was measured at 20 K, with the applied field perpendicular to the membranes (Fig. 2). We interpreted the data, as it is customarily done for elongated single domain particles,[14] in terms of curling and uniform rotation. We took into account the angular dependence of the nucleation field for the curling mode of an infinitely long circular cylinder with radius R (Ref. 15)

$$\frac{H_n}{2\pi M_s} = \frac{h_t(1+h_t)}{[(1+h_t)^2-\sin^2\theta(1+2h_t)]^{1/2}}$$

with

$$h_t = -1.08\left(\frac{R}{\sqrt{A}/M_s}\right)^{-2}, \tag{3}$$

where θ is the angle between cylinder axis and applied field and A is the exchange constant. We used the angular distribution of wire orientations as above and the commonly accepted value of A of 10^{-11} J/m (10^{-6} ergs/cm).[16] As each sample had a distribution of wire diameters,[12] a fraction of

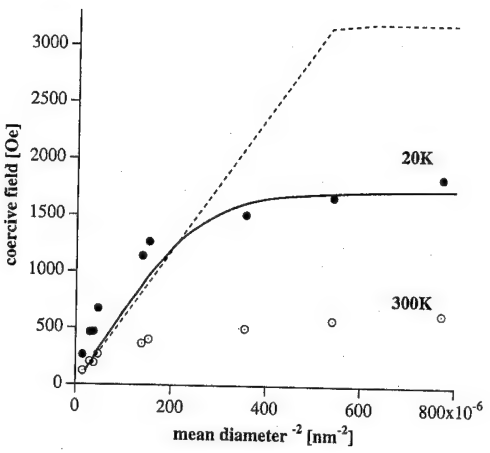

FIG. 2. Coercive field at 20 and 300 K (dots). The full line represents the curling mode for the assembly of misaligned cylinders described in the text. The broken line represents the curling mode for one cylinder aligned with the field.

the wires might undergo uniform rotation and the others curling. The diameter d_0 which characterizes the transition from uniform rotation to curling is $d_0 = 2\times A^{1/2}/M_s = 41$ nm. This simple model gave a fair account of the data with no adjustable parameters (Fig. 2). The angular distribution of the wires, which was known and well reproducible in our samples, plays a major role in the outcome of this calculation. The observed coercive field was found somewhat larger than the prediction of the model, by an amount of the order of 200 Oe (5×10^3 J/m^3). One can expect a contribution of magnetostrictive effects to the coercivity. The coercive field due to the magnetostrictive energy of elongated particles can be estimated by[17]

$$H_c = \frac{3|\lambda\sigma|}{M_s}, \tag{4}$$

where λ is the saturation magnetostriction coefficient and σ the stress. Taking the value of λ of polycrystalline Ni and assuming that the excess coercivity of ~200 Oe was due to magnetostrictive effects, Eq. (4) yields an estimate of the stress of 9×10^7 N/m^2. Electrodeposited Ni films are known to have indeed internal tensile stresses of $\sim7\times10^7$ N/m^2 (Ref. 18). While the data on the low temperature coercive fields can be understood in a commonly accepted view, two observations cast some doubts on this simple interpretation.

First, the temperature dependence of the coercive field was found quite large in wires of the smaller diameters, and nearly linear over a wide temperature range (Fig. 3). This is in contrast with predictions of models of nucleation by thermal activation over an anisotropy barrier, leading to a $T^{1/2}$ variation. Even if a reasonable distribution of barriers is assumed, the temperature dependence is still reminiscent of a $T^{1/2}$ dependence.[19] Linear temperature dependence of the coercive field was observed in acicular Fe_2O_3 (Ref. 20) and in percolating granular Fe–SiO_2 composites.[21]

Second, the presence of large magnetostrictive effects was observed by taking advantage of our template synthesis to produce assemblies of permalloy wires identical to the Ni wire assemblies. The large temperature dependence vanished

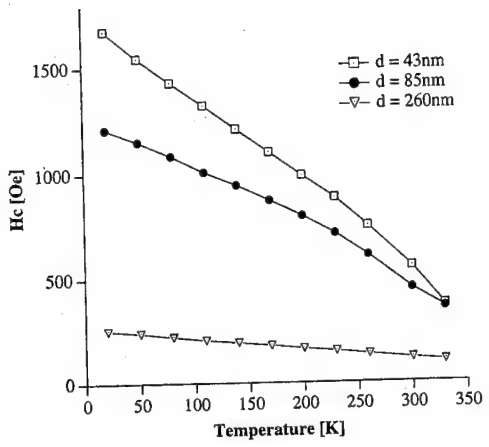

FIG. 3. Temperature dependence of the coercive field for Ni nanowires with different diameters. The lines are a guide to the eye.

in the permalloy wires. Furthermore, when the Ni wires were freed from the membrane by dissolving it, the temperature dependence of the coercive field also disappeared.[12]

These observations suggest that in Ni nanowires, the coercivity is dominated by magnetostrictive effects. Owing to the large mismatch of the thermal expansion coefficients of Ni and polycarbonate, thermal stresses and the resulting magnetrostrictive effects may determine the dependence of the coercive field on both diameter and temperature. Further tests and modeling would be required to ascertain the underlying mechanisms which account for the coercivity of the nanowires.

IV. CONCLUSION

Assemblies of magnetic nanowires were produced by electrodeposition in nanoporous, track-etched, polycarbonate membranes. This template synthesis allows the production of well reproducible nanowire assemblies. However, the commercially available nanoporous membranes have a distribution of wire orientations which at times precludes conclusive characterization, such as the measurement of the angular dependence of the coercive field in order to test for curling or uniform reversal of the magnetization. The high coercive fields of Ni nanowires at low temperature could be accounted for by a model of curling in the larger wires, and uniform rotation with a shape anisotropy only in the smaller wires. However, the temperature dependence of the coercive field and its disappearance when the wires are freed from the embedding matrix or when Ni is replaced by permalloy indicated that the model of curling and uniform rotation might be too simple a picture.

Negative remanence in magnetic nanostructures

X. Yan and Y. Xu
Department of Physics, The Hong Kong University of Science and Technology, Clearwater Bay, Kowloon, Hong Kong

In nearly percolating magnetic granular (Ni,Fe)-SiO_2 films, we observed negative remanence, or a negative remanent magnetization, upon removing the positively applied magnetic field to zero. We propose that there exist both superparamagnetic and ferromagnetic components due to different connectivity of magnetic nanometer scaled particles, as supported by the dark field transmission electron microscopy images. The magnetostatic interaction between them favors an opposite alignment. Moreover, the two-component hypothesis explains satisfactorily the dependencies of the negative remanence on temperature and magnetic volume fraction. © *1996 American Institute of Physics.* [S0021-8979(96)02608-6]

Magnetic granular or nanostructured films, or specifically metal-insulating composite films with nanometer scaled ferromagnetic metal particles, have attracted much attention in the last few decades,[1–3] due to a rich variety of interesting transport, magnetic, and mechanical properties,[4–6] depending strongly on the size of the magnetic particles and its distribution. When x is well below the percolation threshold, or $x<x_p/2$, the ferromagnetic particles are embedded in an insulating matrix and are well isolated, and the collective behavior of the whole system is superparamagnetic with measured magnetic susceptibility inversely proportional to temperature for $T>T_b$, where T_b is the blocking temperature above which the magnetization of the particles can rotate to follow the external magnetic field. The blocking temperature is proportional to the magnetic anisotropic energy and the volume of the particles. Thus when $x>x_p$ where most of the particles are connected, the whole system behaves ferromagnetic globally. In this article, we report the observation of the negative remanence in granular (Ni,Fe)-SiO_2 films where the magnetic particles are nearly percolating. The morphologies of the films were illustrated to have both isolated as well as connected magnetic particles, suggesting the coexistence of both superparamagnetic (SPM) and ferromagnetic (FM) components. We further propose that the magnetostatic interaction between the SPM and the FM components, which can favor the opposite alignment.

Granular $(Ni,Fe)_x$-$(SiO_2)_{1-x}$ films were prepared using a Denton magnetron rf sputtering system.[6] It was determined that the magnetic particles are mainly Ni with less than 20% Fe for x above 0.4, and the magnetic volume fraction x' is not too different from the nominal volume fraction x, while the matrix is the insulating amorphous SiO_2. The average sizes of the magnetic particles are about 3–6 nm, increasing smoothly throughout the percolation threshold ($x_p' \sim 0.6$ according to resistivity[6]). Direct current magnetization was measured for all those films between 5 and 300 K using Quantum Design's SQUID MPMS-5 system for the magnetic field applied parallel to the plane of the films.

Figure 1 shows the M-H loop, or the magnetization as a function of magnetic field from 10 kG to −10 kG to 10 kG at 200 K for $x=0.55$. Although no hysteresis is evident in this scale, the magnification of the curve does show some hysteresis as shown in the inset between ±50 G. It is important to note that the remanent magnetization is negative, upon decreasing the magnetic field from the positively saturated field, such as 10 kG, to zero at 200 K. This remanence is as large as −9% compared to the positively saturated value. The dc magnetic susceptibility near zero is about 0.5, or $4\pi\chi\approx 6.3$.

When the same film was cooled to 5 K where the rotation of the isolated particles were frozen, the measured remanent magnetization upon removing positive magnetic field from 10 kG to zero, M_r, was positive, similar to the behavior in a conventional ferromagnet. Figure 2 shows M_r and zero-field-cooled dc magnetic susceptibility χ as a function of temperature for the same film. Note that upon increasing temperature, M_r changes sign, through 0 at about 100 K, to a negative value of a similar amplitude at 200 K as shown in the inset of Fig. 1. The temperature region where M_r becomes negative is not too different from that where χ reaches maximal and begins to drop very slowly. The drop in χ clearly indicates that there are isolated particles whose magnetization can follow the external magnetic field like superparamagnetic materials. This indicates that the negative remanence is associated with the presence of the superparamagnetism of the system. However, the drop in χ does not follow $1/T$ behavior as expected for a superparamag-

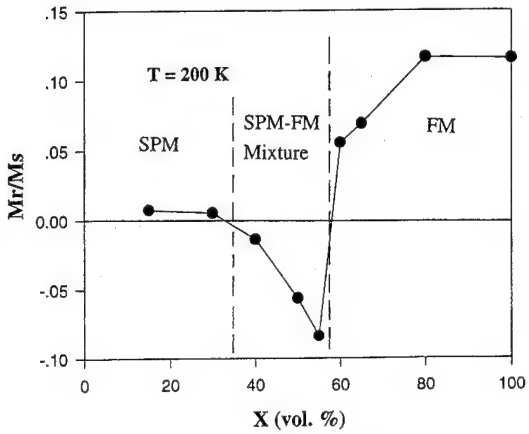

FIG. 3. The remanent magnetization at 200 K, normalized by the saturation magnetization in the positively applied field, vs x, the volume fraction of the magnetic particles.

netism with a uniform size distribution, due probably to the existence of a finite distribution of the particle sizes that lead to a finite distribution of T_b.[7]

Figure 3 shows the remanent magnetization, M_r, normalized by the saturation magnetization at 10 kG, M_s, as a function of x, at $T=200$ K. Notice that the value of M_r/M_s starts from almost zero for $x\leq 0.3$ with a clear SPM behavior, becomes negative only for the nearly percolating films with x between 0.4 and 0.55, and then changes back to a positive value for $x\geq 0.6$ with a FM behavior which is also conducting from the resistivity measurement. From the temperature dependence of χ for various x's, one concludes that both T_b and its uncertainty increase upon increasing x,[7] suggesting that the film with x between 0.4 and 0.55 is likely in a SPM–FM mixture. The negative value of the remanence is larger than (the known) experimental error.[8] Thus the negative remanence might be associated with a special geometry of the magnetic nanostructures, in which both isolated and connected particles are present, corresponding to the SPM and FM components, and that the phenomenon disappears abruptly when the magnetic particles are percolated throughout the film. Systematic studies of temperature dependent remanence[9] and zero-field-cooled ac susceptibility at different frequencies[7] support this hypothesis.

The presence of a sizeable remanence signifies the presence of ferromagnetic component in the sample, and the negative value indicates that its magnetization response is in a direction opposite to the external field. One should note that similar phenomena, such as the reverse thermal-remanent magnetization, was observed in geological materials,[10] explained in terms of two components having different Curie temperatures,[11] and the inverted hysteresis loop in amorphous[12] and multilayered materials,[13,14] explained either in terms of interface exchange interaction[13,14] or exchange anisotropy.[15] It is important to note that the negative remanence is forbidden in magnetically homogeneous materials in which the magnetization is the order parameter to describe its thermodynamic state, and is possible only in magnetically inhomogeneous materials.

The nearly percolating granular films are compositionally uniform but magnetically inhomogeneous systems and the inhomogeneous is due to different magnetic responses of the particles of different sizes. From the labyrinth microstructure as displayed by TEM dark field images on nearly percolating films,[9] it is likely that there are connected particles which behave ferromagnetically with a finite coercivity and a finite positive remanence, and isolated particles which behave superparamagnetically with zero remanence and zero coercivity. Contrary to the interface exchange interaction[13,14] or the exchange anisotropy[15] models, we propose that the FM component was aligned antiparallel with respect to the magnetized SPM component due to the magnetostatic interaction.

By considering dipole–dipole interactions, let us demonstrate that such an opposite alignment is plausible if the anisotropically shaped FM particles are embedded in a SPM medium. Consider first the effective field created at the origin by a volume element $dV(=r^2 dr\ dW=r^2\times dr\times\sin\theta\times d\theta\times d\varphi)$ at position (r,θ,φ), which has a form $M\times dV\times(1-3\cos^2\theta)/r^3$, where M is the magnetization per unit volume of the uniformly magnetized SPM medium. After the integration in angle θ from 0 to π, this will lead to zero in a three dimension (3D). Thus for a uniformly magnetized medium of infinite size, the effective field inside the medium is zero. According to the superposition principle, the effective field in a needle hollow of a uniform medium should have the same value but opposite sign as in a uniform long needle. Here the term "needle" refers to the shape whose length is much larger than its diameter. Thus when there is a needle hollow in a uniformly magnetized medium of magnetization M, the effective magnetic field inside it is $-4\pi M$ for the field applied parallel to the needle axis. Placing a FM needle inside the hollow of the SPM medium, the total magnetic field, which is the sum of the effective field and the applied field H_a on a FM needle, will be $-(4\pi\chi-1)H_a$, where $\chi=M/H_a$ is the magnetic susceptibility. For $4\pi\chi>1$, the magnetization of the FM needle can be opposite to the external field provided that the field is applied along the needle axis.

For nearly percolating films, the length of the connected particles is on the order of the percolation correlation length, which diverges when approaching the percolation threshold. Comparing to the diameter of the particle of about 5 nm, it is reasonable to consider the nearly percolating system as a

TABLE I. Local field on the FM component in the nanostructures.

Type of magnetic nanostructures	Local Field on the FM		Condition for negative remanence
	Parallel	Perpendicular	
1. Oriented FM needles in a SPM matrix	$-4\pi M$	$2\pi M$	$4\pi M > H$, parallel to needles axis
2. Nearly percolating FM particles	$-4\pi M$	$-4\pi M$	$4\pi M > H$, isotropic
3. Oriented FM disks in a SPM matrix	$-\pi M$	$2\pi M$	$\pi M > H$, parallel to film planes

composite consisting of FM needles randomly embedded in a SPM matrix. Due to the shape magnetic anisotropy energy, the magnetization direction of each FM needle is likely to be along its needle axis. Hence, needles with different orientations respond to an applied magnetic field independently. Among the FM needles, there are some that are oriented along the applied field with θ near 0. They will be aligned opposite to the rest of the sample under the applied field. They remain so after the applied field is removed and consequently there is a negative remanence. Thus, when $4\pi\chi > 1$, there could be a net negative remanence in the nearly percolating granular ferromagnetic composites. In this picture, when the FM particles are well connected throughout the system, the FM component starts to response coherently, the negative remanence will disappear abruptly. This hypothesis explains not only the presence of the negative remanence at 200 K but not at low temperatures, but also the dependence of M_r/M_s on the volume fraction.

The local field on the FM component may be calculated in a few specific nanostructures as shown in Table I.[16] This two-component hypothesis predicts that (1) the anisotropically shaped FM particles are important for the observation of the negative remanence, and (2) in oriented FM disks in the SPM matrix where the total magnetization of the SPM is greater than that of the FM, negative remanence should be observed only for the field applied parallel to the disk plane. Subsequent experiments, which will be published elsewhere, show that (1) the negative remanence in these nearly percolating films disappears upon annealing samples for both $x=0.4$ and $x=0.55$, and (2) such a negative remanence was indeed observed predominately for the field applied parallel to the film plane of the SPM/FM multilayers which is the extreme case of oriented FM disks.

There may be a number of possible applications of the negative remanence or the antiparallel alignment of the SPM/FM composite in general. The presence of the antiparallel alignment point out a possible application of the SPM particles as a local magnetostatic shielding element for the FM storage units to achieve ultrahigh density with a controlled media noise. In such a proposed media structure, each FM storage unit is surrounded by the SPM particles whose magnetization may follow the dipole field of the FM unit. The dipole field of these surrounding SPM particles in the long range is in the opposite direction as that of the FM. Hence the effective dipole–dipole interaction in the long range is reduced, resulting in a reduced media noise. The feasibility of this new media structure may depend on the response time of the SPM particles as well as the magnetic ageing of the SPM–FM composite. This feasibility is now being evaluated.

[8] A remanent magnetic field is usually positive in a superconductor due to the trapped flux. But this trapped positive field in the superconducting solenoid could lead to a negative field of the order of 10 G in the sample space. This can cause error due to a finite dM/dH. In our experiments, Pd standard was measured subsequently and the results shown in the insert of Fig. 1 was after the field correction. However, we are not absolutely sure if such a correction is sufficient due to the remaining field error of about 1.5 G in our set-up and a large dM/dH for the sample than the Pd standard.

Preparation of Co–Fe–P amorphous fine needles with anodization technique and measurement of demagnetizing factor

A. Tayaoka, E. Tayaoka, and J. Yamasaki
Department of Electrical Engineering, Kyushu Institute of Technology, Tobata, Kitakyushu Fukuoka 804, Japan

The amorphous Co–Fe–P and crystalline Co fine needles with diameter 0.1–0.2 μm aspect ratio more than 100 were prepared successfully by applying the dc electrodeposition to the anodization technique and their demagnetizing factors were measured. It was found that the demagnetizing factor of film with needles decreases with increasing aspect ratio and tends to take low constant values around 0.07–0.08. To obtain the low demagnetizing factor by using the shape anisotropy of needle, it was estimated that the aspect ratio more than 100 is needed. The equivalent demagnetizing factor defined by a ratio of a field needed to achieve saturation to the averaged flux density is estimated around 0.6 for the film with Co–Fe–P amorphous needles with 0.1 μm diameter.
 [S0021-8979(96)05308-2]

I. INTRODUCTION

Recently, electromagnetic micromachines have been developed and are expected to be applied in various fields. In such a small size machine, a magnetic field in narrow space is used to generate electromagnetic force, so that it is necessary to develop a thin film that can be magnetized with a low field in the direction normal to the surface. It is expected that such a film having the anisotropy perpendicular to the surface can be prepared by the anodization technique. When an aluminum film is anodized in acid solution, a thin aluminum-oxide surface having fine holes with their longitudinal direction normal to the surface is obtained. By depositing magnetic materials into the hole, a magnetic film that has fine magnetic needles with their longitudinal direction normal to the film surface can be prepared. The film thus made has the shape anisotropy with the easy axis normal to the film. So far, the anodizing technique has been applied to prepare the hard magnetic film for perpendicular recording.[1] In the conventional anodization technique, magnetic materials are commonly electrodeposited by using ac current, since Al oxide works as a dielectric material of a capacitor. However, the length of needles obtained by the ac deposition is limited to less than about 2 μm, because of the decrease in dielectric constant with deposition. On the other hand, films as thick as a few ten microns can be obtained by dc electrodeposition. Therefore, we tried to apply dc electrodeposition technique to anodized film by making an electrical contact through the aluminum oxide layer. In this study, we prepared amorphous Co–Fe–P and crystalline Co fine needles with high aspect ratio and evaluated the dependence of the demagnetizing factor on aspect ratio of needles.

II. EXPERIMENT

An aluminum plate (99.99% pure, 20×20×0.5 mm) degreased and cleaned in advance was anodized to a depth of 30 μm in 0.3%-$(COOH)_2$ at a constant dc voltage of 120 V. The plate was anodized again in diluted H_3PO_4 at a constant minute current to make fine holes through Al oxide called barrier layer.[2] The expected cross section of thus treated Al plate is shown in Fig. 1. The fine holes in the barrier layer were confirmed by measuring electrical resistivity in ionic solution. Into the holes, Co–Fe–P amorphous alloy and crystalline Co were electrodeposited under the conditions with current density of 10 mA/cm^2 and 1 pH of solution. For the obtained needles scanning electron microscopy (SEM) observation, electron probe microanalysis (EPMA), and x-ray diffraction measurement were performed. The magnetic properties of the film was measured by a vibrating sample magnetometer (VSM).

III. RESULTS AND DISCUSSION

Figure 2 shows the SEM views of (a) the top surface, (b) and (c) cross section of the Co–Fe–P needles electrodeposited in fine holes of anodized film. In anodizing technique, diameter and spacing of holes are a function of anodizing current and voltage, respectively. We chose the current and voltage higher compared to those used in conventional deposition to fabricate fine needles with large spacing, so as to give a large shape anisotropy. As seen in Fig. 2(a), the obtained fine needles have fairly good circular cross sections. Their averaged diameter and spacing are about 0.1 and 0.3 μm, respectively. In the cross section shown in Fig. 2(b), we can see that needles grown straight from the bottom of the Al substrate over 12 μm in length. The obtained needles have aspect ratio of about 120, which is about six times as large as that of needles fabricated by the ac anodization technique so far. The obtained needles have fairly uniform diameter as

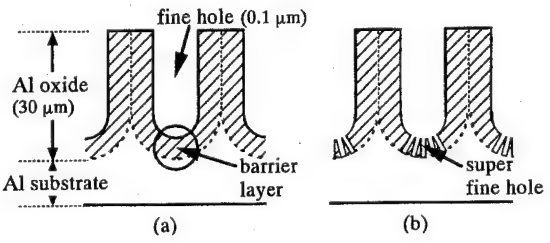

FIG. 1. Schematic diagram showing how super fine holes were made. (a) Before and (b) after making holes.

 0021-8979/96/79(8)/6016/3/$10.00

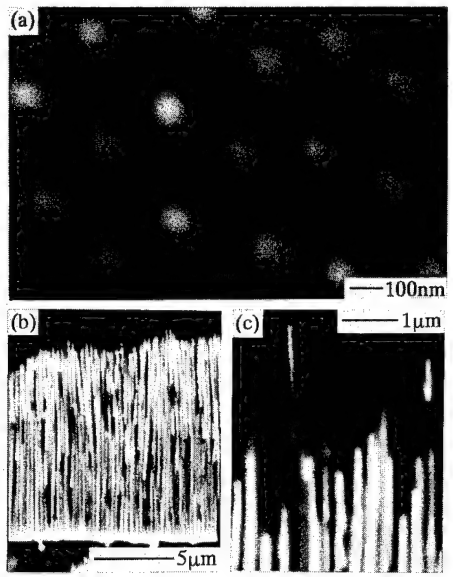

FIG. 2. SEM observation of magnetic needles deposited into holes of anodized films (a) for top surface and (b), (c) for cross section.

seen in enlarged cross section in Fig. 2(c). This was achieved by adjusting the ionic concentration of the solution to keep the resistivity nearly constant.

Figure 3 shows a result of EPMA analysis taken along a needle. The distribution of P is fairly uniform. The EPMA data give a composition of the needle as $Co_{74}Fe_5P_{21}$. Thus, by applying dc deposition technique to anodizing film, it becomes possible to deposit P in fine holes. We tried especially to alloy P around 20% to obtain amorphous phase. This was achieved by keeping pH of solution around 1 pH. The x-ray diffraction shown in Fig. 4 indicates the obtained needles are amorphous, since there is no sharp peak based on crystalline except those of Al substrate. The magnetostriction of amorphous magnetic material is determined by the concentration ratio of Co to Fe.[3] Though the averaged composition is close to that with zero magnetostriction, the bottom of needles having higher Fe concentration would have positive magnetostriction around 3×10^{-6}.

Fine needles with a few microns spacing interact with each other through stray field, so the demagnetizing field of the anodized film would differ from that of a single needle. It is considered that magnetic interaction of fine needles depends on needle diameter so we prepare the needle changing diameter and evaluated the demagnetizing factor as a function of needle aspect ratio. For the evaluation of demagnetizing factor, we used Co fine needles prepared by the dc anodization technique, since the saturation magnetization of Co is strictly known and we do not need to care about compositional variation. Figure 5 shows the magnetization curve for polycrystalline Co needles measured in normal and parallel to the film plane. The Co needle has diameter of 0.1 μm and length of 12 μm. The film with needles can be saturated in the direction normal to the film with a field lower than that need to saturate in the parallel direction. To evaluate the demagnetizing field, a straight line was drawn parallel to the magnetization curve as shown in Fig. 5. From the extrapolation of that line to a saturation magnetization, we obtained the demagnetization field approximately. Using the measured demagnetization field and the saturation magnetization of Co of 17.9 kG (4πMs), we determined the demagnetizing factor.

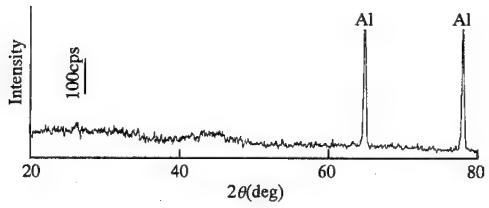

FIG. 4. X-ray diffraction diagrams of $Co_{74}Fe_5P_{21}$ amorphous anodized magnetic film, obtained by a conventional Cu$K\alpha$ diffractometer.

Figure 6 shows the demagnetizing factor of the films with Co needles as a function of aspect ratio with needle diameter as a parameter. The diameters of Co needles are 0.1 and 0.2 μm, respectively, and their spacing is 0.3 μm. The demagnetizing factor of an anodized film having 0.1 μm needles calculated by Masuda *et al.* is also shown.[4] The demagnetizing factor decreases with aspect ratio and tends to take a constant value beyond aspect ratio of 100. The constant values of the demagnetizing factor for needles with 0.1 and 0.2 μm needles are 0.07 and 0.08, respectively. The demagnetizing field that was produced with whole magnetic poles over the surface is not uniform along the length of a needle; it is high near the surface and decreases at the middle region of the needle. When the aspect ratio of a needle increases, it is inferred that the demagnetizing field of the middle region decreases while the demagnetizing field near the surface that has magnetic poles remains high. It seems that nearly constant demagnetizing factor for the aspect ratio beyond 100 is attributable to the high demagnetizing effect near the surface. The calculated demagnetizing factor is the value obtained by averaging the nonuniform demagnetizing

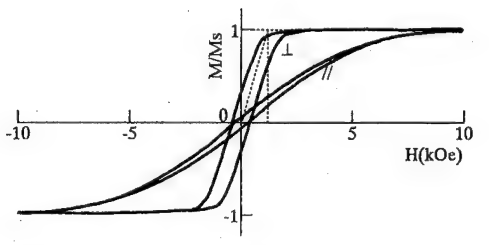

FIG. 5. Magnetization curves for Co anodized magnetic film, when magnetization in the direction normal (⊥) and parallel (||) to the film surface.

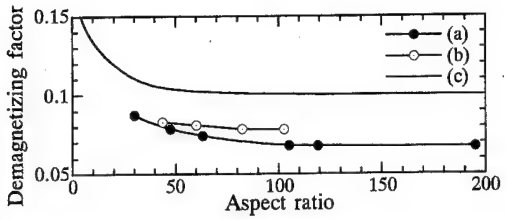

FIG. 6. Dependence of the demagnetizing factor on aspect ratio of Co fine needles (a) for 0.1 μm, (b) for 0.2 μm, and (c) for calculated result.

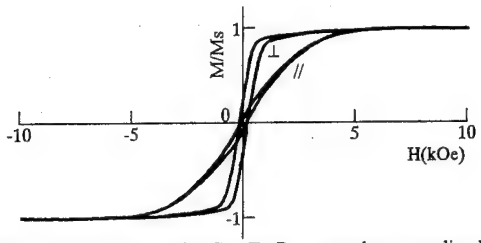

FIG. 7. Magnetization curves for $Co_{74}Fe_5P_{21}$ amorphous anodized magnetic film, when magnetization in the direction normal (⊥) and parallel (||) to the film surface.

field. As shown in Fig. 5, we evaluated the demagnetizing field from the magnetization curves by drawing a straight line. The obtained value corresponds to the demagnetizing field of the middle region of needles that is magnetized easily. This may give the big difference between the experimental and the calculated demagnetizing factors. Thus, the demagnetizing factor takes constant value with increasing aspect ratio. It is considered that the aspect ratio around 100 is enough to decrease the demagnetizing factor of the film using the shape anisotropy of needles.

Figure 7 shows the magnetization curve of the film with $Co_{74}Fe_5P_{21}$ amorphous needles whose cross section is shown in Fig. 2. The diameter and aspect ratio of the needle are 0.1μm and 120, respectively. The amorphous needles have the coercive force of 170 Oe, lower than that of the Co needles shown in Fig. 5. The needles packed in the fine holes may be highly stressed by the Al oxide. The relatively larger coercive force compared to other amorphous materials would be attributable to the residual stress. The demagnetizing factor of this film is around 0.068, almost the same as that of Co needles because of the same diameter and the aspect ratio. The film prepared by the anodization method partially consists of non magnetic material, so that the flux density averaged over the surface decreases markedly. The portion of magnetic materials of the present film is 12%, which gives averaged flux density of 1.44 kG. An external field of sum of the demagnetizing field of 700 Oe and the coercive force of 170 Oe are needed to obtain the flux density of 1.44 kG, so that the equivalent demagnetizing factor is estimated to be about 0.6. This value is expected to decrease down to 0.15 by the amorphous needle with 0.2 μm diameter using the demagnetizing factor shown in Fig. 6.

IV. CONCLUSION

The amorphous Co–Fe–P and crystalline Co fine needles with aspect ratio more than 100 were prepared successfully by applying the dc electrodeposition to the anodization technique and their demagnetizing factors were measured. The results are summarized as follows: (1) The demagnetizing factor of film with fine needles decreases with increasing aspect ratio and tends to take low constant value around 0.07–0.08. (2) To obtain the low demagnetizing factor, the aspect ratio more than 100 is needed. (3) The equivalent demagnetizing factor defined by a ratio of field needed to achieve saturation to the averaged flux density is estimated around 0.6 for the film with Co–Fe–P amorphous needles with 0.1 μm diameter.

We have performed Monte Carlo simulations on 2D circular Ising clusters, studying the distribution of the magnetization within the cluster as well as the magnetization reversal process when an applied external field is suddenly changed. We have shown that for highly anisotropic systems (the Ising-like limit), the magnetization reversal process is not uniform in a wide range of temperatures. Spins having a lower coordination at cluster edges drive the reversal process, acting as nucleation centers. We have found that there is a connection between the roughness transition temperature and the differences in the time evolution patterns of the magnetization. Our simulations agree with experimental results on magnetization reversal of single domain particles. © *1996 American Institute of Physics.* [S0021-8979(96)02708-2]

The study of the reversal magnetization of small particles has received much attention recently due to its broad range of technological applications.[1] Although the theory for the magnetization reversal was initially proposed by Néel,[2] based on the Stonner–Wohlfarth uniform rotation model,[3] recent experimental results[4,5] seem to contradict the basic assumptions of that model.

In the present work we have performed Monte Carlo (MC) calculations[6] in order to understand and characterize the behavior of the magnetization during the reversal process. We have simulated a small ferromagnetic particle by a two-dimensional (2D) circular cluster of radius R. Since MC simulations have been shown to be a useful method for describing experimental Ising-like systems,[6] we have considered that interactions among cluster spins are described via the Hamiltonian

$$\mathcal{H}=-J\sum_{\langle i,j\rangle} S_iS_j-H\sum_i S_i, \tag{1}$$

where S_i represents the spin at the site i, the sum $\langle i,j\rangle$ is over all nearest neighbor pairs in the cluster, J is the exchange constant, and H is the applied magnetic field. In the present study a 2D square lattice has been considered.

The simulations were carried out following a method very similar to that used for analyzing the relaxation processes of metastable states in 2D infinite Ising systems.[7,8] For a system with radius R and temperature T we follow these steps: (i) Starting from a completely ordered configuration the cluster reaches thermal stabilization (using 2000–15 000 MC steps) in presence of an external magnetic field H pointing out along the positive z direction; (ii) H is reversed (this is the zero of our time scale) and the cluster spins evolve towards a new equilibrium situation (which in general implies the magnetization reversal); (iii) steps (i) and (ii) are repeated n times (in our case $400<n<800$) in order to achieve good statistics; (iv) the time evolution of a given quantity is calculated by averaging it over these n independent runs. In particular we are interested in determining the evolution of the total magnetization $\langle m_z(t)\rangle$ as well as its behavior at different cluster regions. The number of MC steps (MCS) needed for reaching the new thermal equilibrium strongly depends on temperature, and in some cases (large radius and low temperatures) the whole reversal process needed above 60 000 MCS.

We have performed magnetization reversal computer experiments for clusters with $3\leqslant R\leqslant 60$ taking into account a wide range of temperatures ($1.2\leqslant k_BT/J\leqslant 2.3$) for two magnetic fields $H=0.05$ J and 0.1 J. In Fig. 1 we show a typical time evolution curve $\langle m_z(t)\rangle$ for a cluster with $R=25$ at $k_BT/J=1.9$, noticing that the evolution of the outermost crowns is different in magnitude to that of the inner ones, giving rise to a nonhomogeneous magnetization reversal process. It can be seen that when the magnetization of the outermost crown is zero, the inner crowns have not started the reversal process. This edge effect is characteristic of our cluster configuration, and cannot be found in 2D infinite systems.

In order to characterize the magnetization evolution we have studied the lifetime t_r, the time at which $\langle m_z(t_r)\rangle=0$. In Fig. 2 we show the dependence of t_r with the temperature T for different radii and for an external field $H=0.1$ J. It can be seen that in the range of temperatures we have considered, there is a well-defined exponential relation between t_r and the temperature

$$t_r\propto\exp(E_a/k_BT), \tag{2}$$

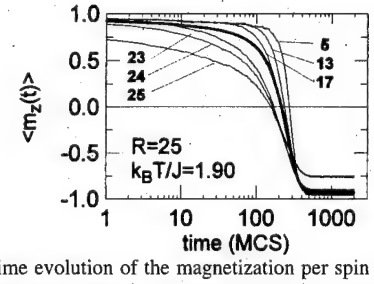

FIG. 1. Time evolution of the magnetization per spin at several distances r from the cluster center ($r=5,13,17,23,24,25$) of a cluster with $R=25$ at $k_BT/J=1.9$. The initial field is $H=0.1$ J. Thick line represents the total magnetization.

 0021-8979/96/79(8)/6019/3/$10.00

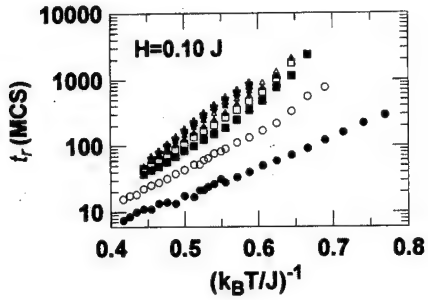

FIG. 2. Reversal lifetime t_r as a function of the temperature for several cluster radii [R=3 (full dots), 5 (open dots), 10 (full squares), 15 (open squares), 20 (black triangles), 30 (open triangles), 40 (full diamonds), 50 (open diamonds), 60 (crosses)]. The applied field is H=0.1 J.

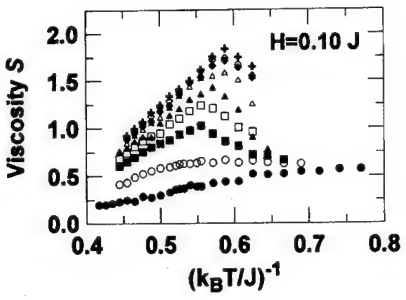

FIG. 4. Magnetic viscosity S as function of the temperature for several cluster radii. Symbols correspond to those of Fig. 2.

where E_a is the activation energy. This indicates that we are considering the region where the reversal process is thermically activated.[2] In Fig. 3 we have represented the dependence of the activation energy on the cluster size. For small radii, there is a fast increase of the activation energy, but for $R>10$ the activation energy is almost independent of the cluster size. This behavior is different from that expected for systems described with the Stonner–Wohlfarth[3] model, where the activation energy is proportional to the cluster size. This anomalous dependence can be interpreted in terms of a more complex evolution than that of the uniform rotation, such as it has been shown in Fig. 1.

A second characterization of the reversal process has been done by fitting the average magnetization $\langle m_z(t)\rangle$ to the logarithmic law

$$\langle m_z(t)\rangle \approx A - S\,\log(t), \tag{3}$$

where A is a constant and S is the so-called magnetic viscosity that depends on the magnetic field, the temperature, and the cluster size. This logarithmic behavior is usually associated with a broad distribution of energy barriers.[9] Notice that Eq. (3) is used to represent the evolution of $\langle m_z(t)\rangle$ around $t=t_r$, so that the viscosity S reflects the slope of the magnetization near the transition between positive and negative direction.

In Fig. 4 we have represented the values of S as a function of the temperature for several cluster sizes, and for a fixed field H=0.1 J. The first remarkable fact is that S presents a well-defined maximum for clusters with $R>8$, whereas for smaller radii S does not present any structure.

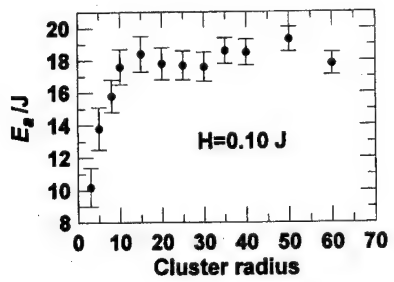

FIG. 3. Activation energy E_a as a function of the cluster radius. The applied field is H=0.1 J.

We have found that the temperature $k_BT/J\approx 1.75$ represents a critical point separating two regions having different reversal mechanisms. Below this temperature the magnetization reversal is originated by the motion of a domain wall from a point of the cluster edge to another opposite point. Above the critical temperature the reversal is very noisy with a continuous nucleation in all the cluster regions, similar to that happening in infinite systems.[7,8] However, in both cases, spins at the cluster edge play a fundamental role, since the reversal process starts mainly at these points. These sites are nucleation points since they have lower magnetization and stronger fluctuations in comparison with the bulk sites.[10,11] These two different behaviors have been noticed in very thin layers with strong anisotropy with defects and domains mismatching.[12] The critical temperature $k_BT/J=1.75$ limiting these two regions with different time-reversal features is very close to the roughening transition temperature of a 2D Ising system with a free edge having a smaller exchange constant J.[13] In our model the exchange constant does not change anywhere, however the effective number of nearest neighbor particles at the cluster perimeter does suffer a considerable decrease with the subsequent decrease of the effective interaction. Therefore, we have found that in a wide range of temperatures the cluster edge acts as a nucleation center, due to the lower magnetization and large fluctuations at the edge particles.

Since the previous simulations can be interpreted as the time evolution of highly anisotropic systems, we have studied whether these 2D clusters satisfy the Néel law[2] which has recently been questioned by experimental results on elongated clusters with large anisotropy.[4,5] We have calculated the probability of not switching $P_{ns}(t)$, as defined in Ref. 4, i.e., the probability of finding at time t the magnetic moment in the direction of the initially applied magnetic field, after a magnetic field inversion at t=0. Figures 5(a) and 5(b) show the curves $P_{ns}(t)$ for two radii (R=5 and R=60) and several temperatures, noticing that the exponential behavior (Néel law[2]) does not correctly describe the cluster reversal process for clusters with $R>10$, in agreement with experiments involving large clusters.[4] In particular, we should remark that the change of the probability is very steep, taking place in a relatively short time.

In conclusion, our simulations show that the magnetization reversal is not homogeneous for the wide range of temperatures we have considered, in good agreement with recent

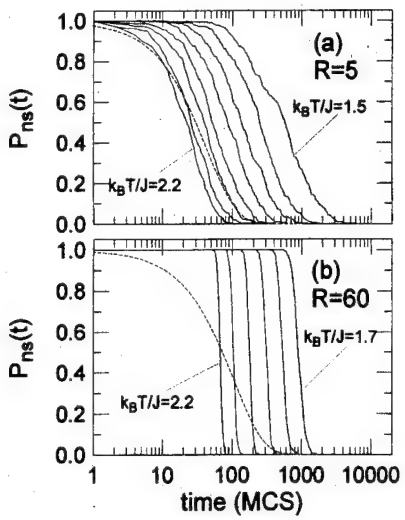

FIG. 5. Probability of not switching $P_{ns}(t)$ vs time, for two clusters with (a) $R=5$ and (b) $R=60$, at several temperatures. Only maximum and minimum k_BT/J values are shown. The temperature change between two subsequent curves is $\Delta k_BT/J=0.1$. Dashed lines correspond to the best fit of the curve with $k_BT/J=2.0$ to the Néel law.

experiments on elongated single-domain particles.[4,5] Thus we can say that the collective motion of spins does not follow a simple path in the configuration space. This fact is reflected by the anomalous behavior of both the activation energy and the notswitching probability. We think that within this perspective, the theory and the interpretation of experiments that claim to have observed macroscopic quantum tunneling (MQT) of the magnetization for small particles,[14,15] on the basis of the coherent rotation model, may need further consideration, incorporating to the theoretical models the nonhomogeneous distribution of magnetization.

Alternating current (ac) susceptibility studies in Ni-SiO_2 granular film

B. Zhao, Jeff Y. Chow, and X. Yan
Department of Physics, Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong

Alternating current (ac) magnetic susceptibility was measured as a function of frequencies (1 Hz–1 kHz) and temperatures (5–300 K) in nominal Ni-SiO_2 granular films for zero field cooled samples. When temperature is well below and well above the blocking temperature T_b, the real part of the susceptibility, χ', remains independent of frequency, while the imaginary part of the susceptibility, χ'', is essentially zero within the experimental error. Near T_b, however, both χ' and χ'' were found to be greatly enhanced, and χ' decreases with increasing frequency following $\log(f)$ dependence. A scaling method was applied for $\chi'(f,T)$ to determine the distribution of energy barriers and that of particle size. © *1996 American Institute of Physics.* [S0021-8979(96)40908-6]

I. INTRODUCTION

The peculiar magnetic properties of granular materials attracted much attention in the last few decades.[1–3] The relaxation time τ of the total magnetic moments for a collective single-domain ferromagnetic particle system was determined by the ratio of anisotropy energy barrier E_a and thermal energy k_BT, where E_a is linearly proportional to the volume of the magnetic particle, if the surface anisotropy can be neglected. Many dc magnetic properties such as saturation magnetization, remanence, and susceptibility of granular system have been well investigated.[2,3] Recently, it was found that there is a negative remanence in the nearly percolating system,[4] and a giant Hall effect enhancement when metallic particles are about to percolate.[5] However, a comprehensive understanding of dynamic magnetic properties is still not well established, though some pioneer works have been done in the related system.[6,7] In the present article, we investigate the dynamic susceptibility of Ni_x-$(SiO_2)_{1-x}$ granular films with different magnetic volume fraction x's. A scaling method was applied to determine the relaxation energy barrier distributions of samples with different x's.

Using the classical probability of jumping over an anisotropy energy barrier, Neel[8] came up with a simple model where the relaxation time of magnetic moment of an individual granular particle is determined by $\tau=\tau_0\exp(E_a/k_BT)$, $E_a=KV$, where E_a, K, and V are particle's anisotropy energy barrier, anisotropy constant, and volume, respectively, k_B is the Boltzmann's constant, and T is the absolute temperature. The pre-exponential factor τ_0 is a constant, which is related to the gyromagnetic procession and may be estimated to be on the order of 10^{-10} s.[8] The temperature at which the magnetic moment relaxation time τ with mean volume size of a particle ensemble is equal to the measurement time τ_m is often called the blocking temperature T_b. Following Neel's theory, at high temperature, the magnetic moment relaxation time τ of the system can be so small that several flips may occur during the measurement time τ_m. Therefore, when $T>T_b$, the magnetization of such an ensemble of particles will be zero in zero applied field, and will behave "superparamagnetically," the same as an ensemble of paramagnetic atoms.

Assuming that the magnetic moment of each particle is μ for an ensemble of N particles, a time-dependent magnetization will have the following form: $M(t)=\nu(t)N\mu\tan h\{-[1-\exp(-t/\tau)]/k_BT\}$, where, $\nu(t)$ is a unit step function. Through Fourier transformation of the above equation, one can obtain ac susceptibility: $\chi(f)=\chi'(f)+i\chi''(f)=\chi^0(1+i2\pi f\tau)$, where $\chi^0=\mu^2V/3k_BT$ is the dc susceptibility of the system. Considering that the energy barrier has a finite distribution $n(E)$, the real part of ac susceptibility can be written as

$$\chi'(f,T)=\frac{\mu^2V}{3k_BT}\int_0^\infty dEn(E)\left(\frac{(1/\tau)^2}{(1/\tau)^2+(2\pi f)^2}\right).$$

Notice that the temperature differential of the bracket part of the above equation is a sharply peaked function of E about the energy $E=k_BT\ln(1/2\pi f\tau_0)$, with width $\delta E=k_BT$, and can be approximated by a constant Dirac delta function. Thus, if $\chi'(f)$ versus temperature at different f's are measured, the relaxation energy barrier distribution $n(E)$ as a function of scaling parameter $E=k_BT\ln(1/2\pi f\tau_0)$ can be obtained by numerical temperature differential of $T\chi'(f)$.[7] This method is called scaling method, and was considered to be one of the best methods to determine the energy barrier distribution, because (a) the measurement time τ_m is well defined, (b) the applied field is very weak, so that the modification of the anisotropy energy of individual granular particle and the perturbation to the system may be neglected, to the first approximation. The latter has a clear advantage compared to the analysis based on the remanence studies which perturb the system.[9]

II. EXPERIMENTS AND RESULTS

Nominal granular $Ni_x(SiO_2)_{1-x}$ films were fabricated using a Denton magnetron rf sputtering system, where nickel and SiO_2 targets were mounted on two separate sputtering guns and the rotating silicon substrate was maintained at 150 °C. Films approximately 1 μm thick with nominal nickel volume fraction $x=0.3$, 0.4, and 0.5 were deposited after presputtering for 30 min. A detailed description of sample characterization can be found in Ref. 9. ac susceptibility $\chi(f)$ measurements (3 Oe zero-to-peak) as functions of frequency f(1, 2, 4, 10, 20, 40, 100, 200, 400, and 1000 Hz) and temperature T(5–300 K) after cooling samples ($x=0.3$, 0.4, and 0.5) in the zero field were performed using a Quantum Design MPMS-5 SQUID magnetometer. lows the simultaneous measurement of in-phase $\chi'(f)$ and out-of-phase $\chi''(f)$ components with a noise level below 10^{-7} emu. Also field cooled (FC) and zero field cooled (ZFC) dc susceptibility were measured to determine dc blocking temperature T_b for different samples using the same magnetometer and the results were listed in Table I.

Figure 1 summarizes the real part of ac susceptibility as a function of temperature for sample with $x=0.3$ at four representative frequencies. In the insert, the real and imaginary part of ac susceptibility, $\chi'(f)$ and $\chi''(f)$, were plotted together at 10 Hz. The data show that both $\chi'(f)$ and $\chi''(f)$ were greatly enhanced near the blocking temperature and as the frequency increases, the peak of $\chi'(f)$ was decreased and was shifted to higher temperature. According to Neel's theory, at T_b, the relaxation time τ of isolated particles with mean particle size V_m is equal to τ_m taken to be the half period of the applied field, namely, $\tau_m=\tau_0\exp(kV/k_BT_b)$. Thus, from the shift of T_b with increasing measurement frequency, the pre-exponential factor τ_0 was determined as shown in Table I. Since the fitting value of τ_0 is not too different from 10^{-10} s for all samples, it may be considered physically reasonable.[7] And the slight increase of τ_0 as increasing x indicates that although the interaction of granular particle became more and more important as increasing x, the sample is still in the range in which Neel's theory is applicable. In Fig. 2, the relation between χ' and $\log(f)$ was plotted at three typical temperatures, namely, well below, well above, and near the blocking temperature T_b for the sample with $x=0.3$. It is clear that (i) when temperature is well above and well below T_b, χ' is essentially frequency independent; (ii) when T is near T_b, χ' decreases with increasing frequency following $\log(f)$ dependence. The reason for (i) is that when temperature is well below T_b, the magnetic moment relaxation time τ of the most particles in the sample were much larger than the measurement time τ_m which is determined by applied ac frequency. Thus the differences among χ' at different frequencies were so small that a constant $\chi'(f)$ was observed. When temperature is well above T_b, τ is much smaller than τ_m, there are no differences among χ' at different measurement frequencies. However, near T_b, because τ_m is in the same order with τ for most particles, χ' was found to be much more sensitive to frequency. When frequency is higher, less particles can follow the ac field, hence χ' is smaller. Physically, $\log(f)$ dependence must be related to particle's energy barrier distribution form, because the broader the distribution, the less particles failed to follow the higher frequency field, leading to a smaller slope in the $\log(f)$ dependence. The inset of Fig. 2 shows χ'/χ_0 vs $\log(f)$ near the corresponding T_b for different x's. Note that the smaller the x, the larger the decreasing rate. Therefore, a sample with $x=0.5$ has the broadest energy distribution, a sample with $x=0.4$ has less, and $x=0.3$, the least. The numerical calculation[6] also indicates that for a broad lognormal distribution in a superparamagnetic system, the low frequency susceptibility can display linear $\log(f)$ behavior, and the broader the distribution, the smaller the slope of the $\log(f)$ dependence, which is in agreement with our experimental results.

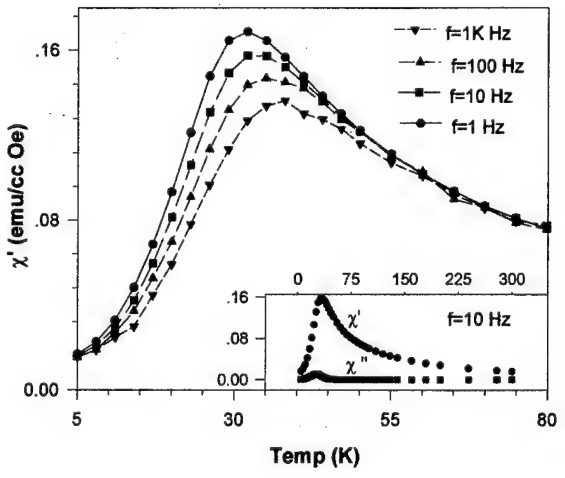

FIG. 1. χ' vs temperature for different frequencies for sample with $x=0.3$. Inset: χ' and χ'' vs temperature for the same sample with 10 Hz frequency.

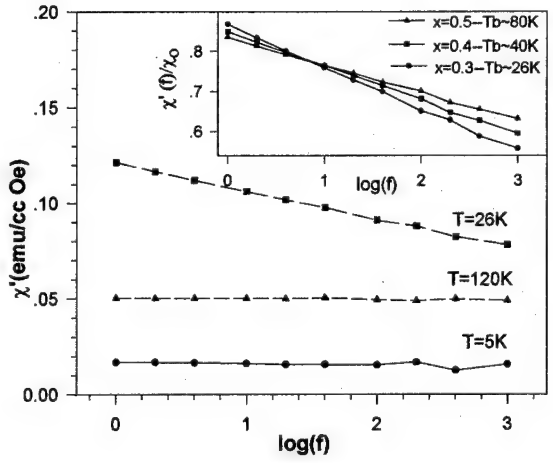

FIG. 2. χ' vs $\log(f)$ for sample with $x=0.3$, for three different temperatures. Inset: χ'/χ^0 vs $\log(f)$ at corresponding blocking temperature for samples with different x's.

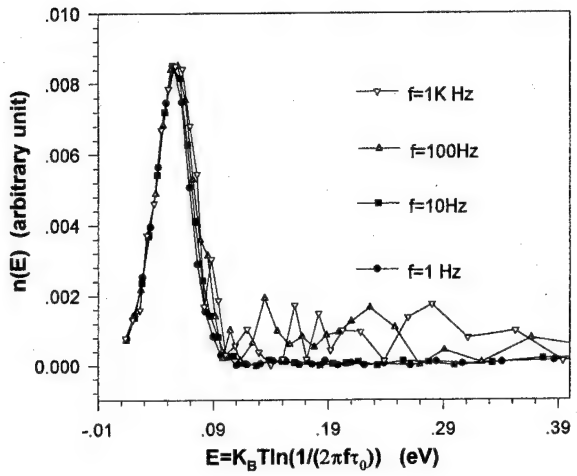

FIG. 3. Master curve of the energy barrier distribution as function of a scaling parameter $E=k_BT\ln(1/2\pi f\tau_0)$ which is obtained by the scaling method for sample with $x=0.3$.

The trend of increasing particles size distribution when increasing x can also be obtained via the scaling method by numerical temperature derivative of $T\chi'(f,T)$ for different f's. Figure 3 shows the master curve of $n(E)$ which describes the energy barrier distribution as a function of scaling parameter $E=k_BT\ln(1/2\pi f\tau_0)$ for magnetic volume fraction $x=0.3$ and the curve was fitted to a lognormal distribution:

$$n(E)=\left(\frac{1}{\sqrt{2\pi}E\ln\sigma}\right)\exp\left(-\frac{[\ln(E)-\ln(E_0)]^2}{2(\ln\sigma)^2}\right).$$

The fitting parameters of mean energy barrier E_0 and the standard deviation σ were listed in Table I. Assuming that the energy barrier is entirely due to the volume of the particles, the same statement on the energy barrier can be said to the particle size. Taking 100 s as dc measuring time, dc blocking temperature and the mean energy barrier E_0 should be related according to $T_b'=E_0/25k_B$. One way to check the validity of this method of determining the distribution is to compare the calculated dc blocking temperature T_b' with that determined by dc susceptibility measurement experiments, T_b, as shown in Table I. Note that the calculated T_b' is consistent with experimental T_b surprisingly well. Moreover, the trend of increasing σ as x increases is also consistent with the increasing slope in χ' vs $\log(f)$ near T_b. Also, the calculated mean particle diameter is similar to that obtained via TEM,[9] as can be seen in Table I.

III. CONCLUSION

ac magnetic susceptibility measurement have been performed on $Ni_x(SiO_2)_{1-x}$ granular thin films with different magnetic volume fraction x. Near T_b, both χ' and χ'' were found to be greatly enhanced, and χ' decreases with increasing frequency following a $\log(f)$ dependence. Also, the scaling method was used to obtain the energy barrier distribution.

Impregnating transition metallic compounds into porous glass is a simple way to form ultrafine particles in a glass matrix. In our studies, ultrafine particles were prepared by impregnating Fe compounds into porous glasses (pore size 70±21 Å) and annealing. After annealing, the samples were studied at different temperatures with a vibrating sample magnetometer. In the annealed glasses two types of particles were formed: (a) superparamagnetic particles and (b) ferromagnetic particles with exceedingly high coercivity (Hc=13 kOe at 298 K). The ratio between superparamagnetic and high coercivity particles depends on the annealing temperature and time. In samples annealed at lower temperatures or at high temperature for short times, only superparamagnetic particles were found. In those annealed at high temperatures after certain times, only high coercivity particles were found. It was also found that the blocking temperature T_B of the high coercivity particles depends on the annealing process. Moreover it was found that the Curie temperature of the high coercivity particles is below 520 K. © *1996 American Institute of Physics.* [S0021-8979(96)05408-9]

I. INTRODUCTION

Decreasing the size of a magnetic particle changes its properties and presents interesting applications for magnetic storage. Nano-sized particles obtained from the decomposition of $Fe(CO)_5$ in porous glass yields superparamagnetic and ferromagnetic particles[1,2] and changing the surface contribution relative to the volume contribution of particles can enhance their coercivity.[3,4] The ratio of superparamagnetic to ferromagnetic particles, which exhibit exceedingly high coercivity (>10 kOe at room temperature), depends on annealing times and temperatures. Superparamagnetic particles are formed at low annealing temperatures, whereas high annealing temperatures results in glass consolidation and ferromagnetic particles.

II. EXPERIMENTAL SECTION

Samples of Corning code 7930 Vycor glass (PVG) were impregnated with iron pentacarbonyl or iron nitrate by previously described vapor deposition[1,2] or solution adsorption technique. For consistency, the impregnated samples were broken into several pieces, and the individual piece was annealed for different temperatures and times.

The magnetization of the samples were measured with a DMS vibrating sample magnetometer with temperature control and up to a maximum field of 13 kOe.

III. RESULT

The magnetic properties of iron impregnated PVG after consolidation are dependent on annealing conditions and the temperature (Fig. 1). At high temperatures, ≥150 °C, the coercivity drops to essentially zero at 200 °C (Fig. 1), and the magnetization decreases rapidly as the temperature increases from 200 to 250 °C. The hysteresis loops measured at 150 °C show that coercivity increases with increasing annealing time and temperature. Increasing the annealing time and temperature also reduces the superparamagnetism in the samples.

Previous studies[5] show that the consolidation of PVG begins at 900 °C, and the presence of absorptions at 1300 and 1900 nm, which are overtones of the surface hydroxyl indicate that samples annealed at 1000 °C are not fully consolidated. However, the extent of consolidation increases with annealing time and this affects the magnetic properties of the samples. With the exception of a slightly larger opening in the loop, samples annealed for one minute at 1000 °C exhibit essential identical loops when measured at 30 and −150 °C [Fig. 2(a)]. Increasing the annealing time to 60 min increases the hysteresis in the high-field region [Fig. 2(b)]. The shape of the hysteresis loop could be due to the superposition of a minor loop with high coercivity and a major with little hysteresis. This suggests that two different types of magnetic particles are present in the glass. One possesses a low coercivity, while the other possesses a temperature-dependent high coercivity.

IV. DISCUSSION

Previous studies[6] show that γ-Fe_2O_3 is formed in a silica matrix when annealed at 900 °C, and Mössbauer spectra of the samples prepared in our experiments are also consistent with the presence of Fe_2O_3. This species is assigned to the superparamagnetic material in the glass. The nature of the ferromagnetic particles is not clear, but the Curie temperature indicates it is different from the bulk material. Figure 1 yields a Curie temperature below 250 °C, and in all samples

 0021-8979/96/79(8)/6025/3/$10.00

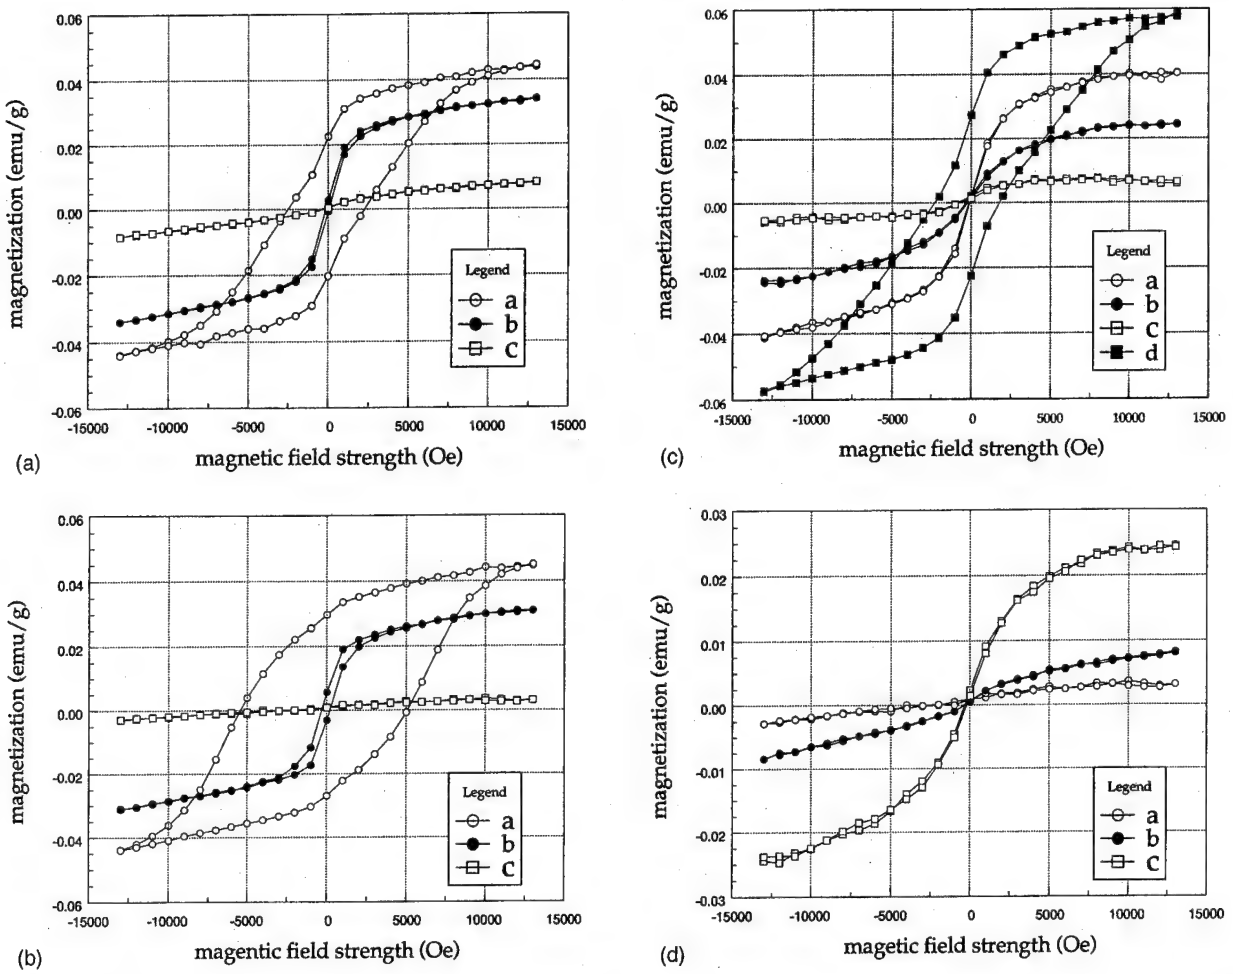

FIG. 1. (a) Magnetization curves of sample annealed at 1200 °C for 15 min at different temperatures: (a) 150 °C, (b) 200 °C, and (c) 250 °C. (b) Magnetization curves of sample annealed at 1200 °C for 90 min at different temperatures: (a) 150 °C, (b) 200 °C, and (c) 250 °C. (c) Magnetization curves of sample annealed at 1100 °C for 120 min at different temperatures: (a) 150 °C, (b) 200 °C, (c) 250 °C, and (d) 30 °C. (d) Magnetization curves at 250 °C of sample (a) annealed at 1200 °C for 90 min, (b) annealed at 1200 °C for 15 min, and (c) annealed at 1100 °C for 120 min.

examined in these experiments, the Curie temperature is below 350 °C. The latter is small in comparison to those reported for bulk iron oxides. The Curie temperature of the Fe_3O_4, for example, is 585 °C.

The blocking temperature of the ferromagnetic particle in these glass matrices increase with increasing annealing temperature and time. For a single domain particle, the blocking temperature is given by[7]

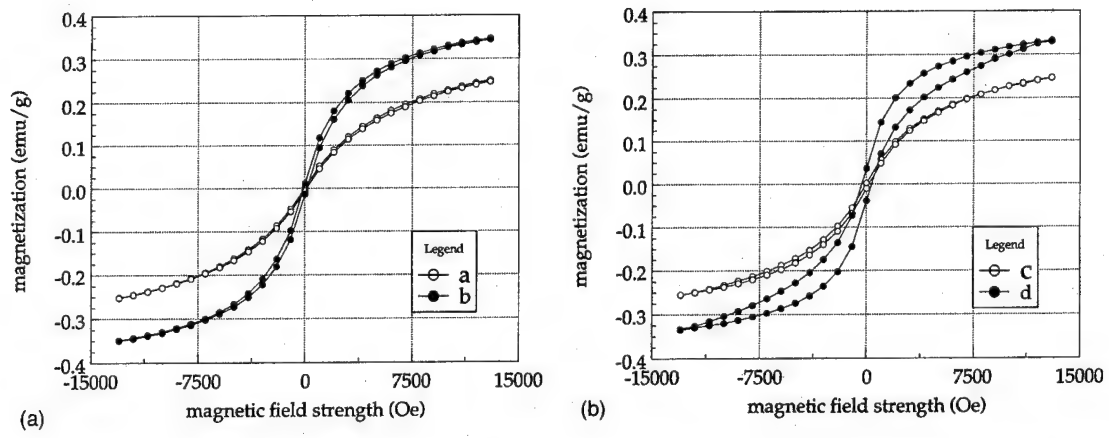

FIG. 2. (a) Magnetization curves of sample annealed at 1000 °C for 1 min at (a) 30 °C and (b) −150 °C. (b) Magnetization curves of sample annealed at 1000 °C for 60 min at (a) 30 °C and (b) −150 °C.

$KV/8 \cong 25 k_B T$,

where K is the magnetic anisotropic constant, V is the volume of the particle, k_B is Boltzmann's constant, and T is temperature. Since the blocking temperature increase with particle size, Figs. 1 and 2 suggest that the size of the ferromagnetic particles increases during the annealing. In addition, the different temperature dependencies of the ferromagnetic and superparamagnetic particles suggest that the consolidation of the matrix changes some of the superparamagnetic particles to ferromagnetic particles.

V. CONCLUSION

Regardless of the precursor, impregnation of porous Vycor glass and subsequent annealing of the impregnated glass yields superparamagnetic and ferromagnetic particles that exhibit a high coercivity. The temperature dependence of these impregnated glasses suggests applications as magnetic storage materials where the field cooling method could be used to write data onto the material.

Fe_x–Cu_{100-x} alloys ($40 \leqslant x \leqslant 90$) prepared by ball milling nominally pure (99%) Fe and Cu powders and warm compacted (at ~300 °C) were investigated by differential scanning calorimetry, scanning electron microscopy, x-ray diffraction, and magnetic susceptibility measurements. Both fcc and bcc diffraction peaks (indicative of pure Fe and Cu) showed that the mixtures were still two phase even after milling for 400 h, and that they were comprised of 6–10 nm diameter grains. Surprisingly, however, calorimetric measurements indicate the presence of a large endothermic peak for these nanocrystalline composites on heating near 600 °C and an exothermic peak near 400 °C on cooling. Magnetic measurements show that these materials are ferromagnetic at room temperature and remain so (with decreasing saturation magnetization) up to near the Curie point of α-Fe, 770 °C. However, near 600 °C on heating (and also near 400 °C on cooling), the magnetic susceptibility indicates the existence of a magnetic phase change. High-temperature x-ray diffraction data show these effects are due to the oxidation of Fe to form magnetite which subsequently decomposes into wustite. The thermal hysteresis observed in the magnetic and thermal data is due to the sluggishness of the latter transformation. Furthermore, heating to temperatures in excess of 600 °C results in the dissolution of Cu into the iron oxides which does not reprecipitate on cooling. [S0021-8979(96)05508-5]

I. INTRODUCTION

Fine dispersions of magnetic particles in nonmagnetic matrices have been found to possess different magnetic characteristics than the same particles compacted together into a bulk material without the non-magnetic constituent.[1] In fact, the properties may be tailored by proper adjustment of the relative composition of the two species (an easy variable to control) and the thermal-magnetic treatment given the material. Applications of such materials to recording heads, high-density recording media, color reproduction, and magnetic refrigeration have been suggested.[2] One particularly exciting new effect found in multilayers[3] and thin granular metal films[4] of such composites is the "giant magnetoresistance (GMR) effect."[3] In a recent study to prepare bulk GMR-exhibiting Fe–Cu nanocomposites by ball milling and consolidation,[5] the presence of a magnetic transition near 600 °C (on heating) was indicated by magnetization measurements. As there is no equilibrium magnetic (or even crystallographic) phase change in this system at 600 °C,[6] it was suggested that the nanocrystalline morphology had reduced the $\alpha \rightleftarrows \gamma$-Fe transformation temperature in these materials. This effect would be similar to the reduction in the fcc⇄hcp transformation temperature found in pure Co,[7] when prepared in the nanocrystalline state. In order to clarify the nature of this new magnetic transition in the Fe–Cu system, the present study was initiated.

II. EXPERIMENTAL PROCEDURE

Fe_xCu_{100-x} composites ($40<x<90$, atomic percents) were prepared by ball-milling powders of pure Fe (99.9% purity; average particle size <9 μm) and Cu (99% purity; average particle size <8 μm) in a 318-mm-diam steel tumbler mill using steel balls under a dry-nitrogen atmosphere for 400 h.[5] This method has previously been found successful for preparing fine dispersions of these materials in large quantities.[8] X-ray diffraction of the milled powders indicated the presence of three phases: α-Fe, fcc Cu, and a little Fe_3O_4 (magnetite). From the widths at half maximum of the (110) and (111) diffraction lines for Fe and Cu, respectively, the average grain sizes were calculated using the Scherrer formula and found to range between 3 and 10 nm.[5]

Prior to measurement of the magnetic and thermal behavior of these composites, 18-mm-tall compacts were prepared by consolidation under a dry-nitrogen atmosphere inside a specially designed 8-mm-diam mold with a steel plunger, sealed with vacuum grease. Typically, the compacts were cold compacted at room temperature in an MTS model 810,[9] followed by warm compaction at 300 °C and 1.5 GPa for 5 h. X-ray diffraction of the compacted samples again only indicated the presence of α-Fe, fcc Cu, and a small amount of Fe_3O_4. During consolidation the Fe and Cu grains increased to 11–13 nm and 6–9 nm, respectively. Following consolidation, the samples were analyzed using energy dispersive x-ray analysis (EDAXS) in a JEOL JXA-840II scanning electron microscope.[9] Since there were found to be significant variations from the nominal compositions, unless otherwise noted, all compositions in this paper are quoted in their analyzed atomic percentages. Differential scanning calorimetry (DSC) of the consolidated samples was performed in a Perkin–Elmer DSC 7 (Ref. 9) at a heating and cooling rate of 10 °C/min, and magnetization measurements were performed at elevated temperatures under flowing helium gas in a vibrating sample magnetometer using a boron

nitride sample holder. High-temperature x-ray diffraction (HTXRD) was performed using Cu $K\alpha$ radiation in a Siemens D5000 theta-theta[9] diffractometer equipped with a Buhler 3000 K hot stage,[9] a Braun linear position sensitive detector, and a theta compensating slit. For this latter data, the 1 cm×1 cm×1 mm sample foil was placed on top of an Al_2O_3-coated Pt-heater strip surrounded by He gas, and each spectrum measurement took approximately 30 min.

III. RESULTS AND DISCUSSION

Figure 1 shows the magnetization data measured at 748 kA/m (9.4 kOe) applied field for the $x=57$ nanocomposite. These data are similar to those measured in the earlier study[5] on a different sample. During heating there are two major features: (1) a large broad decrease in M starting at near 400 °C and ending near 600 °C and (2) a smaller sharp decrease in M at near 710 °C. Both features are suggestive of ferromagnetic to paramagnetic transitions. Also, since the magnetization changed by 93% in feature (1), the majority of the sample transformed between 400 and 600 °C. Indeed, the isotherms in Fig. 2 for this sample show that at room temperature the material is ferromagnetic and at 790 °C it is paramagnetic. However, as shown in the phase diagram for the major constituents,[6] Fe and Cu, at this composition there are no magnetic phase changes near 600 °C. Since the lattice constant of Fe in this sample was measured to be only 2.87 Å (only 0.15% larger than that of pure Fe), the 600 °C transition does not come from a Curie temperature (T_C) depression of α-Fe due to increased solubility of Cu. The smaller sharp decrease in M at near 710 °C, however, probably is due to the Curie point depression of α-Fe due to the equilibrium 1% Cu solubility.

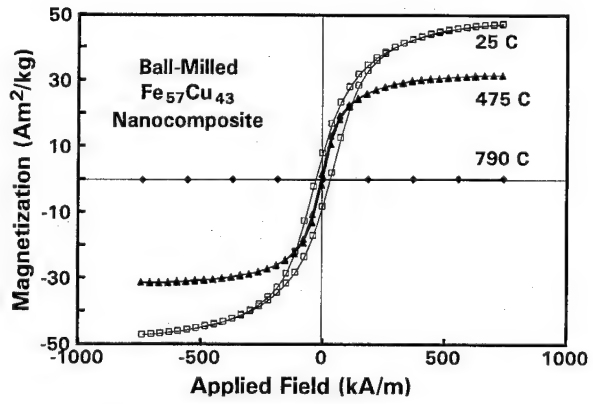

FIG. 2. Magnetization vs applied magnetic field isotherms for the ball-milled $Fe_{57}Cu_{43}$ nanocomposite measured at the indicated temperatures. The central temperature isotherm was measured following the first thermal cycle.

Similar to the magnetization heating data, the cooling data in Fig. 1 also show two prominent features: (1) a small sharp increase in M at near 680 °C and a much larger sharp increase in M beginning at near 400 °C. It is attractive to ascribe both these features to the same phenomena that cause the two drops in M during heating, but with their transition temperatures displaced toward lower temperatures. If this assumption is true, then these features are not likely to be Curie temperatures. Furthermore, the measured hysteresis suggests that the magnetic effect is probably due to a crystallographic change between ferromagnetic and paramagnetic phases.

The DSC data for this sample, Fig. 3, further support the likelihood that the large features in the M vs T data are due to phase transformations. Notable are the endothermic reaction near 600 °C and the exothermic reaction near 425 °C which roughly repeat with thermal cycling. The similarity in the temperatures of these two arrests to the temperatures of the largest magnetic effects is suspiciously coincidental. For a first-order phase transformation between equilibrium crystallographic phases, one would expect these heat effects. However, no heat effect should occur at a Curie point since the ferromagnetic to paramagnetic transformation is of second order. Consequently, the magnetic phenomena occurring at 600 °C on heating and at 400 °C on cooling are unlikely to be Curie point effects. Also notable from the thermal data (and also measured in the magnetometer) is that this phase transformation is repeatable, indicating the transforming phases are stable with respect to the composition and morphology. Consequently, the possible explanation of the above results by a remarkable reduction (by a factor of 2) in the $\alpha \rightleftarrows \gamma'$ transformation of Fe from its equilibrium value of 1100 °C (since these two phases are ferromagnetic and para-

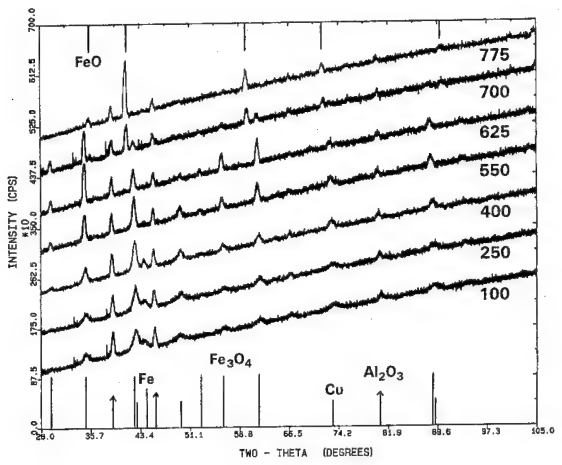

FIG. 4. X-ray diffraction data for the ball-milled $Fe_{57}Cu_{43}$ nanocomposite, measured during heating at the indicated temperatures. The baselines have been shifted for clarity. magnetic, respectively) is not likely.

HTXRD data provide the most definitive results on the identification of the unknown magnetic transformations described above. Figure 4 shows that during heating of the 57% Fe nanocomposite, much of the α-Fe oxidizes to Fe_3O_4 between 550 and 625 °C[10] followed by a dissolution of Cu into the magnetite at temperatures up to 700 °C to form $[Fe(Cu)]_3O_4$. Consequently, the large decrease in M observed near 600 °C is a combination of the α-Fe transforming to the less magnetic Fe_3O_4 and the subsequent ferromagnetic $\rightleftarrows$ paramagnetic transition of magnetite at its Curie point: 580 °C. Surprisingly, the HTXRD data show that the large endothermic reaction seen in the DSC data at near the same temperatures as the large magnetic transition on heating does not derive from the same cause, but comes from the slightly higher temperature (700 to 775 °C[10]) transformation of the Cu-containing magnetite into a paramagnetic Cu-containing wustite, [Fe(Cu)]O. Without Cu present, this transformation would occur at 570 °C, only 10 °C different from the T_C of magnetite.[11] Cu dissolution, however, does occur in both the magnetite and wustite as indicated by the shift in all the Bragg peaks for these phases to lower angles because of the larger Cu atoms. On cooling, the x-ray data show that the [Fe(Cu)]O does not transform back to $[Fe(Cu)]_3O_4$ until between 625 and 550 °C,[10] i.e., 150–200 °C below that observed during heating. This hysteresis has been observed in the binary Fe-O system,[11] and explains the thermal hysteresis effect observed in the DSC and magnetic data. For the latter data, the large increase in M observed on cooling near 400 °C is due to the creation of the ferromagnetic magnetite from the paramagnetic wustite. In the final transformation of [Fe(Cu)]O to $[Fe(Cu)]_3O_4$ (near 550 °C[10]) during cooling, Cu-containing hematite, $[Fe(Cu)]_2O_3$, is also formed. It is interesting to find that on further cooling, no Bragg peaks for the fcc Cu were observed, indicating that the thermal cycling resulted in all the Cu being contained in the magnetite and hematite.

For an 87% Fe nanocomposite, only a 30 percent magnetic arrest was observed near 600 and 450 °C during heating and cooling respectively while a 60 percent effect was measured during both heating and cooling at near 780 °C. Consequently, it appears that in this more concentrated Fe sample only some of the Fe oxidized to form magnetite during heating, and the two magnetic transitions again reflect the Curie points of magnetite and α-Fe, consistent with the data described above for the 57% Fe sample.

IV. CONCLUSION

Ball-milled and compacted Fe_xCu_{100-x} nanocomposites ($40 \leqslant x \leqslant 90$) are ferromagnetic at room temperature and become paramagnetic at temperatures between 700 and 780 °C depending on their composition. During heating they will oxidize (externally and internally) if all processing (e.g., milling, compaction, and sample transfers) and measurements have not been performed to preclude contact with air and water vapor. The unexpected magnetic transition observed earlier near 600 °C is due to the Curie point of magnetite and its phase transformation into paramagnetic wustite. Heating to temperatures in excess of 600 °C results in the dissolution of Cu into the iron oxides. Furthermore, once the Cu is dissolved in the oxides, it does not reprecipitate on cooling. Care should consequently be taken in the thermal treatment of these and other nanocomposites.

We report the first observation of steps in the hysteresis loop of a high-spin molecular magnet. We propose that the steps, which occur every 0.46 T, are due to thermally assisted resonant tunneling between different quantum spin states. Magnetic relaxation increases dramatically when the field is in the neighborhood of a step. A simple model accounts for the observations and predicts a value for the anisotropy barrier consistent with that inferred from the superparamagnetic blocking temperature. © *1996 American Institute of Physics.* [S0021-8979(96)41008-0]

INTRODUCTION

The large-spin molecule $Mn_{12}O_{12}(CH_3COO)_{16}(H_20)_4$, has been the subject of much experimental[1–5,10] and theoretical[6,7] work since it was first synthesized by Lis[8] in 1980. This molecule (often referred to as Mn_{12}) contains four Mn^{+4} ($S=3/2$) ions and eight Mn^{+3} ($S=2$) ions. Experiments[1] indicate that it has an $S=10$ ground state. These molecules crystallize into a tetragonal lattice in which magnetic interactions between molecules are thought to be negligible.[3] All experimental work[1–5,10] to date on this system indicates that it has a large magnetocrystalline anisotropy. Superparamagneticlike behavior has been reported.[1–4] Below a blocking temperature of ~3 K, hysteresis is observed[3,5] and slow exponential relaxation of the magnetization has been found[3] with relaxation times that obey an Arrhenius law, $\tau = \tau_0 e^{\Delta E/k_B T}$, down to 2.1 K; studies[4,10] at temperatures down to 175 mK show deviations from this form that have been interpreted as possible signs of temperature-independent quantum tunneling.

In this article, we report the observation of steps in the hysteresis loops of a powdered sample of Mn_{12}. We suggest that the steps are manifestations of thermally assisted, field-tuned resonant tunneling through the molecule's anisotropy barrier. We show that the relaxation rate increases dramatically when the applied field is tuned to a field at which one of the steps occurs.

EXPERIMENTS AND RESULTS

The sample was prepared following the published procedure[8] and was then ground into a powder consisting of submicron-sized crystallites. The powdered sample was mixed into Stycast 1266 and allowed to set in a field of 5.5 T at 300 K. This served to orient the crystallites suspended in the epoxy such that their easy axes aligned with the field due to the anisotropy of the susceptibility tensor. No corrections were made for the diamagnetism of the epoxy, which was considered negligible. The dc magnetization measurements were taken at temperatures between 1.7 and 15 K with a Quantum Design MPMS5 magnetometer equipped with a 5.5-T superconducting magnet.

Figure 1 shows the hysteresis loops taken with the field applied along the easy axis of the oriented sample at six different temperatures from 1.7 to 2.8 K, as indicated. The steps in the loops are clearly visible. In contrast, no steps were seen in a control sample prepared in the absence of a field. It is noteworthy that after the system is saturated and the field is reduced back to zero field, the curve is temperature independent and no steps are apparent. The steps occur only at specific values of magnetic field. The inset to Fig. 1 shows the field at which a step occurs plotted versus step number, where the steps are labeled by integers and the fields plotted are the points in the hysteresis curves where the slope, dM/dH, is maximal. The excellent linear fit indicates that a step occurs at approximately every 0.46 T. If data from all temperatures are used, then a total of seven steps, including the one at zero field, are observed and it is quite possible that more would be seen at lower temperatures. We note that as temperature is lowered, steps that were apparent at higher temperatures seem to disappear. These steps can still be observed, however, if the rate at which the field is swept is

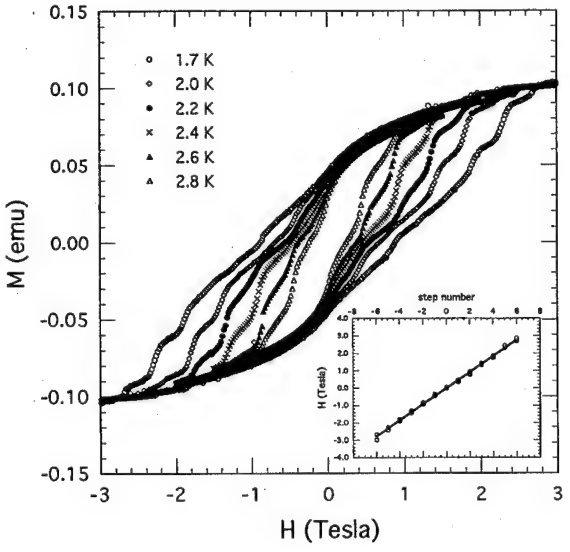

FIG. 1. Hysteresis loops of Mn_{12} for six different temperatures, as shown. The inset shows the fields at which steps occur as a function of step number. The straight line is a least-squares fit.

 0021-8979/96/79(8)/6031/3/$10.00

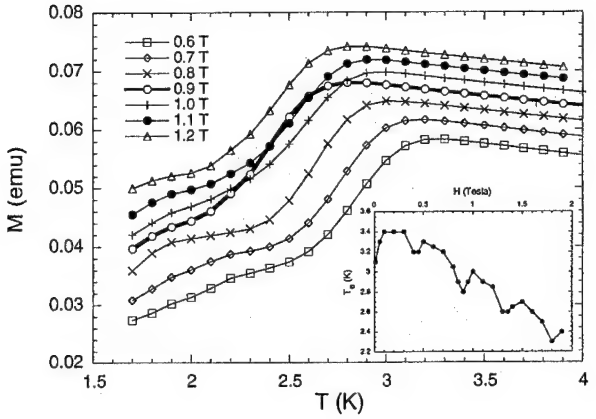

FIG. 2. Zero-field-cooled data for seven different measuring fields. The data for 0.9 T (bold line) is anomalous, shifting abruptly toward lower temperatures. The inset shows the superparamagnetic blocking temperature, T_B, as a function of magnetic field. The anomalous dips occur at approximately the same fields as the steps in the hysteresis loops.

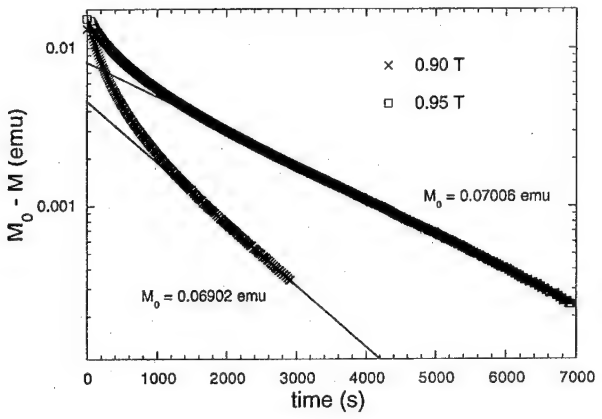

FIG. 3. Magnetic relaxation at 2.4 K plotted on a semilogarithmic scale. After cooling in zero field, a field of 0.9 or 0.95 T was applied, as indicated. M_0 is the asymptotic value of the magnetization; the straight lines indicate exponential behavior for $t>2000$ s.

reduced sufficiently. Similar steps have been observed[9] at 0.6 K in $[Fe(OMe)_2(O_2CCH_2\ Cl)]_{10}$, a molecular paramagnet comprised of a ring of Fe^{3+} ions which order antiferromagnetically and exhibit no hysteretic effects. Our results appear to be the first observation of such steps in a hysteretic molecular system.

In Fig. 2 we show magnetization data of the Mn_{12} sample after it was cooled from 5 to 1.7 K in zero field and then measured in an applied field as the temperature was raised. Data for seven different measuring fields, as indicated, are shown. (Some curves at other fields were omitted for clarity.) As expected for a superparamagnetic system, the blocking temperature T_B (the temperature of the curve's maximum) decreases systematically as the measuring field is raised. However, the curve at 0.9 T shifts abruptly toward lower temperatures. In the inset, we show the blocking temperature as a function of magnetic field from 0.01 to 1.9 T. Superimposed on the monatonic decrease of these temperatures with increasing field are several sharp dips. These dips occur at approximately the same fields as the steps in the hysteresis loops of Fig. 1. Ignoring these anomalous dips, we extrapolate the zero-field blocking temperature to be ~3.5 K. This corresponds to an energy barrier, ΔE, of 45 cm^{-1}.

An interesting feature of the zero-field-cooled curves is that some of them cross: in Fig. 2, one can see that within a certain temperature range the magnetization attains a higher value at 0.9 than at 1 T and sometimes even 1.1 T. This implies that the relaxation rate of the system must be significantly faster at the lower field value than at the higher ones. Direct evidence for this is provided in Fig. 3, where we have plotted the difference between the magnetization and its asymptotic value, M_0, as a function of time on a semilogarithmic plot. The curves show the relaxation of the magnetization after the sample was cooled to 2.4 K in zero field and then exposed to a field of 0.9 or 0.95 T, as marked. There is a dramatically faster relaxation rate at 0.9 than at 0.95 T. During the initial ~2000 s, the magnetization decays faster than exponentially. The data for $t \geq 2000$ s can be fitted very well to an exponential, $M = M_0(1 - e^{-(t-t_0)/\tau})$, as shown by the straight lines in Fig. 3. The fit yields time constants, τ, of 1048 and 2072 s at 0.9 and 0.95 T, respectively.

DISCUSSION

We suggest that the observed steps are due to thermally assisted resonant tunneling between quantum spin states in the Mn_{12} system. In zero field, the molecule has two degenerate ground states, corresponding to the spin being parallel ($m=S$) or antiparallel ($m=-S$) to the easy axis. An anisotropy barrier separates the states and a magnetic field breaks the symmetry, making one state a true ground state and the other a metastable ground state. This model is illustrated in Fig. 4. When an excited level in the right well is resonant with the metastable $m=S$ ground state on the left, transitions across the barrier are induced. Once the system has crossed the barrier, there is presumably a rapid spontaneous decay from the excited state to the ground state. In this way the metastable state is depleted and the system enters the $m=-S$ state.

The simplest Hamiltonian for this system is

$$\mathcal{H} = -DS_z^2 - g\mu_B \mathbf{S}\cdot\mathbf{H}, \tag{1}$$

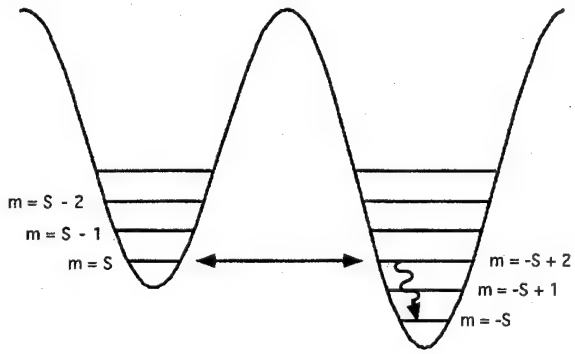

FIG. 4. A schematic representation of the resonant tunneling mechanism proposed to explain the observations. Tunneling from the metastable state $m=S$ to an excited state $m=-S+n$ is followed by a rapid spontaneous decay into the ground state.

where D represents the anisotropy energy that breaks the zero-field Zeeman degeneracy. If the field is applied along the easy axis, then the eigenstates of this Hamiltonian are $|S,m\rangle$. The first term in Eq. (1) implies that the ground state will be $m=\pm S$, as expected; the sign depends on the direction of the field. For clarity, we take $|S,S\rangle$ as the initial state of the system. We propose that a step occurs when the energy of this state is equal to the energy of a state on the other side of the anisotropy barrier. A simple calculation reveals that the field at which the state $|S,S\rangle$ crosses the state $|S,-S+n\rangle$, is

$$H_{S,-S+n}=\frac{-Dn}{g\mu_B}. \tag{2}$$

Thus, steps occur at even intervals of field, as observed. Interestingly, when the field is tuned such that the metastable ground state in the left well is resonant with a state in the right well, all of the excited states in the left well are also resonant with states on the other side of the barrier. Thus, a multiple resonance is set up whenever the field is tuned to a step. Using the fact that a step occurs every 0.46 T, we find $D/g=0.21$ cm^{-1}, which is consistent with the published values[1] of $D\sim0.5$ cm^{-1} and $g\sim1.9$ cm^{-1}. As a further check of this model, we can estimate the size of the anisotropy barrier: at zero field, the barrier is $g(D/g)S^2\sim41$ cm^{-1}, consistent with the estimate of 45 cm^{-1} obtained above from the blocking temperature data. Given that $S=10$ in this system, there should be exactly 21 steps ($n=0$–20), the last corresponding to the elimination of the barrier. Measurements at lower temperatures are needed to observe additional steps.

As noted above, as temperature is reduced, any given step becomes less prominent and the transition rate decreases rapidly. This implies that the resonant tunneling mechanism responsible for the steps is thermally assisted. It is possible that acoustic phonons provide the angular momentum necessary for the transition between different spin states. As temperature is lowered, the population of phonons (or other excitations) drops and the transition rate decreases. More work is needed to understand precisely what role thermal excitations play in this resonant process.

We would like to stress that the above model of field-tuned, thermally assisted resonant tunneling out of a metastable spin state explains many of the observations presented herein. When the field is reduced from saturation, no steps are seen because the system is already in the true ground state $m=S$. It is only when the field is reduced to near zero or reversed that the state becomes metastable allowing resonant transitions and the corresponding steps. The higher-numbered steps have progressively faster magnetic relaxation times since the tunnel barrier is lowered by the applied field.

In summary, we have found steps in the hysteresis curves of $Mn_{12}O_{12}(CH_3COO)_{16}(H_20)_4$ and propose that they result from thermally assisted resonant transitions between spin states. The magnetic relaxation rate of the system increases dramatically when the field is tuned to a step; that is, when there is a level crossing. A simple model has been proposed that accounts for the even interval of field between neighboring steps and is in quantitative agreement with measurements of the anisotropy barrier.

Note added in proof: Since we submitted this manuscript, two papers[11,12] have appeared on Mn_{12}, reporting anomalously fast relaxation rates at zero field[11,12] and 0.3 T.[12] Novak and Sessoli[12] suggest that these results are due to thermally assisted resonant tunneling. A similar suggestion has been made previously by Barbara *et al.*[10] to explain the zero-field anomaly.

Computer simulation of microstructure and interaction effects in fine particle systems (abstract)

G. N. Coverdale and R. W. Chantrell
Keele University, Keele, Staffordshire ST5 5BG, United Kingdom

M. El-Hilo and K. O'Grady
University College of North Wales, Bangor, Gwynedd, United Kingdom

The behavior of the magnetization of a fine particle system is partly determined by the interaction effects between the grains. In a previous study by El-Hilo *et al.*,[1] the magnetic particles were considered to be randomly distributed. Many fine particle systems are expected to exhibit a microstructure that has been influenced by intergrain interactions. This effect on the microstructure will be important during the formation of the solid where the magnetic particles exhibit significant mobility. We have developed a 3D Monte Carlo model of a fluid dispersion which after reaching equilibrium is then allowed to "freeze" to produce a fine particle system with microstructures which vary from clusters in the case of zero field to chains of particles in the saturated field case. This provides an excellent model system for the study of interaction effects. Our previous model[1] is then used to study the resulting magnetic properties of the materials. These include the remanence curves in addition to the hysteresis loops. The local microstructure is shown to have a significant effect on the δI plots which are often used to characterize interaction effects. The simulation of the systems in a solid matrix exhibits an interaction dependent magnetic after effect. Because of the interaction fields, the magnetic configuration also changes with time following a change in temperature leading to a "waiting time" dependence of magnetic properties, an effect also found in spin glasses. © *1996 American Institute of Physics.* [S0021-8979(96)63308-2]

Periodic breathing oscillations and instabilities in ferrofluids (abstract)

Weili Luo and Tengda Du
Department of Physics, University of Central Florida, Orlando, Florida 32816

Periodic breathing oscillations and instabilities are observed in diffraction patterns of ferrofluids in the presence of a magnetic thermal lens effect. The results crucially depend on (1) the boundary conditions, (2) the strength of external magnetic field, (3) the concentration of magnetic particles, and (4) the thickness of the sample layer. There is a critical field above which instabilities occur. Under a semifree surface boundary condition, the observed oscillation frequency ω is found to vary with external magnetic field according to $\omega \sim H^{1/2}$ for small field. In the confined geometry, diffraction patterns show random rotation of various shapes between H_{c1} and H_{c2}. The mechanisms responsible for these phenomena will be discussed. © *1996 American Institute of Physics.* [S0021-8979(96)63408-7]

Effects of Zn ion on magnetic properties of Fe_3O_4 magnetic colloids (abstract)

C. H. Lin

P. C. Kuo and J. L. Pan
Institute of Materials Science, National Taiwan University, Taipei, Taiwan, Republic of China

D. R. Huang
Opto-Electronics and Systems Laboratory, ITRI, Chutung, Hsinchu, Taiwan, Republic of China

The effects of Zn ion on magnetic properties Fe_3O_4 magnetic colloids were investigated in this study. Fe_3O_4 magnetic colloids were produced by the chemical coprecipitation method, i.e., mixing an acidic solution containing $FeCl_2 \cdot 4H_2O$, $FeCl_3 \cdot 6H_2O$, $ZnCl_2 \cdot 4H_2O$, with a NaOH alkali solution at 70 °C, and then centrifuging them from the mixed solution. Various reaction times, solution pH values, and Zn ion contents were also used. Fe_3O_4 magnetic fluid was obtained by adding ammonium oleate into the mixed solution, precipitating the colloids from the solution, neutralizing the colloids by hydrochloric acid, and dispersing the colloids in n-hexane. XRD, EDX, TEM, and VSM were used to determine the structure, chemical compositions, particle sizes, and magnetic properties of the colloids and the magnetic fluid. The spinel colloids was easily form at a higher pH value in solutions where the pH value ranged from 7 to 12. Fe_3O_4 colloids were completely formed within the first minute of mixing and the particle size of Fe_3O_4 colloids did not increase with time after the first minute. The lattice parameter of Fe_3O_4 colloids increased linearly with the Zn ion content because the diameter of Zn ion is larger than that of Fe ions. The particle size of Fe_3O_4 colloids was found to be 10 nm by TEM. For an initially fixed Zn content of 8 wt % in solutions, the Zn content in the Fe_3O_4 colloids ranged from 3.32 wt % at pH=5 to a maximum value of 7.85 wt % at pH=10. Later, it reduced to 7.51 wt % at pH=12 because Zn ion has the lowest solubility at pH=10. At 8 wt % of zinc ion in the solution, the σ_s of the Fe_3O_4 colloid increase sharply from 0 at pH=3 to 92 emu/g at pH=8 and then reach a maximum value of 94 at pH=10. The σ_s value and H_c value of the Fe_3O_4 colloid were found significantly improved by adding a suitable amount of Zn ions, e.g., ranging from 70 emu/g and 48 Oe at Zn=0 wt % to a maximum 94 emu/g and 50 Oe at Zn=7.14 wt %. Later they reduced to 70 emu/g and 44 Oe at Zn=12.52 wt % when prepared at pH=10. The σ_s value of the magnetic fluid was found linearly proportional to the colloid content in the magnetic fluid. For a colloid containing 7.51 wt % of Zn ion, the σ_s value of the magnetic fluid is 9.8 emu/g at 25 wt % of colloid. © *1996 American Institute of Physics.* [S0021-8979(96)82708-1]

Measurements of local magnetization by Kerr effect on Si-Fe nonoriented sheets

S. Defoug and R. Kaczmarek
SUPÉLEC, Plateau de Moulon, 91192 Gif-sur-Yvette, France

W. Rave
Institut für metallische Werkstoffe, I.F.W. Dresden, Postfach, 01171 Dresden, Germany

Magnetic domains have been visualized by Kerr effect on nonoriented silicon-iron sheets. A simple methodology on how to determine the surface magnetization is proposed. For complex patterns, this method provides interesting results which could not be obtained by any reasoning based on physical principles. © *1996 American Institute of Physics.* [S0021-8979(96)75708-3]

I. INTRODUCTION

Domain analysis on nonoriented silicon-iron sheets are virtually nonexistent. We found only one picture of magnetic domains visualized by Kerr effect on a Si-Fe sample[1] which may correspond to stress patterns either induced by polishing or by a considerable disorientation of the grain.

Other studies[2,3] forecast complex and hard to interpret magnetic structures due to the disorientation of the grains in nonoriented steels.

For interpretation of such images, an analytic method is necessary to determine the magnetic orientation in each domain. Using the Kerr effect observations, Hubert, Schäfer and Rave[4,5] developed a method that consisted of taking two pictures of the sheet for two different incident polarization, each with the same excitation. This method was successfully tested on materials that show high magnetic contrast such as permalloy and grain-oriented silicon-iron sheets.

However, the method is reliable only if the pictures can be normalized by comparing them with saturated images in several directions. Sometimes the saturation cannot be achieved even in high fields, which introduces inaccuracies. With high field values the Faraday effect can be disturbing. Also, this method is not very fast because about sixteen images must be recorded sequentially, with the polarizers being readjusted in between. This time-consuming procedure can enhance the optical, thermal, and magnetic instability of the measurement bench.

FIG. 1. Magnetic domains on *N.O.* Si-Fe.

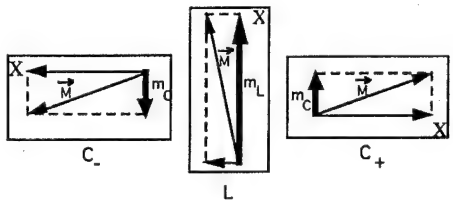

FIG. 2. The different positions of the sample.

In their last relevant study[6] the authors concluded that the method has proven to be of limited usefulness in practice. They proposed a modified method where the calibration procedure was replaced by the interactive assignment of magnetization directions to certain domains (at least to three domains) for which the magnetization directions are known. However, this specific requirement limits the method application.

The drawbacks of both methods have prompted us to look for a simple, reliable, and general strategy. That method would be of more practical application for the nonoriented silicon-iron steels, such as those used in the construction of electrical turning machines. First, however, the regular magnetic domains on this type of material should be visualized.

II. VISUALIZATION OF MAGNETIC DOMAINS ON NONORIENTED SHEETS

The tests conducted until recently in our lab as well as the bibliography[5,7] have shown that the use of a saturated image as a reference image does not give a satisfying contrast because of the difficulty to entirely saturate the polycrystalline samples and due to the electro-dynamic and optical parasite effects which appear near saturation.

TABLE I. Grey levels on the subtracted pictures.

 0021-8979/96/79(8)/6036/3/$10.00

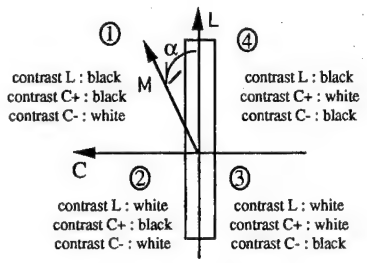

FIG. 3. (L,C) base.

We chose to use the magnetic averaging[8] as the way to obtain the reference images from the samples in a periodically varying excitation field. The utilization of such a reference image enables direct visualization of the domains on nonoriented Si-Fe sheets as shown in Fig. 1.

On this kind of images the different levels of black and white zones correspond to the different orientations of the magnetization. Yet, measurements of the magnetic contrast obtained inform us about only one component of the domain's magnetization. In some easy cases, we can deduce the direction of the magnetization from physical principles (flux closure, minimum magnetic poles) which govern the magnetization of this material.

The visualization of regular domains on Si-Fe sheets being no problem any more we have elaborated an original general method for the determination of the magnetic direction at each point of the acquired images.

III. DETERMINATION OF THE DIRECTION OF MAGNETIZATION

For soft materials, the calculations prove the polar magnetization component to be negligible. It was also verified experimentally by positioning the aperture diaphragm in the center of the back focal objective, where only the polar Kerr effect should be observable and no contrast was found.

Unlike the cited authors[4,5] who combined the optical information from two different incident polarizations, using both longitudinal and transverse Kerr components to determine the planar magnetization components, we used only the longitudinal effect combined with a 90° rotation of the sample.

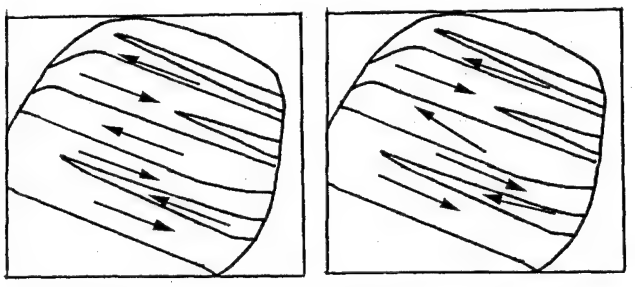

FIG. 5. Classical arrowing (left), magnetization determined by calculation (right). Note: the deviation of the middle arrow is due to the presence of a vertical white band (a problem of the acquisition card) which slightly distorts the values of the grey levels.

The experimental procedure is shown in Fig. 2. The usual positions of the sample holder are lengthwise (L) and crosswise $(C+$ or $C-)$. The figure is a view of the turntable as seen from above, thus illustrating the various positions of the sample. The component drawn in fat line in the figure is the component that is actually detected with the Kerr effect.

With the pure in-plane magnetization and the use of longitudinal effect, the luminous intensity after the analyzer[9] is of the form

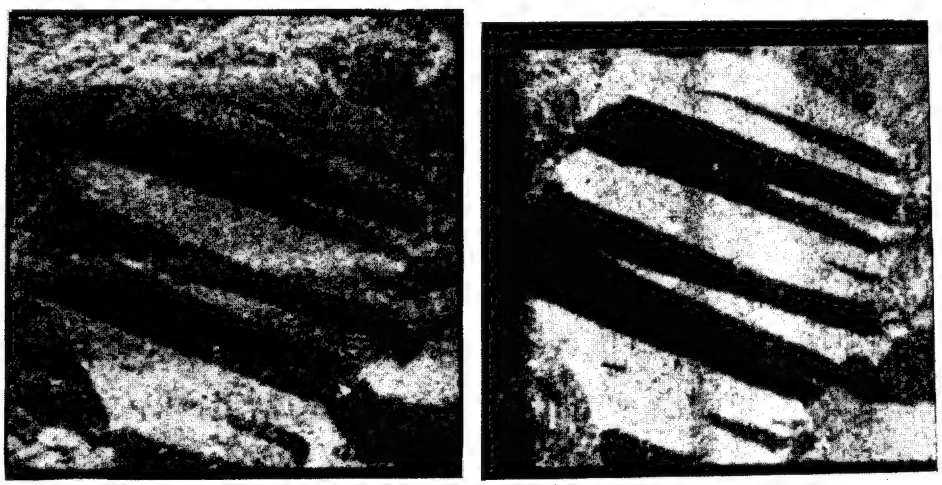
$$I=I_0+I_0Km+D, \tag{1}$$

where the three terms correspond to contributions due to:

(1) the nonmagnetic reflectivity of the metal,
(2) the magneto-optically generated light intensity, and
(3) a quadratic term of the magneto-optical effect, which can be neglected if polarizer and analyzer are uncrossed.

As the acquisition chain is linear, the grey level Δn evaluated in our difference images is proportional to the intensity I. Different orientations of the sample holder lead to the relations shown in Table I.

Let (L,C) be a base linked to the sheet's surface as shown in Fig. 3. L is parallel to the length of the sheet, and



position L position C+

FIG. 4. Positions L and $C+$, validation in a simple case.

FIG. 6. Example of complex domains analysis.

C to its width. Then let α be the angle between the direction of magnetization M- and the L-axis.

From the relations $1a-1c$ above, the equation

$$tg\ \alpha = \frac{m_c}{m_l} = \frac{\Delta n_{c+}}{\Delta n_l} = \frac{-\Delta n_{c-}}{\Delta n_l}, \tag{2}$$

follows immediately. Since both signs of the lengthwise and crosswise difference intensities are known, the vector **M** can be unambiguously put into the proper angular quadrant as shown in Fig. 3.

IV. PRACTICAL IMPLEMENTATION

We applied the following principles:

(1) Since the exact domain structure is nonrepetitive, there should be no variation in the excitation between the different shots of the images with magnetic data;
(2) Since the spatial correspondence of the images to be subtracted is fundamental, both the reference image and the image at a certain level of excitation should be acquired without rotating the turntable in the meantime.

Also, the spatial correspondence between two subtracted images L and C should be carefully treated. The rotation of the sample generates a rotation of the acquired image. The digital image rotation and a correction for residual translations via image processing software has proven to be the best way to cope with the problem.

Although the sampling frequency of the acquisition card was set to get square pixels and the rotation axis of the sample carefully controlled, it was not possible to treat the images pixel by pixel. Consequently, we chose the areas of homogeneous intensity where the magnetization direction was determined locally.

V. RESULTS OBTAINED

Our method to determine the magnetization vector has been validated on classical examples where the magnetization is well known, as shown in Figs. 4 and 5.

On regions with a certain disorientation, where the material develops complicated branching structures, the method can provide results which are impossible to derive with classical inductive approach based on domains theory. An example of such a structure is given in Fig. 6.

VI. CONCLUSION

The disadvantage of our approach is the necessity to rotate and align the two images by computer for further quantitative analysis, which slightly limits the resolution. The main advantage is that by using only the longitudinal Kerr effect the measured intensities do not have to be related to the saturated images, what is necessary when using both longitudinal and transverse effects.[4–6] As a matter of fact, the new method assures that the proportionality constants in the contrast transfer function (see Table I) are cancelled by taking the ratio of the signal from the two images L and C. Thus the parasite effects like the Faraday effect are avoided and no particular operational limitations are to be taken into account: the new method may be applied to any material, without prior requirements of magnetic saturability or partially known domain structure and without the limitations as to the sample form and size. It is a relatively rapid and memory sparing method that assumes better stability of measurements.

The energy loss per cycle in bar domain Si–Fe

Bryen E. Lorenz
Electrical Engineering Department, Widener University, Chester, Pennsylvania 19013

Theoretical investigations into the average energy loss per cycle of oriented, bar domain silicon–iron samples, has been typically carried out by treating the static hysteresis and eddy current losses separately. Since all losses ultimately are related to the motion of the domain walls in soft magnetic materials, this differentiation is at best artificial and at worst misleading. A simple model is proposed in this paper, based on the empirical properties of silicon iron, which when incorporated into the loss calculation yields results that predict the presence of both contributions to the total loss. In addition, the model places a limit on the frequency dependence of the domain widths (domain refinement). The implications of this constraint are investigated. © *1996 American Institute of Physics.* [S0021-8979(96)75808-5]

INTRODUCTION

The energy loss per cycle due to sinusoidal excitation of 180° domain walls in single crystal, oriented, 3%–4% silicon iron has been studied with the hope of understanding the fundamental loss mechanisms involved. By extension, these investigations should shed light on the properties of oriented, silicon iron transformer steels. (An excellent review of this area of research is contained in Ref. 1.)

From the experimental findings contained in the literature, it appears that two types of contributions are associated with the overall loss per cycle (at least for losses below ~100 Hz): the static hysteresis loss and the eddy current loss. The former loss is predominant below 1 Hz and is frequency independent, while the latter becomes prominent above 1 Hz and is linear in frequency. In the theoretical treatment of this behavior, researchers have sought to explain these contributions separately (since, at least on experimental grounds, this expedient seems justified) and then simply assume that these contributions can be added together. On the contrary, since these losses ultimately stem (for magnetization below saturation) from domain wall motion, both types of loss should be handled in a unified manner. The model proposed in this paper seeks to remedy this problem by incorporating the observed characteristics of oriented, silicon–iron material into the appropriate calculations for the energy loss per cycle.

MODEL

Figure 1 depicts a generalized static characteristic (i.e., where data are obtained under conditions of nearly constant applied field) which relates the domain wall velocity ($\dot{y}_0$) to the applied field (H). The literature contains many specific examples illustrating this relationship, most notably in the work carried out by Hellmiss and Storm.[2] By inspection of Fig. 1, one can see that if H_a, the amplitude of a given applied magnetic field, is less than some threshold field H_0, no domain wall motion is observed. Yet if $H_a > H_0$, $\dot{y}_0$ is linked to H_a, to the extent that it exceeds H_0, by the constant slope q. By extension, if one were to excite this system by a sinusoidal driving force of frequency f, then the resulting waveform of $\dot{y}_0$ as it evolves in time would appear as shown in Fig. 2. The output waveform ($\dot{y}_0$ vs t) can be analyzed by simple Fourier series techniques to yield the relation:

$$\dot{y}_0(t) = (2/\pi) q H_a \cos^{-1}(a)\cos(\omega t) + \left(\frac{4}{\pi}\right) q H_a \sum_{\substack{n=3 \\ n=\text{odd}}}^{\infty} \left(\frac{\sin((n+1)\cos^{-1} a)}{(n+1)} - \frac{a \sin(n \cos^{-1} a)}{n} \right) \cos(n\omega t), \quad (1)$$

where $a = H_0/H_a$, $\omega = 2\pi f$, and $a \leqslant 1$.

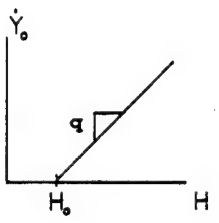

FIG. 1. Typical graph of the domain wall velocity ($\dot{y}_0$) vs the applied magnetic field (H).

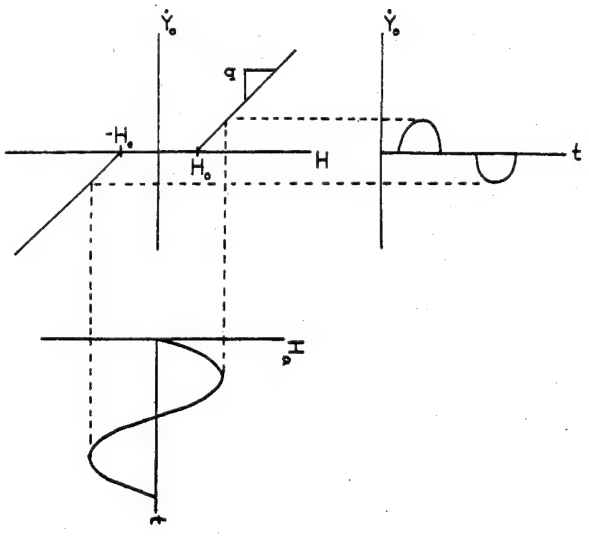

FIG. 2. Input waveform (i.e., H_a vs t) subject to the characteristic of Fig. 1 yielding a distorted output waveform (i.e., $\dot{y}_0$ vs t).

 0021-8979/96/79(8)/6039/3/$10.00

The average power loss per cycle ($\bar{p}$) can be calculated from the relation:

$$\bar{p}=\left(\frac{1}{T}\right)\int_0^T p(t)dt=\left(\frac{1}{T}\right)\int_0^T \beta(\dot{y}_0)^2\,dt, \tag{2}$$

where $\beta\dot{y}_0$ is the damping force and β is the damping coefficient. A further trivial refinement, used in the literature, is to convert these losses into the energy loss per cycle (ϵ) through the relation:

$$\bar{\epsilon}=\bar{p}/f. \tag{3}$$

However, before applying Eqs. (2) and (3) to Eq. (1) to determine $\bar{\epsilon}$, the maximum wall velocity can be described in either of two ways:

$$(\dot{y}_0)_{\max}=q(H_a-H_0), \tag{4}$$

where $H_a>H_0$, which was given in Fig. 1. Equally, one may describe the maximum wall velocity as

$$(\dot{y}_0)_{\max}=2\pi fL(B_m/B_s), \tag{5}$$

where $2L$ is the spacing between the static domain walls, B_m is the mean magnetic induction, and B_s is the saturation magnetic induction.[3] Although Eq. (5) assumes sinusoidal wall velocity and this disagrees to some extent with Eq. (4), we equate the maximum wall velocity and obtain:

$$H_a=(2\pi fL(B_m/B_s)+qH_0)/q. \tag{6a}$$

This result is suggested, if not implied, in Ref. 1:

$$H_0/H_a=qH_0/(2\pi fL(B_m/B_s)+qH_0), \tag{6b}$$

where $H_a>H_0$ and $B_m<B_s$.

Finally, using Eqs. (2), (3), and (6) in Eq. (1) yields

$$\bar{\epsilon}=(2/\pi^2)\beta[4\pi^2L^2(B_m/B_s)^2f+4\pi L(B_m/B_s)qH_0 +q^2H_0^2/f]\Bigg\{(\cos^{-1}a)^2 +4\sum_{\substack{n=3\\ n=\text{odd}}}^{\infty}\left(\frac{\sin((n+1)\cos^{-1}a)}{(n+1)} -\frac{a\sin(n\cos^{-1}a)}{n}\right)^2\Bigg\}. \tag{7}$$

From the expression given in Eq. (7), we note that as f becomes large, $\bar{\epsilon}$ takes on the form

$$\bar{\epsilon}_\infty=2\pi^2\beta L^2(B_m/B_s)^2f +2\pi\beta L(B_m/B_s)qH_0 \quad \text{limit } f\to\infty. \tag{8}$$

The first term in (7) is linear in f and in this regard resembles the Pry–Bean loss or the standard classical loss.[4] The latter term is constant in f and predicts the presence of a frequency independent contribution to the total loss. On the other hand, if f were to go to zero, the energy loss/cycle becomes

$$\bar{\epsilon}_0=(8/\pi)\beta L(B_m/B_s)qH_0 \quad \text{limit } f\to 0 \tag{9}$$

A graphical interpretation of Eqs. (7) and (8), for a small range of frequencies, is given in Fig. 3 in terms of the reduced loss, $\bar{\epsilon}/(2\beta/\pi^2)$ versus the frequency, f. The value for (B_m/B_s) and L were taken from Narita and Imamura to be 0.5 and 0.59 mm, respectively, while the product qH_0 was taken from the results of Hellmiss and Storm to be 1.22 mm/s.

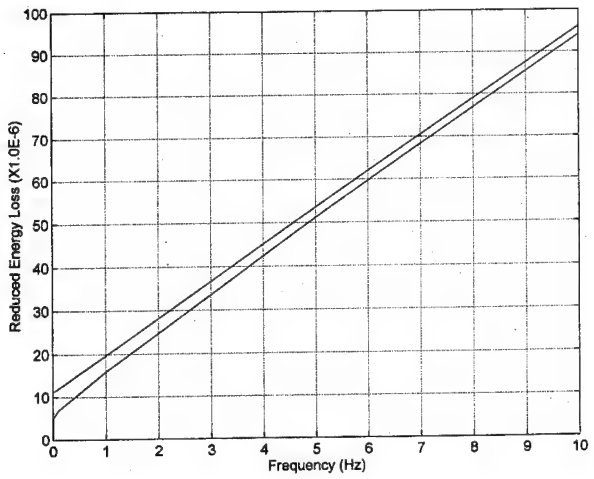

FIG. 3. Reduced energy loss per cycle vs magnetizing frequency. The upper line represents the linear asymptote ($\bar{\epsilon}_\infty$), while the lower curve represents the calculated values ($\bar{\epsilon}$).

At 1 Hz, the discrepancy between the curves, as pictured in Fig. 3, amounts to about 24% of $\bar{\epsilon}$ (the lower curve), while at 50 Hz, a typical power frequency, this difference (not shown in the figure) is slightly less than 1%.

DISCUSSION

In testing the predictions of the model versus experimental results, we note that in finding the static hysteresis loss, the standard laboratory practice is to extrapolate the approximate linear relationship observed at higher frequencies down to zero. The intercept of $\bar{\epsilon}_\infty$ at zero frequency is considered to be the static hysteresis loss.[3] From Eq. (8), this corresponds to an extrapolated energy loss:

$$\bar{\epsilon}_{\text{ext}}=2\pi\beta L(B_m/B_s)qH_0.$$

However, in the limit as f goes to zero, the actual loss according to Eq. (9) is

$$\bar{\epsilon}_0=(8/\pi)\beta L(B_m/B_s)qH_0.$$

Therefore, the ratio of the extrapolated to the predicted losses, far from being unity (i.e., exhibiting no difference), is $\pi^2/4$. This discrepancy was noted by Bishop[5] in comparing the experimental results of Narita and Imamura and the static hysteresis losses obtained by Hellmiss and Storm. (Both sets of researchers used single crystal, cube-on-side, 3%–4% Si–Fe samples.) Bishop comments that this difference amounts to roughly an order of magnitude.

From (8), the dependence of $\bar{\epsilon}_\infty$ on L comes about through a linear and squared term. However, it is well known that L changes discontinuously through a process of domain refinement with increasing excitation frequency, for instance as shown in the work of Shur and his co-workers,[6] through domain wall nucleation. (Recently reported findings by Kim,

et al.[7] indicate that this is also true in very thin, 33–35 μm, grain-oriented silicon steels.) Haller and Kramer[8] were able to show that domain widths varied, on average, approximately as $(1/\sqrt{f})$. However, if $L=rf^{-0.5}$, where r is some appropriately chosen constant, then the term in L^2 in Eq. (8) would be independent of frequency, while the remaining term would vanish as the frequency went to infinity. Saturation in total losses has not been observed experimentally. For this reason, it appears that domain refinement follows the relation, $L=rf^{-\alpha}$ where $0<\alpha<0.5$. If $\alpha=0$, no domain refinement would occur, while the condition $\alpha\geqslant 0.5$ is physically unrealizable.

Mohri and his fellow researchers,[9] working on samples of grain-oriented, 3% silicon–iron transformer steel, found such a relation where $\alpha=0.4$ and r were dependent upon a fixed power of B_m/B_s. More recently, in an article authored by Bishop and Pfützner,[10] reported results seem to indicate that r and α are both functions of B_m/B_s where α assumes a range of allowable values somewhere below 0.5 when domain wall bowing is not significant. The relationship between L and f could be rewritten as $L=L_0(f/f_0)^{-\alpha}$, where L_0 is the domain wall spacing in the demagnetized state and f_0 is on the order of 1 Hz.

CONCLUDING REMARKS

The approach, as presented here, allows one to generate both the eddy current loss (i.e., those losses linear in frequency) as well as the hysteresis loss (i.e., residual losses at low frequency) simultaneously from the physical (albeit ideal) properties of silicon iron. As a consequence, the relationship between these losses appear together in a natural way as given in Eq. (7). This model avoids the questionable practice of treating contributions separately and simply adding them together to find the total loss. In addition, the limit placed on the exponent in describing domain wall refinement is less than 0.5 (i.e., $\alpha<0.5$ for $L=rf^{-\alpha}$). This is based on the fact that the energy loss per cycle monotonically increases with excitation frequency.

Correlation between the Barkhausen noise power and the total power losses in 3% Si–Fe

M. Birsan and J. A. Szpunar
Metallurgical Engineering, McGill University, 3450 University Street, Montreal PQ H3A 2A7, Canada

T. W. Krause and D. L. Atherton
Queen's University, Kingston Ontario, Canada

We present results on Barkhausen noise power in grain oriented 3% Si–Fe samples of different quality (power losses). Barkhausen noise is measured at constant values of the magnetic field applied in the rolling direction of the sheet. The measurements indicate a strong correlation between the Barkhausen noise power and total power losses. A model is proposed to interpret the results according to which the Barkhausen noise power is related to the density of pinning centers per unit coercive field, an intrinsic parameter of the material. It is shown that this parameter characterizes the ability of the external field to increase the number of moving walls. The model and the experiment demonstrate that the power losses in grain oriented 3% Si–Fe are improved either by dynamic homogenization of magnetization, or by decreasing the domain wall spacing in static conditions. © *1996 American Institute of Physics.* [S0021-8979(96)75908-6]

INTRODUCTION

Grain oriented 3% Si–Fe steel sheets are engineered to minimize power losses arising from magnetic hysteresis and eddy currents during their cyclic magnetization along the rolling direction (RD). The magnetic anisotropy of these materials is associated with a crystallographic {110} ⟨001⟩ texture. The main domain structure consists of two types of domains whose magnetizations are parallel or antiparallel to the rolling direction. When the magnetic field is applied along the rolling direction, the whole magnetization process takes place exclusively by the displacement of domain walls. The most important origin of losses accompanying the magnetization of grain oriented steels is the eddy current. In a material containing many domain walls, the eddy currents are localized at the wall. To reduce eddy current losses accompanying the movement of the walls, these materials are manufactured so that they have a higher number of domain walls,[1] i.e., the magnetic flux is uniformly distributed over the sample. This is accomplished by a uniform domain structure, obtained using a domain refining technique (e.g., mechanical or laser scribing). As a result of domain refinement, the number of walls which move effectively under alternating field increases, and the velocity (eddy current loss) of an individual wall in a constant flux density decreases. We use this information to interpret the experimental data relating the domain wall spacing to the magnetic Barkhausen noise, and to power losses.

Statistical investigation of the microscopic processes contributing to the total power loss can be done through detection and analysis of the magnetic Barkhausen noise (MBN). In the present paper, a method based on the measurement of clustered Barkhausen transitions in grain oriented 3% Si–Fe is proposed and tested to investigate nondestructively the statistical correlation between the Barkhausen phenomenon and the total power losses. The method relates the MBN to power losses through a model based on domain wall displacement after they are released from pinning centers.

EXPERIMENTAL RESULTS AND DISCUSSION

Magnetic Barkhausen noise (MBN) measurements were performed using the instrument described in Ref. 2. Briefly, the apparatus consisted of a magnetic transducer, a magnetization generator, a preamplifier, and output equipment. The quantity measured in this experiment is the magnetic Barkhausen noise power, defined by the time integral of the squared voltage signal:

$$P_{\mathrm{MBN}}=\int_0^{\infty} V^2(t)dt=\frac{1}{2\pi}\int_0^{\infty} F(\omega)d\omega, \tag{1}$$

where $F(\omega)$ is the power spectrum.

The relationship between the irreversible change in magnetization produced by the sweep field H and the sample magnetic properties has been developed elsewhere.[3] For the case where the macroscopic induction rate is approximately constant for the investigated samples, the MBN power is described by the equation

$$P_{MBN}\propto f_0\,\frac{\langle\tan\gamma\rangle^2}{T}\,H^{1/2}, \tag{2}$$

where T is the thickness of the sample, γ is the angle between the magnetic dipole moment and the direction of the magnetizing field, and f_0 has the dimension of a density of pinning centers per unit critical field, dH_0, which is an intrinsic parameter of material.[4]

The samples used in the present investigation were grain oriented 3% Si–Fe laminates of different quality (power losses) having thicknesses of either 9 mil (≈0.22 mm) or 7 mil (≈0.17 mm). For the quantitative description of material texture, the (110), (200), and (211) pole figures were obtained for each specimen using the x-ray technique (Schulz's reflection method). The material texture was represented using the orientation distribution function (ODF), obtained following the pole figure inversion.[5]

Magnetic measurements were conducted using the conventional Epstein test. The samples were classified as a function of the value of power losses and identified using a combination of numbers and letters. For the materials of the same

Sample	S-9A	S-9B	S-9C	S-9D	S-9E	S-7A	S-7B	S-7C
Losses [W/lb] at 1.5 T	0.376	0.404	0.408	0.432	0.438	0.362	0.369	0.390
Losses [W/lb] at 1.7 T	0.551	0.603	0.621	0.652	0.666	0.543	0.572	0.591
$\langle \sin \gamma \rangle$	0.14	0.07	0.19	0.09	0.11	0.09	0.14	0.07

thickness, 9 mil, the letters *A* to *E* indicate the quality of the sample. Power loss increases continuously from sample S-9A through to sample S-9E. The materials with thickness of 7 mil are represented by three specimens of different quality (power losses), identified as *A*, *B*, and *C*, respectively. The values of power losses measured for different samples are listed in Table I.

The results obtained from the MBN experiments performed on these 3% Si–Fe samples are presented in Figs. 1(a) (9 mil samples) and 1(b) (7 mil samples). From these graphs, one can see that the relationship (2) is strongly supported by the experimental data.

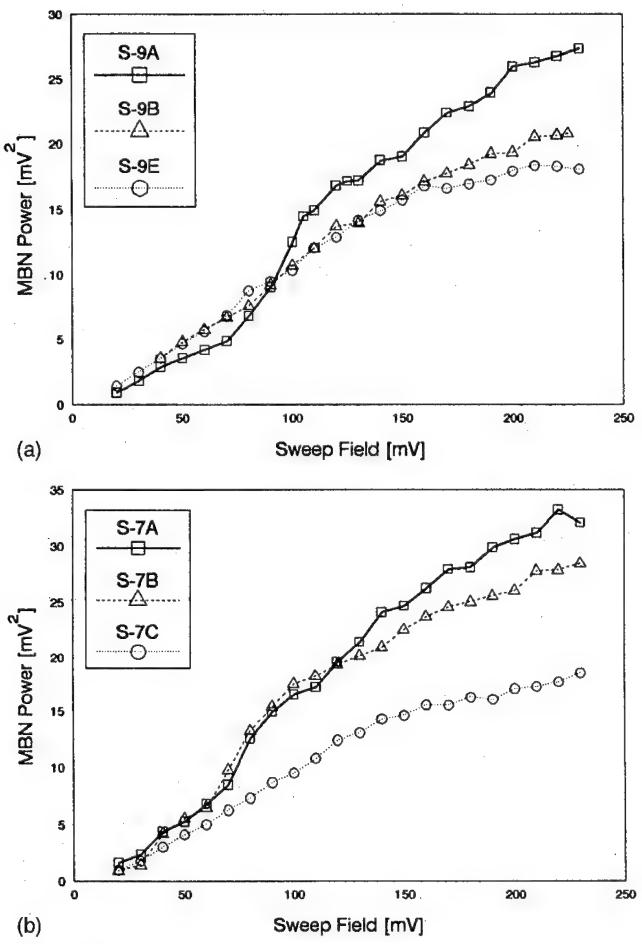

FIG. 1. MBN power versus sweep field in (a) 9 mil samples, and (b) 7 mil samples.

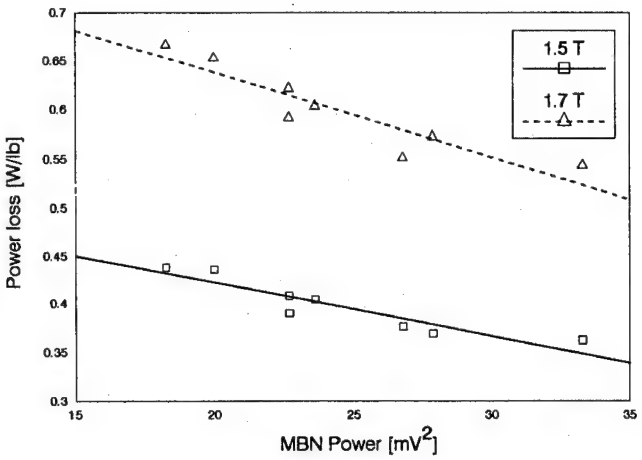

FIG. 2. MBN power versus total power losses in grain oriented silicon steels.

For the samples investigated, the power losses presented in Table I are inversely proportional to the MBN power. The regression of MBN power as a function of power losses is shown in Fig. 2. This graph clearly indicates a correlation between the power loss and the measured Barkhausen noise power, which is explained using Eq. (2). In this expression, there are two terms related to material structure which are analyzed: $\langle \tan \gamma \rangle^2$ is a texture parameter, and f_0 is a structural parameter characterizing the material.

The texture parameter is calculated using the averaging over the grain orientation distribution function.[5] If the grain orientation in the sample reference frame is represented by the three Euler angles $(\varphi_1, \phi, \varphi_2)$ and the grain orientation distribution function $f(g)=f(\varphi_1, \phi, \varphi_2)$ is known, the average value of $\tan \gamma \approx \sin \gamma$ (for small values of angle γ), is given by

$$\langle \sin \gamma \rangle = \frac{1}{8\pi^2} \oint \sin \gamma(g) f(\varphi_1 . \phi, \varphi_2) \sin \phi \, d\varphi_1 \, d\phi \, d\varphi_2, \tag{3}$$

where

$$\sin \gamma(g) = \cos \phi. \tag{4}$$

For the analyzed samples, the values of $\langle \sin \gamma \rangle \approx \langle \cos \phi \rangle$ calculated using Eq. (2) are presented in Table I.

It was demonstrated[6] that, in a single crystal of silicon iron, there is an inverse proportionality between the domain wall spacing d measured in static conditions, and the out-of-plane angle of $\langle 100 \rangle$ easy magnetization direction. Generalizing this relationship to a polycrystalline material, one could write that the average domain wall spacing is

$$\langle d \rangle \propto \frac{\sqrt{T}}{I_s \langle \sin \gamma \rangle}. \tag{5}$$

where T is the sample thickness, and $\langle \sin \gamma \rangle$ is calculated using Eq. (3). The highest value of $\langle \sin \gamma \rangle$ means a lower value of domain wall spacing, or, equivalently, a lower value of eddy current loss.[1] Calculating the domain wall spacing with Eq. (5), we found that there not exists a proportionality

between the calculated values and the values of power losses, which implies that the domain wall spacing is not the only parameter involved in the loss problem.

The other structural parameter in Eq. (2) is f_0. The higher value of f_0 is equivalent to a higher number of walls contributing to magnetization when the magnetic field increases from H to $(H+dH)$, because the number of moving walls is proportional to $f_0 \cdot dH$. As a result, the magnetization process is more homogeneous in dynamic conditions.

According to the proposed model, the MBN power depends on the product $f_0 \cdot \langle \sin \gamma \rangle^2$. Both parameters contribute to the increase in the active domain wall population. In conclusion, the magnetization process is more homogeneous in samples where the value of the product $f_0 \cdot \langle \sin \gamma \rangle^2$ is higher and, as a result, the corresponding eddy current loss is significantly decreased.

HOMOGENIZATION OF THE MAGNETIZATION PROCESS

In a series of articles,[7–10] Bertotti found that the number of active domain walls in several iron-based alloys, including grain oriented silicon steels, obeys the linear law:

$$\tilde{n} = n_0 + \frac{H_{\text{exc}}}{V_0}, \tag{6}$$

where n_0 is the number of moving walls when the magnetizing frequency $f_m \to 0$, H_{exc} is a fictional field acting on each domain wall and the field V_0 is controlled by the material microstructure.

To move on isolated wall, we must apply a field higher than the coercive field:

$$H = H_c + \Delta H = H_0 + H_{\text{exc}}, \tag{7}$$

where ΔH represents the excess field required to balance the opposite field produced by eddy currents surrounding the moving wall. Generalizing the above relation to the whole sample, the number of walls which move when the external field is increased with $\Delta H = H_{\text{exc}}$ is

$$\tilde{n} = f_0 H_{\text{exc}} = \frac{H_{\text{exc}}}{1/f_0} = \frac{H_{\text{exc}}}{V_0} \tag{8}$$

and the excess field acting on a single domain wall is decreased accordingly. In this way, the characteristic field V_0 is related to a microstructural parameter, $1/f_0$, which represents the critical field per unit pinning center in the interval from H_0 to $(H_0 + \Delta H_0)$.

According to the previous discussion [see Eq. (2)], the characteristic field V_0 is expected to contain also the texture parameter $\langle \sin \gamma \rangle^2$, so that it has the form

$$V_0 \propto \frac{1}{f_0 \langle \sin \gamma \rangle^2 T}. \tag{9}$$

Bertotti's experimental results[9] prove that V_0 decreases with increasing sample cross section (T increases), decreasing grain size (f_0 increases), and decreasing degree of magnetic orientation ($\sin \gamma$ increases); no analytical relationship between the characteristic field and these microstructural parameters was suggested.

CONCLUSIONS

It was found that, in grain oriented 3% Si–Fe, there is an inverse proportionality between the MBN power and the total power loss. A nondestructive method was developed to study the effects of texture and microstructure on the magnetic Barkhausen noise (MBN), and also on the total power losses. The method relates the MBN power to the core loss through a model based on domain walls displacement after they are released from pinning centers. The parameter controlling this process is the characteristic field V_0. Even if we are not able to calculate the value of this parameter using the information related to the material structure, it can be directly evaluated from the magnetic Barkhausen noise (MBN) measurements. The basic result of this study is that the lower power losses in grain oriented materials are obtained in samples where the distribution of the magnetic flux is more homogeneous.

Using the MBN measurements, the power losses of different grain oriented silicon steels could be readily compared. Quantitative measurements of power losses are also possible if the instrument is calibrated using the specimens with known values of the power losses.

Temperature changes during mechanical processing such as grinding of steel parts can cause phase changes in the microstructure. Thermal shock during the process can give rise to localized surface residual stress. The net result can be reduced wear resistance and fatigue life leading to early failure during service. Effective methods for the detection of such damage are necessary. Barkhausen emissions, which arise from discontinuous motion of domain walls, are sensitive to microstructual changes that affect domain dynamics. Detected Barkhausen signals are predominantly from a surface layer about 200 μm thick, those from deeper being attenuated due to eddy currents. An analysis of the detected signals can provide an indication of the surface condition of the material. Barkhausen signals from parts ground under controlled conditions were found to be dependent on the grinding process conditions. The signal changes were consistent with residual stress measured by x-ray diffraction and with hardness measurements that are indicative of changes in microstructure. © *1996 American Institute of Physics.* [S0021-8979(96)76008-0]

I. INTRODUCTION

Surface microstructure plays an important role in determining the mechanical properties of materials.[1] Improper manufacturing process conditions for structural components can adversely affect the microstructure and residual stresses in the material and lead to early fatigue failure.

Barkhausen emissions in steels arise from discontinuous changes in the magnetization and are predominantly the result of spontaneous motion of domain walls in the presence of a changing magnetic field.[2] The Barkhausen emissions, typically detected as voltage pulses in a field coil, appear as a burst of pulses localized in time regions where the magnetization in the material changes polarity as seen in Fig. 1. The signal is influenced by stress, which changes the differential permeability of the material and hence the height of the detected signal, and by microstructure, which determines the defect density in the material and hence the overall shape of the emissions.[3,4] The sensitivity of this technique can also be adjusted to different depths in the material since the higher frequency components of the emissions from deeper inside the material are selectively attenuated due to eddy currents before being detected at the surface.[4]

Grinding involves the removal of material from the surface of a part for the purpose of attaining dimensional tolerance and surface conditioning. A significant portion of the energy used in removing the material results in localized heating.[5] An abnormal rise in temperature during the process can result in detrimental metallurgical phases in the surface microstructure, and the thermal and mechanical shock from the process can introduce localized surface stress.[6]

Damage from improper grinding procedures can arise from several conditions including reduced coolant flow, and is broadly classified by the rise in temperature. Retempering damage occurs when the temperature of the part rises high enough to relieve some of the compressive surface stress, previously introduced by induction hardening for example, leaving regions less resistant to wear. At significantly higher temperatures, rehardening damage occurs which results in a phase change from ferrite to austenite. On quenching by the cooling fluid this produces regions of martensite, a hard and brittle phase, which is prone to cracking.[6] Effective methods are necessary for the detection of such metallurgical changes in the material.

II. EXPERIMENTAL DETAILS

Automobile wheel bearing components were ground to required dimensional specifications under progressively reduced coolant flow rate (normal flow rate, half, quarter and no coolant) in order to induce different degrees of grinding damage in the surface. Barkhausen measurements were conducted on these components using the Magneprobe.[7] Other measurements using x-ray diffraction, for the determination of the absolute stress level, and Vickers surface microhardness, for the estimation of surface mcirostructure, were conducted on similarly ground components, and correlated with the Barkhausen measurements. Barkhausen signal was detected from regions where most damage was expected using a customized magnetic sensor. Discrimination frequencies for depth were set for maximum sensitivity to physical changes in a region approximately 20 μm thick.[8]

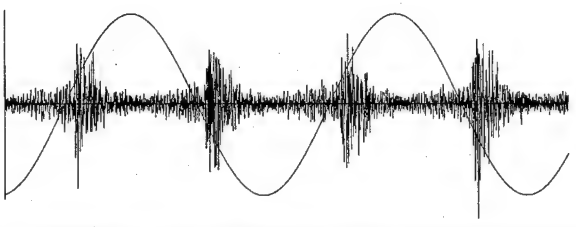

FIG. 1. Magnetizing signal and Barkhausen emissions as a function of time.

 0021-8979/96/79(8)/6045/2/$10.00

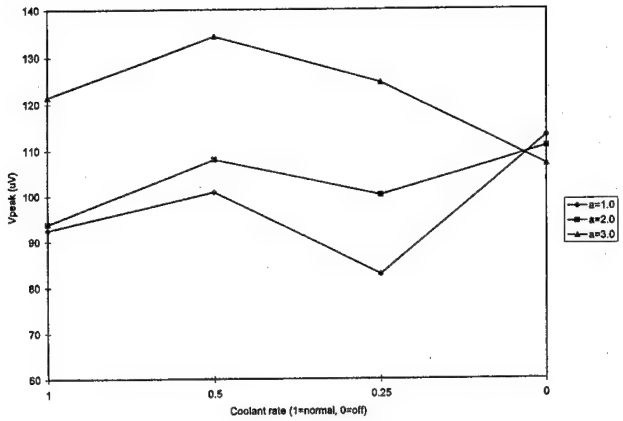

FIG. 2. Change in peak value of smoothed Barkhausen signal from variously ground specimens at different magnetizing amplitudes.

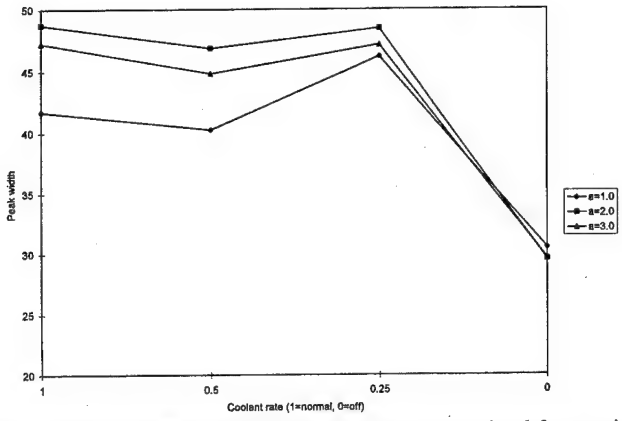

FIG. 3. Change in peak widths of smoothed Barkhausen signal from variously ground specimen at different magnetizing amplitudes.

III. RESULTS AND DISCUSSION

The change in the peak amplitude of the smoothed signal envelope and the width of the peak, (determined simply as the ratio of the envelope area to the peak height) for specimens that had undergone progressively greater surface damage are shown in Figs. 2 and 3. The peak amplitude is an indicator of the local residual stress, since tensile stress in materials with positive differential magnetostriction $d\lambda/dM$ increases the maximum differential permeability and hence the amplitudes of the Barkhausen signal. The peak width on the other hand is an indicator of the distribution and strength of sites pinning the domains walls. The observed decrease in the peak widths is an indication of the altered microstucture. These trends were verified by x-ray measurements of the surface residual stress and the surface hardness for similarly treated specimens.

IV. CONCLUSION

The Barkhausen technique has been shown to be a viable method for assessing residual stress and microstructural phase changes in steel components and the detection of unfavorable surface conditions. Residual stress, measured by x-ray diffraction, and changes in microstructure, estimated by hardness measurements, verified the measured changes in Barkhausen signals.

Simultaneous Barkhausen discontinuities of multiple die-drawn Fe-Si-B amorphous wires connected with amorphous ribbons (abstract)

M. Soeda and J. Yamasaki
Department of Electrical Engineering, Kyushu Institute of Technology, Tobata, Kitakyushu 804, Japan

In-rotating water quenched Fe-Si-B amorphous wire exhibits the Barkhausen discontinuities (BD) in the as-cast state. Its minimum length to exhibit the BD depends on the demagnetizing effect. The minimum length is around 9 cm for the as-cast wire with 120 μm diameter. For sensor application of the wire as a pulse voltage generator, small size sensor elements are needed. Die-drawn wires with reduced diameter and minimum length of up to 2 cm exhibit BD1 and are expected for such use. But the pulse voltage induced in the sense coil by the BD decreases because of decreased volume of the wire. In this study, an attempt was made successfully to develop a small size BD sensor element with higher pulse voltage using multiple $Fe_{77.5}Si_{7.5}B_{15}$ die-drawn wires having 30 μm diameter and 4 cm long. Three die-drawn wires were put together closely in parallel and two pieces of $Co_{74.26}Fe_{4.74}Si_{2.1}B_{18.9}$ amorphous ribbon (5 mm$\times$2 mm$\times$25 μm) were attached to the wire ends. It was found that the BD of the three wires occur simultaneously at the same threshold field. Domain change of ribbon before and after the BD was observed with a Kerr microscope. It was found that the amorphous ribbons were magnetized by the stray field from the ends of the wires in the direction opposite to the magnetization of the wire and that the magnetization of the ribbon changes discontinuously synchronizing with the magnetization of the wire. So it is likely that the magnetizations of the multiple wires and ribbon form stabilized flux closure and that the simultaneous BD of multiple wires is triggered by the flux jump of the wire having the lowest threshold field. The influence of domain activities on MR head performance

Weichun Ye
Magnetics Technology Centre, National University of Singapore, Singapore 0511

Jinyue Yu and Bingchu Cai
Information Storage Research Center, Shanghai Jiao Tong University, 200030, People's Republic of China

The relation of signal distortion of MR heads to the domain structure and the domain activities was studied in this paper. Several kinds of MR elements were fabricated and a measurement system was set up to measure magnetoresistivity. A large drop near the peak of the output wave form was found for some MR elements. And the magnetic structure of the MR element was investigated by the "Bitter pattern." It was seen that there existed multidomain in the part of the lead without gold coating. Furthermore, it was also found that the multidomain existed in the junction of leads and the MR element, and the new domain looked like a hook. The appearance of this hook-shaped multidomain has not been reported up to now in literature. The design of the MR element was modified to eliminate the drop in the output wave form and the drop was reduced substantially. Our study shows that suitable geometric dimensions and structures of leads are also very important to high performance of MR head in head design in addition to select the optimum biasing conditions.
 [S0021-8979(96)76108-7]

I. INTRODUCTION

The read/write head is a key component in computer disk drives. Due to increasing demands for lower cost and smaller diameter disk drives, large volumes of lower cost heads with high reliability and high areal density, suitable for products even at smaller linear speed between head and media, are required. MR head offers potentially the highest areal density for disk drives and tape recorders. The read back signal of a MR head is velocity independent and is large even for the smaller diameter disk drives. However, the signal response of MR heads is puzzled by the Barkhausen noise which originates from irreversible processes of buckling domains.[1,2] Many studies including longitudinal biasing for suppressing Barkhausen noise have been reported.[3,4] In this paper we studied the relation of signal distortion of MR head to domain structure and the domain activities which appear in some part of leads and in the junction of leads and MR active regions.

II. EXPERIMENTAL SETUP AND MEASUREMENT

The 81%–19% Ni/Fe permalloy film with 400 Å thickness and 3–4 μm height was sputtered onto substrate (glass or ferrite) and patterned to MR element with the easy-axis along the longitudinal direction. The reason of putting Ni/Fe film on ferrite substrate was that the ferrite substrate was patterned as a part of shield. As shown in Fig. 1, leads were deposited to the center of the MR element for electrical contacts. Regions I and II were two parts of a lead. The shadowed region I was coated with gold while region II was not. In that case, the Ni/Fe film in region II actually became a part of the MR element.

The measurement system in Fig. 2 was set up by ourselves to measure magnetoresistance. The solenoid was activated by an alternating signal of 50 Hz. There is a uniform magnetic field inside the solenoid which strength ranges between +400 and −400 Oe by changing the activating signal. The MR sample to be measured was placed in this uniform magnetic field of which direction was parallel to the hard axis of the MR bar. A noninductive heater was used to keep the temperature of MR element above the Curie temperature

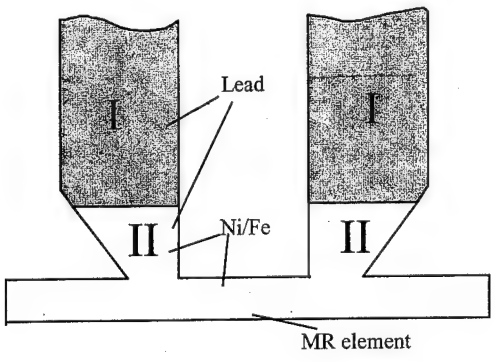

FIG. 1. Original MR element with two deposited leads, each of which consists of two regions, region I—with gold coating and region II—without gold coating.

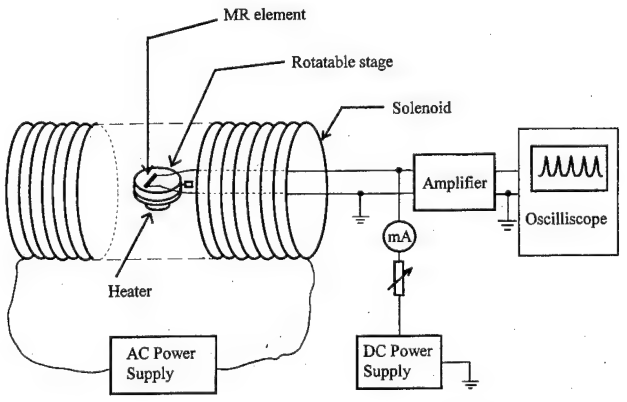

FIG. 2. Measurement system used to measure magnetoresistance.

 0021-8979/96/79(8)/6048/3/$10.00

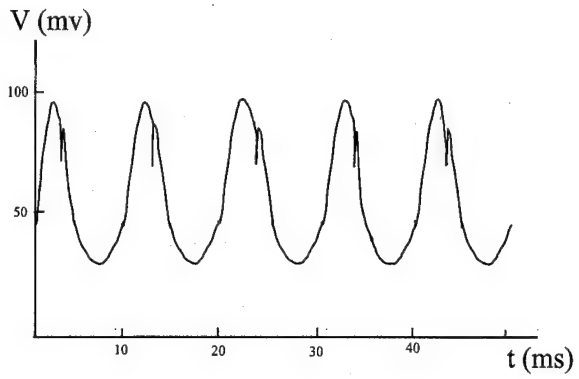

FIG. 3. Output wave form from original MR element.

of ferrite substrate. The ac output signal derived from the MR element could be obtained from an oscilloscope.

III. RESULTS AND DISCUSSION

Both biased and unbiased Ni/Fe films were studied in our experiments. For simplicity, only output wave forms from unbiased elements were shown as examples in this paper. The frequency of output signals for unbiased film was twice as of the stimulating ac field. In Fig. 3, it could be seen that there existed a large drop near the peak of the output wave form. Obviously, the drop was harmful to the read back signal detection, no matter which type of data detection was adopted, either peak detection or PRML detection. The drop degraded the output signal. The magnetic structure of the MR element under different magnetic field strengths was investigated by "Bitter pattern." The MR element was first covered by a thin layer of ferrofluid, then by a thin layer of glass. The particles of Fe_3O_4 were under the influence of the stray fields of magnetic domain walls. Therefore the pattern observed by optical microscope reflects the domain structure. These domain structure patterns were thereafter depicted manually due to equipment limitations.

It was shown in Fig. 4 that there existed multidomain in region II of the lead without gold coating when the field strength was less than 5–6 Oe. The domain structure would

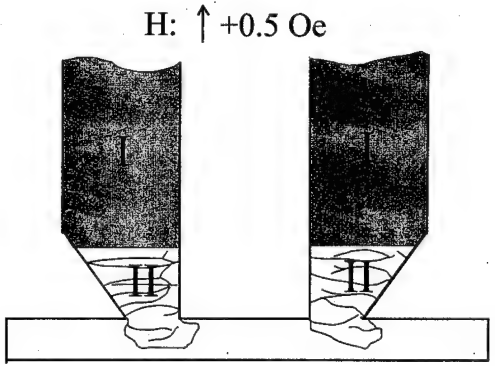

FIG. 4. Magnetic structure showing the existence of multidomain in lead region without gold coating and hook-shaped domain in the junction of lead and MR element.

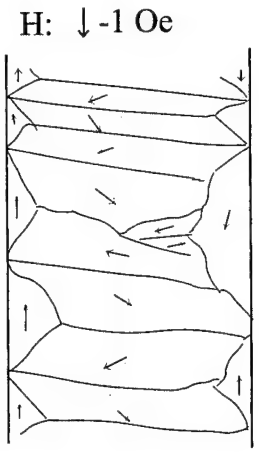

FIG. 5. Multidomain structure in the lead when magnetic field strength $H=-1$ Oe.

change with various field strengths. When the magnetic field strength decreased from the saturation value to about 6 Oe, the multidomain began to appear. As the strength continued to decrease, the domain wall density increased as depicted in Fig. 5. When the field strength decreased to zero and began to increase in the opposite direction, the upward closure domains gradually shrank and disappeared finally, whereas the downward closure domains appeared and grew (Fig. 6). The arrow direction in Figs. 5 and 6 indicates whether its domain is an upward closure domain or a downward one. If the magnetic field strength in opposite direction became more than 6 Oe, the domain walls disappeared and the multidomain state returned to single domain state. The existence of multidomain in region II of the lead in weak magnetic field explains the drop found near the peak of output wave form in Fig. 3.

Furthermore, it was found that the multidomain structure in the leads usually spread into the active region of MR element and the new domain looked like a hook. When the external magnetic field was along the positive direction, the magnetization direction was at the elevation angle. As the positive external magnetic field decreased to zero and thereafter increased in the opposite direction, the magnetization

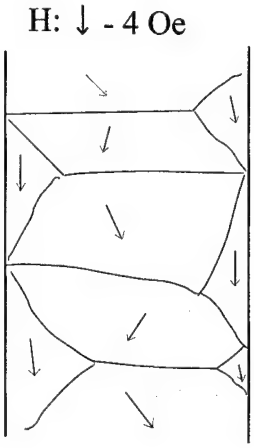

FIG. 6. Multidomain structure in the lead when magnetic field strength $H=-4$ Oe.

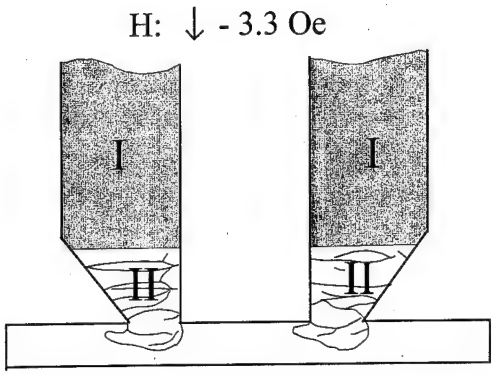

FIG. 7. Magnetic structure change of the "hook-shaped" domain when magnetic field strength $H=-3.3$ Oe, as opposed to its structure in Fig. 4.

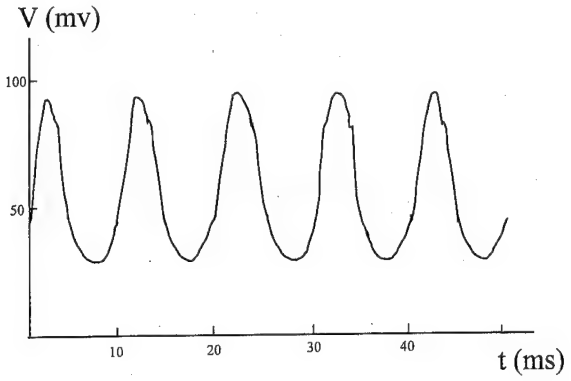

FIG. 9. Output wave form of the improved MR element, in which drops near the peak are substantially reduced.

direction rotated from the elevation angle to depression angle direction and the shape of the domains varied in such a mode that its stretch direction also changed from elevation to depression direction and the direction of the hooks transited from right to left abruptly as in Fig. 7. This phenomenon also leads to the drop found near the peak of output wave form. The appearance of hook-shaped domains has not been reported in any literature yet.

Obviously, the motion of domain walls and the generation of new domains caused Barkhausen noise. The design of MR element was modified, as shown in Fig. 8, in order to eliminate the drop. The region II was also coated with gold as region I. It was discovered that the drop was reduced substantially and the wave form of output signal was improved for this modified MR element (Fig. 9).

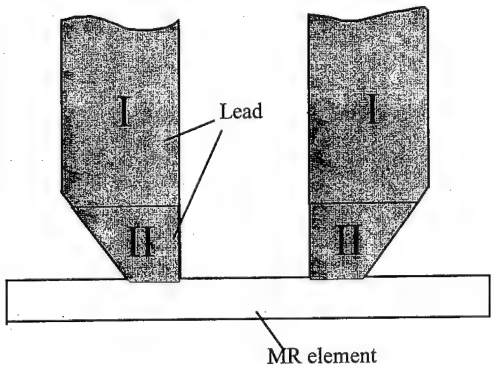

FIG. 8. Improved MR element structure, where two deposited leads are coated entirely and uniformly with gold.

It is one of the explanations that the gold coating shunted current in the Ni/Fe permalloy layer of the leads. Therefore, it reduced the distortion of output signals caused by the multidomain in the Ni/Fe layer.

This observation shows that the multidomains in region II of leads and the hooked domain structure appeared in the junction of leads and MR active regions are related to MR element geometry and structure. The motion and merge of domain walls as well as the generation of new domains cause the noise and the drop of output signals.

IV. CONCLUSION

The relation of signal distortion of MR heads to domain structure and the domain activities which appeared in part of leads and in the junction of the leads and MR active regions was studied in detail. It was shown that there existed multidomain in some region of leads and in the junction of leads and MR active regions for some MR elements. The motion and merge of domain walls as well as the production of new domains cause the noise and the drop of output signal. Suitable geometric dimensions and structure of an MR element are also very important to its high performance in the head design in addition to select the optimum biasing condition.

Iron whisker domain patterns imaged by garnet films

J.-G. Lee, S. A. Govorkov, and A. S. Arrott
Simon Fraser University, Burnaby, British Columbia V5A 1S6, Canada

Bismuth doped yttrium iron garnet thin films formed on the surfaces of a gadolinium gallium garnet substrate are used as magneto-optical indicators for quantitative studies of the micromagnetics of an iron whisker. The method does not require image processing. A field applied perpendicular to the whisker axis splits a 180° domain wall into two 90° sections slightly separated by a section magnetized in the direction of the perpendicular field. A field along the axis of the whisker has a similar effect. Where the region between the two split 90° sections intersect the surface, there is a magnetic charge that strongly affects the domain pattern of the indicator film. More generally, domain walls become visible because the local internal susceptibility is greater at the walls than in the domains. The magneto-optical indicator can be used to measure both susceptibilities. © *1996 American Institute of Physics.* [S0021-8979(96)76208-3]

I. INTRODUCTION

Thin films of garnets are useful as magneto-optical indicators.[1] Though they were first used for studying magnetic materials, it is the development of films for studying high temperature superconductors that led us to use domain patterns in garnet films to study the micromagnetics of an iron whisker with current flowing along its axis.[2] The iron whisker is placed on the garnet film as shown in Fig. 1 and viewed between almost crossed polarizers using an optical microscope. An explanation is given for why a 180° wall is visible this way.

The indicator film is a Bi doped yttrium iron garnet formed on the surfaces of a gadolinium gallium garnet substrate of high perfection, flat and smooth on the scale of optical wavelengths.[3] The film is on both sides of the substrate, but because the substrate is 230 μm thick, only one surface is in focus at a time. The indicator films are several microns thick. Below a characteristic field $H_c \sim 120$ Oe the films exhibit stripe domains and, sometimes, bubbles. The field at the end of a stripe domain depends on whether the applied field is increasing or decreasing. A fully quantitative use of the technique should include calibration of the hysteresis of the films.

The finger pattern seen in Fig. 2 is from the film adjacent to the whisker. There is an applied field $H_p \sim 35$ Oe perpendicular to the film. As shown below, this results in a total field at the film which is ~55 Oe and uniform over most of the surface. The field exceeds 120 Oe at the edges of the whisker (see Sec. II) and in the center at the position of the 180° wall (see Sec. III). The spacing and width of the fringes changes with perpendicular field.[4] There was no applied field H_0 parallel to the axis nor is there a current in the whisker for Fig. 2. That the fields are large at the edges follows from the magnetostatics of an ideally soft ferromagnetic material, which is a good approximation for the iron whisker.[5] The large field above the 180° domain wall is the result of H_p separating that wall into two 90° sections joined by a section magnetized in the direction of H_p.

Observations and explanations of some effects of H_0 and a current in the whisker are given briefly in Secs. IV–VI.

II. EXTERNAL FIELDS IN RESPONSE TO A PERPENDICULAR FIELD

In a perpendicular field H_p the charges on the surface of an ideally soft ferromagnetic material can be calculated using the Ritz method where a suitable functional form of the charge distribution is assumed. The parameters are adjusted to produce a uniform field in the whisker that precisely cancels the applied field. For a whisker with square cross section and area d^2, the charges on the top surface are approximated by the function $M_y(x)$ and the charges on the side surfaces are approximated by the function $M_x(y)$. These functions are shown in Fig. 3(a) along with the fields from the charges, $H'_y(x,y)$ and $H'_x(x,y)$, calculated for the planes just outside the top surface for $y=1.02d, 1.04d$, and $1.06d$. In the center of the surface, the external susceptibility, $1/\chi_{\text{ext}} \sim 0.55\times 4\pi$, was calculated assuming that the local internal susceptibility is infinite. More properly, $1/\chi_{\text{ext}} \sim 1/\chi_i + (0.55\times 4\pi)$, where $\chi_i = M_s/H_k$, which is 3, changing χ_{ext} by one part in $3\times 0.55 \times 4\pi = 20$. The present experiment is not quantitative enough to measure the effect of the anisotropy field H_k in the presence of the dominant demagnetizing fields.

For the whisker shown in Fig. 2 $d=320$ μm. This is a rather fat whisker, but not quite fat enough to favor more than one 180° wall. Its length is $L=6$ mm. There is a one

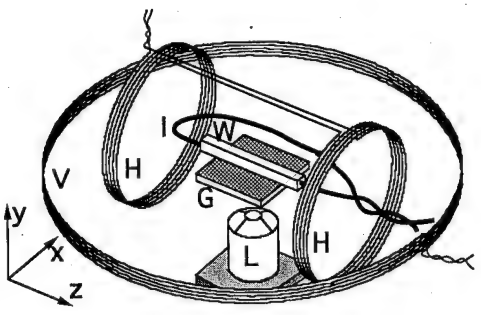

FIG. 1. Perspective sketch of an iron whisker W placed on a garnet magneto-optical indicator G viewed between crossed polarizers using an optical microscope represented by the objective lens L. There are three magnetic fields: H_0, from a Helmholtz pair H to magnetize the whisker along its axis; H_p, from a coil V to bias the indicator; and H_I, from the current I along the whisker axis. The coordinate system used here is indicated.

 0021-8979/96/79(8)/6051/3/$10.00

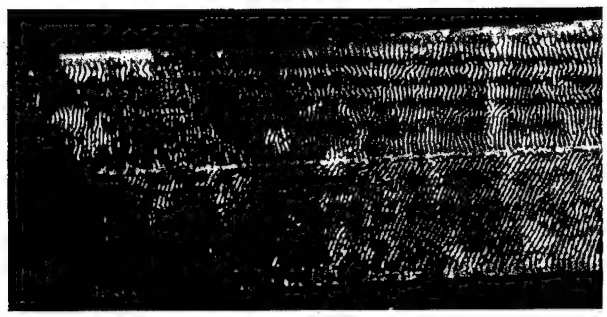

FIG. 2. The striped domain patterns in the garnet film indicate where the fields from the 320 μm wide iron whisker are less than 120 Oe. The application of H_p=35 Oe results in a total field at the film of ~55 Oe, uniform over most of the surface, except at the edges of the whisker and at the position of the 180° wall where it is greater than 120 Oe. The horizontal bands of light and dark background are optical interference fringes.

degree inclination of the indicator film with respect to the whisker surface. This tilt accounts for the optical fringes seen running almost parallel to the edges of the whisker. The surface of the whisker is partially oxidized, but this has negligible effects on the response of either the whisker or the indicator film.

III. EXTERNAL FIELDS AT A 180° WALL IN A PERPENDICULAR FIELD

The calculation in Sec. II does not account for the visibility of the 180° wall running along the middle of the whisker. In a bulk material with cubic anisotropy a 180° wall is really two 90° walls held together by magnetoelastic forces. Magnetoelastic forces are very long range and depend on the boundary conditions. For the whisker one can make the approximation that the strains, which are different for each of the three cubic axes, are nevertheless uniform. In an internal field greater than $H_{m\text{-el}}$ (for iron $H_{m\text{-el}}$=0.6 Oe) the wall will split into two 90° sections separated by a region magnetized in the direction of H_p; that is, the local internal susceptibility at the wall goes through infinity to negative values if the magnetization in the center of the wall was already along H_p. The degree of splitting is determined by the magnetic energy of the surface charges generated at the two surfaces in the process. The separation, t, of the walls, controlled mainly by the magnetostatic energy, is given by

$$H_p = H_{m\text{-el}} + \frac{4tM_s}{d_y}\left(\log\frac{d_y}{t} + 1\right), \tag{1}$$

where d_y is the thickness of the whisker in the direction of the perpendicular field H_p. This relation is shown in Fig. 4 for d_y=320 μm. The separation of the two sets of finger patterns in the garnet indicator is given by the positions where the total perpendicular field is equal to the critical field H_c. This occurs at $\pm x_c$. The separation is $2x_c$ given by

$$2x_c = 2\sqrt{\frac{2stM_s}{H_c - 1.55H_p} - s^2}, \tag{2}$$

where s is the vertical distance from the charge at the surface of the whisker to the film. The factor 1.55 multiplying H_p comes from the fields produced by the charges on the entire surface of the whisker; see Fig. 3(a). As H_p approaches H_c/1.55=77 Oe, the separation of the finger patterns diverges. Equations (1) and (2) can be used to calculate the dependence of the observed separation, $2x_c$, on t (or H_p) for a given s. This is shown in Fig. 4. It takes a separation of the walls by a few hundreds of nanometers to produce a separation of the finger patterns by tens of microns. An applied field of 35 Oe gives a splitting of the wall by about 0.2 μm which for s=6 μm produces an additional 115 Oe at the indicator film just above the wall.

IV. EXTERNAL FIELDS IN RESPONSE TO A PARALLEL FIELD

There are large fields $H'_\perp$ perpendicular to the surface caused by the magnetic surface charges σ that give rise to the demagnetizing field that all but cancels H_0 in this magnetically soft material. The charges are proportional to H_0 and depend on z, the distance along the axis from the center of the whisker. These fields can be assessed from calculations of demagnetizing effects in ideally soft magnetic materials.[6]

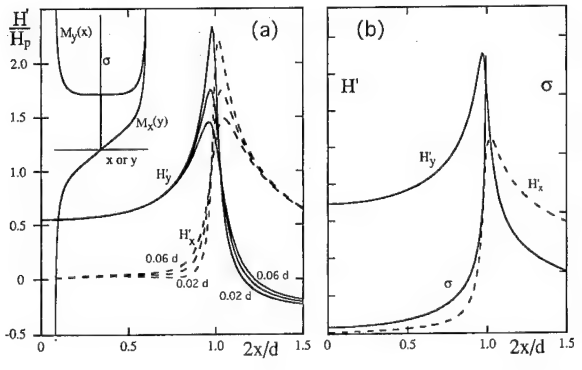

FIG. 3. Calculated components H'_y and H'_x of the external fields from the charges on the whisker surfaces, induced by applied fields: (a) H_p; (b) H_0. In (a) H'_y and H'_x arise from the charge distributions $\pm M_y(x)$ on the top and bottom surfaces and $\pm M_x(y)$ on the side surfaces. The curves are for three separations (s=0.02 d,0.04 d, and 0.06 d) between the top surface and the indicator film. In (b) H'_y and H'_x arise from σ (x or y,z), Eqs. (3)–(4), which is the same on all four surfaces and starts out linearly in z from the midplane.

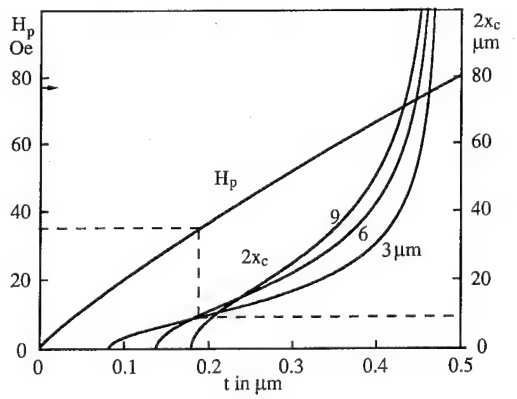

FIG. 4. Relations between the applied perpendicular field H_p, the separation t of the two 90° sections of the split 180° wall, and the separation $2x_c$ of the two sets of finger patterns in the indicator film, for 3, 6, and 9 μm spacings between the indicator film and the top surface of the whisker.

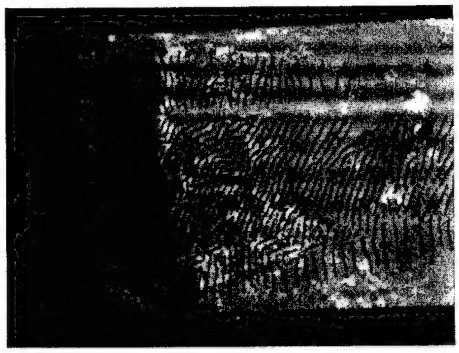

FIG. 5. Striped domain patterns in the indicator film for $H_0 \sim 50$ Oe. This displaces the 180° wall and develops charges on the surfaces as calculated in Fig. 4. The contour of the extremity of the finger pattern is described by $z \propto 1/f(x)$, where $f(x)$ is given by Eq. (4).

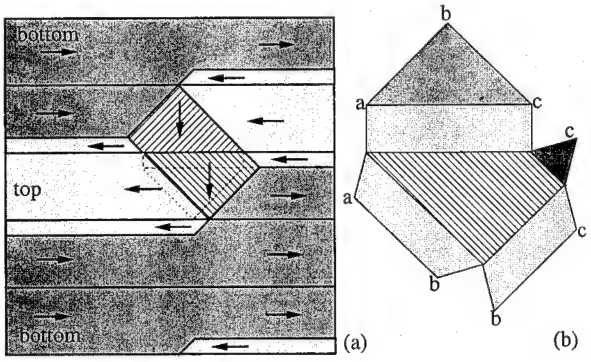

FIG. 6. The transition structure which connects two orthogonal 180° walls, illustrated for an H_0 which almost saturates the central cross section. One of the two identical connecting domains is shown from the top in dotted outline in (a) and in cut out form in (b). This structure can be moved by perpendicular fields and by currents along the whisker.

To a crude approximation for $10 < L/d < 100$, in the center of the whisker face at a distance z from the midplane, $H'_\perp(0,z) \cong (3.5+0.2L/d)(2z/L)H_0$. For a whisker with $L/d = 25$ at $z = L/4$, $H'_\perp(0,L/4) = 4H_0$. The profile of the surface charges and the components of the external fields that they produce are shown in Fig. 3(b) as calculated from

$$\sigma(x,z) = \frac{\lambda(z)}{24} f\left\{\frac{2x}{d}\right\}, \tag{3}$$

where

$$f\{x\} = [1.024\{(1-x)^{-1/3} + (1+x)^{-1/3}\} - 0.0913 - 0.036x^2 - 0.066x^4], \tag{4}$$

where $\lambda(z)$ is the charge on all four sides per unit length. For $\lambda(z) \propto z$, contours of constant external field, in the limit of small separation between the indicator film and the top surface of the whisker, are given by $z \propto 1/f\{x\}$ which are approximately ellipses centered on the midpoint of the surface. Figure 5 shows such a contour, distorted slightly by the small angle between the indicator film and the whisker surface.

The wall is visible for moderate values of H_0, as shown in Fig. 5, for almost the same reason that the walls are visible for H_p. In both cases it is easier to create charge by breaking the 180° wall into two 90° sections than to rotate the magnetization out of the plane in the domains. One could say that the local internal susceptibility is higher at the wall than in the domain. Indeed, the local internal susceptibility for the splitting of the 180° wall goes to infinity when the perpendicular component of the internal field $H_{i\perp} = H_{m\text{-el}}$ and is negative for $H_{i\perp} > H_{m\text{-el}}$.

V. MOVING DOMAINS WITH PERPENDICULAR FIELDS AND CURRENTS

The position of the 180° wall is determined by H_0 and is not affected by H_p. For more complicated domain structures and in the presence of the field from the axial current, there can be interactions of the domain configurations with H_p. The well-known diamond structure moves under the influence of the perpendicular field. A particularly interesting effect occurs for the transition structure, explained by DeBlois and Graham,[7] shown in Fig. 6, which connects two 180° walls that are orthogonal to one another. This structure can be generated by combinations of H_0 and H_p. When the structure is near one end of the whisker, it is stable up to a critical current or a critical perpendicular field at which it propagates down the whisker switching the dominate 180° wall from the xz plane to the yz plane.

VI. PARTIALLY SATURATED IRON WHISKERS

If $H_0 > H_d$, which saturates the center of the whisker, there will be very little charge on the surface for $|z| < z_s$, the limit of saturation. The fringes follow z_s as the field draws the magnetic charge, the sum of which does not change for $H_0 > H_d$, closer to the ends. Then the contours of H_c are observed to be much flatter across the whisker, as predicted[5] for partially saturated whiskers, compared to the case shown in Fig. 5.

Temperature and field dependence of domain wall dynamics up to the Curie point of EuO

A. Flosdorff, D. Görlitz, and J. Kötzler
Institut für Angewandte Physik, Universität Hamburg, Jungiusstrasse 11, D-20355 Hamburg, Germany

Using a broadband vectorial microwave reflectometer, the dynamic susceptibility has been measured on a EuO sphere in the range from 0.3 to 20 GHz. The data taken at zero field between 4.2 K and the Curie temperature T_c=69.5 K were analyzed using a phenomenological model of a damped harmonic oscillator for the domain walls, that has been successfully applied to the early investigations on ferrites. Based on the micromagnetic Landau–Lifshitz (LL) model, the temperature variation of the intrinsic resonance and damping frequencies are explained up to T=0.98 T_c. The resulting LL-kinetic coefficient, $L_\perp = 1.1\times 10^{11}$ s^{-1}, remains independent of temperature and is related to the dipolar induced relaxation rate of the longitudinal magnetization fluctuations. In fields along the easy [111] axis and the symmetric [100] direction this wall process prevails for magnetizations smaller than $M_s/4$ and $M_s/\sqrt{3}$, respectively. Above these thresholds, the characteristic frequencies of the dominant process decrease with field, possibly due to rotational dynamics, and for $\mathbf{H}\|[111]$ a second dynamics associated with the paraprocess is contributing.
 [S0021-8979(96)76308-X]

I. INTRODUCTION

Recently, investigations of domain wall (DW) dynamics of the cubic model ferromagnets EuS (T_c=16.6 K) and EuO (T_c=69.1 K) have been started[1,2] in order to gain a more quantitative understanding of the effects of thermal fluctuations, microscopic damping mechanisms, anisotropy, and domain structure on this collective phenomenon of practical importance. The present work examines in further detail the temperature variations of the wall dynamics of EuO and, in particular, the influence of magnetic fields and of the cubic anisotropy H_A=240 Oe ($M_s(T)/M_s(0)$)[5,3] We also try to explain the values of the characteristic frequencies which turn out to be rather high compared to corresponding results for ferrites,[4] garnets,[5] and thin films.[6]

First results obtained by measurements of the dynamic susceptibility $\chi(\omega)$ in zero magnetic field between 4.2 K and T_c of needle-shaped ellipsoids (demagnetization coefficient $N_z \leqslant 0.1$) of EuS (Ref. 1) and EuO (Ref. 2) have been explained assuming a damped oscillator shape for the dynamic wall susceptibility

$$\chi_w(\omega)=(\chi_w^{-1}-(\omega/\Omega_w)^2+i\omega/L_w)^{-1}. \tag{1}$$

This shape derives from the Landau–Lifshitz (LL) equation of motion with the damping term $(L_\perp/M_s^2)(\mathbf{M}\times\mathbf{M})\times\mathbf{M}$ and also follows from a recent more general ansatz[7] in the micromagnetic limit. Instead in terms of the conventional wall-damping and mass,[4] we have represented $\chi_w(\omega)$ by using the kinetic coefficient of the damping,

$$L_w=\frac{(\gamma M_s)^2+L_\perp^2}{L_\perp}\frac{2\delta}{d} \tag{2a}$$

and the resonance frequency of the walls

$$\Omega_w^2=L_\perp L_w, \tag{2b}$$

because these quantities do not depend on the static wall susceptibility χ_w. Basically, they are determined by the ratio of the widths of the walls (δ) and the domains (d) and by the LL coefficient $L_\perp$. Note that the kinetic coefficient determines the mobility of the walls $\mu_w \equiv v/\Delta H = L_w d/2M_s$. Effects of sample demagnetization and contributions of other processes to $\chi(\omega)$ have been taken into account by the form

$$\chi(\omega)=\left[\left(\sum_{i=1}^{2}\chi_i(\omega)\right)^{-1}+N_z\right]^{-1} \tag{3}$$

which means that in a first-order approximation[6] the coupling of the walls to the other processes is only provided by the ac-demagnetization field. The results for the less anisotropic EuS [$H_A(T=0)$=24 Oe (Ref. 3)] could be well described by Eq. (3), surprisingly for temperatures extending to T_c, i.e., far away from the micromagnetic limit.

Using a broadband microwave reflectometer described elsewhere,[8] we measured the linear complex susceptibility of a single crystalline sphere, ∅=3 mm, between 0.3 and 20 GHz. External fields up to 10 kOe were applied parallel to the ac-field and oriented along either a hard [100] or an easy [111] axis of the crystal. No significant hysteresis effects have been detected in the present range of temperatures and fields which indicates a rather weak DW pinning. This is not inconsistent with the fairly large δ/d ratios following from the analysis of our data in Sec. III. [Using SQUID magnetization data[9] exemplified by Fig. 3(a), all applied fields H_a have been corrected for demagnetization, $H=H_a-N_zM$.]

Typical frequency scans for dispersion and absorption taken at fixed temperature, T=0.43 T_c are shown in Fig. 1. In zero applied field, Fig. 1(a), there is no anisotropy, as expected, and the full curves represent the fit to Eq. (2) considering only $\chi_w(\omega)$. The same single oscillator model describes the dynamic susceptibility measured for H=18 Oe applied parallel to the [100] and [111] directions, Fig. 1(b). Though this internal field is small compared to the anisotropy field, $H_A(T=0.43T_c)$=110 Oe, a distinct influence on the dynamic susceptibility is already realized. Before discussing this interesting feature let us consider the effect of temperature at zero field.

 0021-8979/96/79(8)/6054/3/$10.00

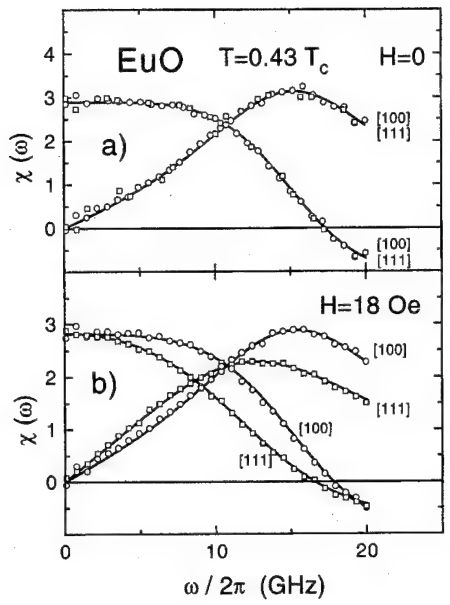

FIG. 1. Dynamic susceptibility of a EuO sphere (a) in zero magnetic field and (b) at internal field 18 Oe applied along the easy [111] and a hard [100] axis. Full lines are fits to Eq. (3) with $\chi_2=0$.

II. TEMPERATURE VARIATION AT $H=0$

The intrinsic resonance frequencies and the kinetic coefficients of the DWs obtained from fits for data measured in the two crystallographic directions to Eq. (3) are depicted in Fig. 2. Both quantities decrease continuously towards the Curie temperature and the solid lines have been obtained by fits to Eq. (2). Except for temperatures very close to T_c, which will be discussed in a future paper,[10] we find excellent agreement using a temperature independent value for the LL parameter, $L_\perp=1.1(2)\times10^{11}$ s^{-1}, and for the ratio $\delta/d=0.08(2)m_s^{-\alpha}$, where $\alpha=1.0(1)$. The reduced magnetization $m_s=M_s(T)/M_s(0)$ has been inferred from neutron data.[11] These results agree with those published previously for a EuO needle ($N_z=0.06$)[2] indicating the validity of the dynamic demagnetization, Eq. (3).

Let us first discuss the ratio δ/d by assuming (i) closure domains at the surface, which give rise to DW period of $d\approx\sqrt{D\delta_B}$ in a sample of effective thickness D and (ii) 180°-Bloch walls of width $\delta_B=\chi_A^{1/2}/q_d$ (Ref. 12) to dominate the mobility at low fields. Since the susceptibility associated with the anisotropy field of EuO varies as $\chi_A(T)=M_s/H_A\sim M_s^{-4}(T)$,[3] we find for the ratio, $\delta/d\approx\chi_A^{1/4}/(q_dD)^{1/2}\sim M_s^{-1}(T)$, which corresponds exactly to the temperature variation derived from DW resonance. This gives further evidence for the validity of the micromagnetic approach up to temperatures as high as 0.97 T_c probed here.

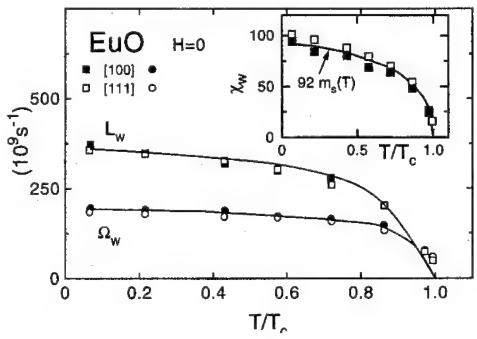

FIG. 2. Temperature variations of the wall resonance Ω_w and damping L_w defined by Eq. (1) in zero field. Solid curves represent fits to Eq. (3). Inset: static wall susceptibility.

Addressing the magnitude of the LL coefficient, $L_\perp$, we are not aware of any rigorous approach to it. We note here that the analysis of relaxation data in the homogeneously magnetized state of EuO, $H\gg H_A$,[13] revealed a correlation frequency of the torques flipping the magnetization with exactly the same value. There for EuO and also for EuS (Refs. 2 and 14) this (high) frequency could be identified with the decay rate $\Gamma_l(q\to0)$ of longitudinal magnetization fluctuations, $\mathbf{M}(\mathbf{q}\|\mathbf{M})$, which recently has been measured directly by inelastic neutron scattering on EuS.[15] Since this relaxation rate was also in numerical agreement with a prediction of mode coupling work,[16] it remains a challenge to establish the possible relation between $L_\perp$ and $\Gamma_l(\mathbf{q}\to0)$.

Finally we note that the (internal) wall susceptibility shown by the inset to Fig. 2 decays in a rather simple way, $\chi_w(T)=92(4)M_s(T)/M_s(0)$, to zero. If we assume that the static DW response arises from reversible oscillations about local minima of the potential energy $U(x)$ for the walls, then the present finding implies that the restoring force constant $\partial^2U/\partial x^2$ acting on the walls varies with $M_s^2(T)$.

III. FIELD EFFECTS AT $T=0.43T_c$

The significant effect of an even small internal field parallel to the easy [111] direction on the dynamic response $\chi(\omega)$ is seen in Fig. 1. Whereas for all fields parallel to the [100] axis, $\chi(\omega)$ can be fitted by taking one Lorentzian in Eq. (2), for $\mathbf{H}\|[111]$ there are two processes required for fields $H\geqslant H_1\approx20$ Oe. Interestingly, at this threshold field H_1 the magnetization has reached one quarter of the spontaneous value [see Fig. 3(a)], which may be associated with the disappearance of the $[\bar1\bar1\bar1]$ domains due to 180°-wall motion. Above H_1, the kinetic coefficient L_1 [Fig. 3(b)] and the resonance frequency Ω_1 [Fig. 3(c)] of the process with the dominant static susceptibility χ_1, which is depicted in Fig. 3(a), rapidly decrease with field. The second dynamic process, $\chi_2(\omega)$, contributing $\chi(\omega)$ for $\mathbf{H}\|[111]$ arises from the homogeneous magnetization in the domains, the so called paraprocess with $\chi_2\ll\chi_1$, which is studied in a separate work.[13] This process survives at large fields $H\gg H_A$, where the six unfavorably oriented domains have been turned into the field direction, i.e., parallel to [111]. More details of the dominant process $\chi_1(\omega)$, for which coherent domain rotations have to be considered, will be given in a fuller paper.[10]

For fields along the [100] direction, on the other hand, the kinetic coefficients and resonance frequencies retain their zero field values until a larger threshold field is reached, $H_2=45$ Oe. Looking at the magnetization reached at that field in Fig. 3(a), we find $M(H_2)=M_s/\sqrt{3}$, which suggests that for $H\leqslant H_2$ the four unfavorably oriented (111) domains with magnetization components antiparallel to $\mathbf{H}$ are removed. This would imply, that as for $H=0$, 180° walls are

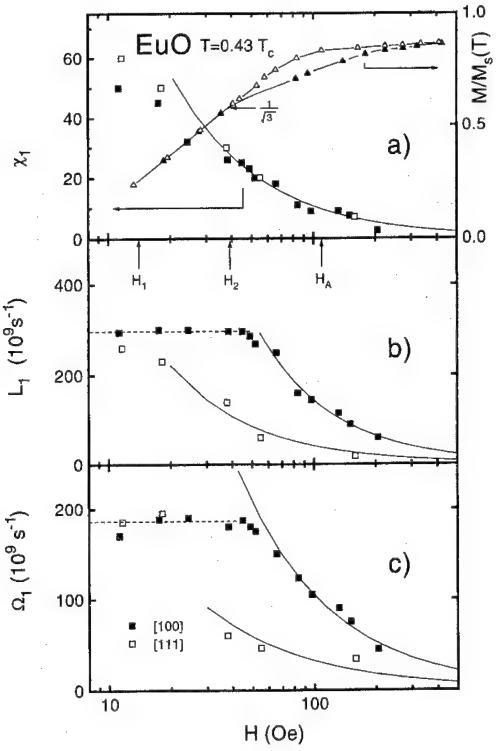

FIG. 3. Field variation of the internal (a) susceptibility, (b) kinetic coefficients of the damping, and (c) resonance frequencies of the dominant dynamic process for two principal orientations of H at $T=0.43T_c$. Full lines represent empirical power laws in H. Panel (a) includes magnetization data (Ref. 9).

operative and this conclusion is fully confirmed by the field independence of L_1 and Ω_1, so that we identify $\chi_1(\omega)$ with $\chi_w(\omega)$.

Above H_2, the characteristic frequencies of the dominant process decrease with field $\mathbf{H}\|[100]$ in qualitatively the same way as for $H>H_1$ when $\mathbf{H}\|[111]$. For the present fully symmetric configuration, the anisotropy field keeps the magnetizations along the easy directions, and for internal fields $H\approx H_A$ [Fig. 3(a)] coherent rotations are expected to dominate, $\chi_1(\omega)=\chi_R(\omega)$. Interestingly, Fig. 3(a) shows that the static susceptibility of this rotation agrees with that associated with the rotation for $\mathbf{H}\|[111]$ $(H>H_2)$, and that we can describe the field variation by an empirical power law, $\chi_R\sim H^{-a_\chi}$ with $a_\chi=0.80(5)$. Such power laws can also explain the decay of the resonance and kinetic coefficients, indicated in Figs. 3(b) and 3(c), with slightly different exponents, $a_L=1.06(9)$ and $a_\Omega=1.00(2)$. More details, in particular on the temperature variation and the interference of all three magnetization processes in the dynamics will be published in the near future.

The dependence of magnetoacoustic emission on magnetizing frequency in nickel and mild steel

D. H. L. Ng,[a] C. C. Yu, and C-D. Qin
Department of Physics, The Chinese University of Hong Kong, Shatin, Hong Kong

C. C. H. Lo and J. P. Jakubovics
Department of Materials, University of Oxford, Parks Road, Oxford OX1 3PH, United Kingdom

Magnetoacoustic emission (MAE) measurements have been made on nickel and mild steel samples subjected to a magnetizing field of various frequencies f. In both samples, the MAE signals are found to increase with increasing f. The experimental results are in good agreement with the predictions of a model relating the generation of MAE to domain wall nucleation-annihilation and domain wall motion. When f is large, the contribution of wall motion to the generation of MAE is predicted to be dominant. Conversely, when f is small, MAE is generated mainly by domain wall nucleation-annihilation processes. At high frequencies, the amount of MAE from both nickel and mild steel samples is found to vary linearly with $f^{0.5}$. As f decreases, the MAE deviates from the $f^{0.5}$ relationship for $f<10$ Hz in mild steel, and for $f<2$ Hz for nickel. The results suggest that in nickel, wall motion remains the dominant source of MAE generation over a wider frequency range than in steel. © *1996 American Institute of Physics.* [S0021-8979(96)76408-6]

I. INTRODUCTION

Magnetoacoustic emission (MAE) is the generation of elastic waves due to changes of magnetostrictive strains during the process of magnetization. It is known that MAE is produced by the motion of domain walls and the processes of domain wall nucleation and annihilation.[1,2] The amplitude of the MAE signal generated is determined by the rate of change of magnetostrictive strain, which depends on (i) the magnitude of the magnetostrictive behavior of the material, and (ii) the rate of change of the magnetic induction, dB/dt.[3] In this article we report a study of the dependence of the MAE signals on dB/dt, which is determined by the frequency f of the magnetizing field, and the magnetic induction B inside the sample. We formulate a model, in which the MAE signal is expressed explicitly as a function of f by relating the MAE to domain wall motion and the nucleation-annihilation of domain walls. This model provides information about the relative contributions of wall motion and of wall nucleation and annihilation processes involved in the MAE generation. We have calculated the relative MAE output for nickel and mild steel at different frequencies using this model. The result is compared with MAE measurements made on these materials.

II. EXPERIMENTS AND RESULTS

The dependence of MAE on the frequency of the applied field was investigated on a nickel bar and a mild steel bar, both of thickness about 6 mm. During the measurements, an alternating magnetizing field of triangular wave form and amplitude up to 43 kA m^{-1} was produced by a c-core electromagnet placed at the center of the bar as shown in Fig. 1(a). The magnetizing frequency f was varied from 0.5 Hz to 60 Hz. A plastic spacer was inserted between the c-core magnet and the sample to minimize the electrical and acoustic noises. The MAE signals detected by a piezoelectric transducer were amplified, rectified and filtered. The mean signals were then plotted as a function of the field over the complete hysteresis cycle. Each measurement was repeated 25 times and averaged in order to improve the signal-to-noise ratio. The MAE profiles for half of the hysteresis cycle usually contain a single central peak for nickel and two outer peaks (initial and final) for mild steel. Typical MAE profiles of both nickel and mild steel are shown in Fig. 1(b). All the MAE profiles obtained are characterized for analysis by their peak heights. Logarithmic plots of the MAE signal (normalized at 0.5 Hz) V_{tot}, against f for the nickel bar and the steel bar are

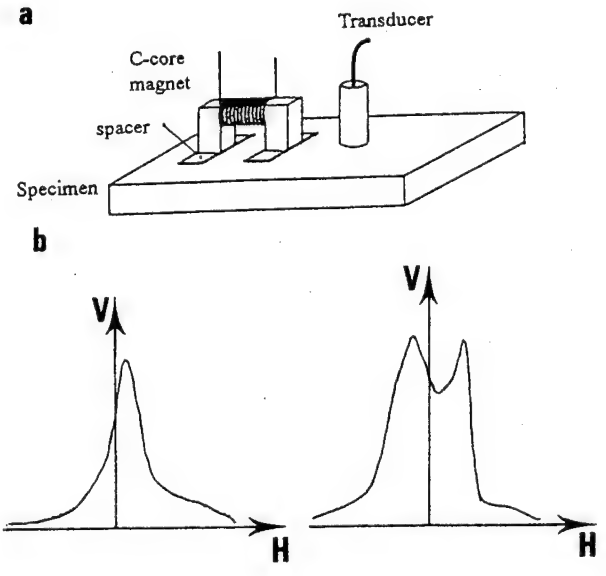

FIG. 1. (a) A diagram to show the experimental arrangement for the MAE measurements. (b) The MAE profiles of nickel (left) and mild steel (right) samples obtained with a magnetizing field frequency of 0.5 Hz. The two profiles are not in the same vertical scale, V is the MAE signal and H is the applied field.

shown in Figs. 2 and 3 respectively. The results show that V_{tot} increases steadily with increasing f when f is large, being a linear function of $f^{0.5}$. However, V_{tot} deviates from the $f^{0.5}$ dependence when $f<10$ Hz in the case of steel (Fig. 3), whereas the $f^{0.5}$ dependence is followed down to $f\approx 2$ Hz for nickel (Fig. 2).

III. THE MAE MODEL

Based on a classical domain wall motion model,[4] the MAE output V_{dm} within a period of time τ is given by

$$V_{dm}\sim\frac{1}{\tau}\int \delta E\frac{dH}{dt}n(H)dt, \tag{1}$$

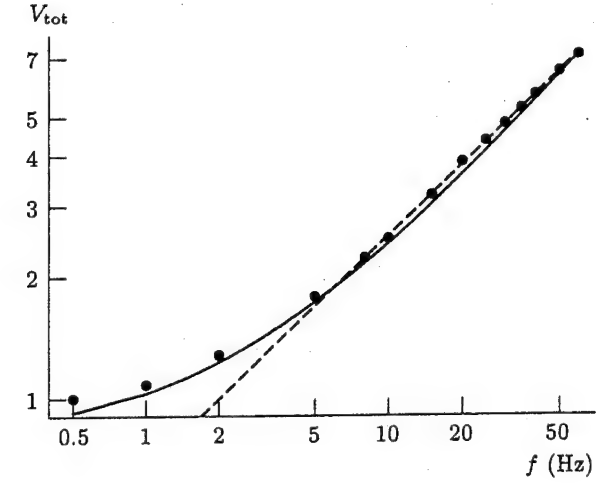

FIG. 3. Logarithmic plot of V_{tot} (normalized at a frequency of 0.5 Hz) against f for the steel bar. The points (full circles) correspond to experimental results, the dashed line shows the $f^{0.5}$ variation fitted to the points at higher f, and the full curve was deduced from the model.

where δE is the change of elastic energy during the motion of non-180° domain walls, and $n(H)dH$ is the corresponding number of emission sites when the magnetizing field changes from H to $H+dH$. As seen from Eq. (1), the MAE signal is proportional to the rate of change of applied field dH/dt. We can therefore write V_{dm} in the form of the rate of change of magnetic induction B, which varies as a triangular wave form inside the sample,

$$V_{dm}=C_{dm}\frac{dB}{dt}=C_{dm}B_{max}f. \tag{2}$$

Here dB/dt has been replaced by $B_{max}f$ where B_{max} is the maximum magnetic induction in the sample corresponding to the maximum magnetizing field, and C_{dm} is the proportional constant. Because of the eddy current shielding, significant values of B can only be found within the skin depth, which is proportional to $f^{-0.5}$, and thus the total MAE signal V'_{dm} detected will depend on f in the following way:

$$V'_{dm}=C'_{dm}B_{max}\sqrt{\frac{\rho}{\mu\pi}}f^{0.5}, \tag{3}$$

where ρ and μ are the resistivity and permeability of the material respectively, and the proportional constant C'_{dm} is equal to C_{dm}/l_0 where l_0 is the thickness of the sample. In a study of the frequency dependence of the number of domain wall nucleation-annihilation events, it was found that by minimizing the total energy dissipated during the magnetization process with respect to the number of nucleated domain walls,[5] that the total number of domain walls N_{dw} is proportional to $B_{max}f^{0.5}$ when f is above a threshold frequency. When considering the MAE output due solely to the processes of domain wall nucleation-annihilation, the corresponding MAE signal V_{na} is then given by

$$V_{na}=C_{na}B_{max}f^{0.5}, \tag{4}$$

where C_{na} is a constant. When taking the eddy current shielding into consideration, we replace C_{na} by C'_{na} which is equal to C_{na}/l_0, the total MAE signal V'_{na} is therefore given by

$$V'_{na}=C'_{na}B_{max}\sqrt{\frac{\rho}{\mu\pi}}, \tag{5}$$

and is independent of the frequency of the applied field. Based on the above results, we can attribute the total MAE signal V_{tot} to a combination of domain wall motion and domain wall nucleation-annihilation processes. We can obtain V_{tot} by combining V'_{dm} and V'_{na} as follows:

$$V_{tot}=(V'^2_{dm}+V'^2_{na})^{1/2}=B_{max}\sqrt{\frac{\rho}{\mu\pi}}(C'^2_{dm}f+C'^2_{na})^{1/2}. \tag{6}$$

The magnetic induction B_{max} inside the sample is not easy to determine. To find B_{max}, we have to consider the magnetic circuit formed by the c-core magnet, the two spacers (one for each pole), and the specimen. The reluctance of the circuit $\mathfrak{R}$ is given by

$$\mathfrak{R}=\sum_i \frac{l_i}{\mu_i A_i}, \tag{7}$$

where l_i, μ_i and A_i are the length of the flux path, the permeability, and the cross-sectional area respectively of the different sections of the circuit in series. The magnetic induction B which is equal to the flux per unit area, for a given magnetomotive force NI of a coil of N turns carrying a current I, is therefore inversely proportional to the product of $\mathfrak{R}$ and A_s, the cross-sectional area of the magnetic flux path in the specimen.[6] Therefore Eq. (6) can be written as

$$V_{\text{tot}} \sim \frac{1}{\mathfrak{R}A_s}\sqrt{\frac{\rho}{\mu\pi}}(C'^2_{\text{dm}}f + C'^2_{\text{na}})^{1/2}. \tag{8}$$

It is also difficult to evaluate the constants C'_{dm} and C'_{na} appearing in Eqs. (6) and (8), since they depend on various parameters of the samples such as domain dimensions and density of pinning sites, which cannot be found directly from measurements. We therefore introduce a parameter $r = C'_{\text{na}}/C'_{\text{dm}}$ to characterize the relative strength of the MAE output due to the wall motion and the nucleation-annihilation processes. The value of r can be approximated by the ratio of the amplitude of the outer peaks to the amplitude of the central portion of the MAE profile. For the nickel specimen, the MAE profile usually contains a single peak around the coercivity. However, the contribution of wall motion and nucleation-annihilation to MAE can be differentiated by splitting the single peak into three peaks in the same profile by making measurement using thicker spacers.[3] The average values of r was found to be 0.99 for the nickel bar. For steel, the average V_p of the two outer peaks of the MAE profile is attributed to a combination of wall motion and nucleation-annihilation processes, while the central dip of height V_c is a measure of MAE generated only by wall motion. Therefore r can be found from

$$r = \frac{(V_p^2 - V_c^2)^{1/2}}{V_c}. \tag{9}$$

The average value of r was found to be 1.56 for the mild steel bar. A separate experiment was performed to determine the permeabilities of the samples. The values of μ are 170 and 200 for the nickel and mild steel bars respectively. These values were measured in the low field regions of the magnetization loops of the samples, because in our analysis, the MAE results were characterized by the height of the peaks which usually appeared near the low field regions in the profiles. The values of r, μ and the pre-determined values of ρ, $\mathfrak{R}$, and A_s for the nickel bar and steel bar were substituted into Eq. (8), and the normalized V_{tot} values were then calculated and plotted against f. Plots of these calculated values are shown also in Figs. 2 and 3.

IV. DISCUSSION
